**Lawrence H. Cohn, MD,** is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology,* now available in its second issue, *Cardiology 1982.*

**Vincenzo Gallucci, MD,** is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

## Table of Contents

**Section 1 CLINICAL ANALYSIS 1.** The Evolution of the Biological Valve **2.** Heart Valve Replacement with the Hancock Bioprosthesis: A 5-11 Year Follow-up **3.** A 14-Year Experience with Valvular Bioprostheses: Valve Survival and Patient Survival **4.** A Thousand Porcine Bioprostheses Revisited. Do They Conform with the Expected Pattern? **5.** Clinical Durability of the Pericardial Xenograft Valve: 11 Years' Experience **6.** Long-term Results of 159 Porcine Valve Implantations **7.** Mid- and Long-term Evaluation of Porcine Bioprosthetic Valves: A 6-Year Experience

**Section 2 HEMODYNAMICS 8.** Hemodynamic Evaluation of the Hancock Bioprosthesis in the Mitral Position: A 1-7 Year Follow-up **9.** Hemodynamic Evaluation of the Carpentier-Edwards Standard and Improved Anulus Bioprostheses **10.** Hemodynamic Evaluation in Valvular Patients Carrying Low Profile Bioprostheses **11.** Noninvasive Scintigraphic Assessment of Left and Right Ventricular Function in Patients with Bioprosthetic Mitral Valves at Long-term Risk **12.** Orifice View Roentgenography for Evaluation of the Orifice Area of Bioprosthetic Valves

**Section 3 THROMBOEMBOLISM 13.** Alterations in Valvular Surgery: Biological Valves **14.** Early and Late Results of Porcine Bioprostheses Versus Mechanical Prostheses in Aortic and Mitral Positions **15.** Mitral Bioprostheses in 202 Patients with Chronic Atrial Fibrillation, Giant Left Atrium, and Atrial Thrombi: Long-term Results with No Anticoagulation **16.** Thromboembolism and Anticoagulation after Isolated Mitral Valve Replacement with Porcine Heterografts **17.** Preoperative Determinants of Return to Sinus Rhythm after Valve Replacement **18.** Porcine Bioprostheses Versus Mechanical Valvular Substitutes: A Retrospective Comparative Analysis

**Section 4 PEDIATRIC VALVE REPLACEMENT 19.** Valved Conduits: A Panacea for Complex Congenital Heart Defects? **20.** Factors Influencing Late Results of Extracardiac Conduit Repair for Congenital Cardiac Defects **21.** Calcification of Porcine Bioprostheses in Children **22.** Valve Replacement in Children: Biological Versus Mechanical Valves **23.** Bioprosthetic Valve Replacement in Children **24.** Aortic Root Replacement **25.** Conduits Containing Antibiotic Preserved Homografts in the Treatment Of Complex Congenital Heart Defects **26.** Dura Mater Bioprosthesis in Young Patients

**Section 5 EXPERIMENTAL PATHOLOGY 27.** Experimental Evaluation of Bioprosthetic Valves Implanted in Sheep **28.** Role of Mechanical Stress in Calcification of Bioprostheses **29.** Inhibition of Mineralization of Glutaraldehyde-fixed Hancock Bioprosthetic Heart Valves **30.** Prevention of Tissue Valve Calcification by Chemical Techniques

**Section 6 EXPLANT PATHOLOGY 31.** Complications of Replacement of either the Mitral or Aortic Valve or Both by either Mechanical or Bioprosthetic Valves **32.** Pathogenesis and Stages of Bioprosthetic Infection **33.** Structure and Classification of Cuspal Tears and Perforations in Porcine Bioprosthetic Cardiac Valves Implanted in Patients **34.** Pathological Substrates of Porcine Valve Dysfunction **35.** Mode of Failure in 226 Explanted Biological and Bioprosthetic Valves

**Section 7 BIOPROSTHETIC BIOENGINEERING 36.** The Unileaflet Heart Valve Bioprosthesis **37.** Hancock II - An Improved Bioprosthesis **38.** Design and Stress Analysis of Bioprosthetic Valves In Vivo **39.** In Vitro Comparison of the Newer Heart Valve Bioprostheses in the Mitral and Aortic Positions **40.** In Vitro and In Vivo Assessment of the Flow Characteristics of the Xenomedica Porcine Xenograft **41.** The Structure/Function Relationship of Fresh and Glutaralhyde-Fixed Aortic Valve Leaflets

**Section 8 LONG-TERM FOLLOW-UP 42.** Bioprostheses in the Tricuspid Position Versus Valvuloplasty and Mechanical Valves **43.** The Role of Porcine Heterografts in a 14-Year Experience with Tricuspid Valve Replacement **44.** Patient Prosthesis Mismatch in the Tricuspid Position: The Rationale for an Oval Pericardial Tricuspid Valve **45.** The Porcine Bioprosthesis: Failure Rates in the Elderly **46.** Causes of Valve Failure and Indications for Reoperation After Bioprosthetic Cardiac Valve Replacement **47.** Clinical Analysis of the Hancock Porcine Bioprosthesis **48.** Valve Replacement in the Small Anulus Aorta: Performance of the Hancock Modified-Orifice Bioprosthesis **49.** Decreasing Incidence of Porcine Bioprosthetic Degeneration

**Section 9 SUMMING UP 50.** A Cardiologist's Point of View and a Cardiac Surgeon's Point of View

| | | | | 120 | 185 |
| | | | | 165 | 140 |
| | | | | 250 | 55 |

## Important Information—Sequicor, Models 233D and 233E

**Indications and Contraindications**
The medical literature describes currently accepted indications for various pacing modes. The physician's clinical experience and judgment must ultimately be the guide in selecting the pacing mode best suited to the patient's needs. *The physician should be thoroughly familiar with the pacing mode chosen.*

Pacing of the ventricles (VVI) is indicated for control of heart rate in patients with A-V block or sick sinus syndrome. *Asynchronous pacing is contraindicated when inherent activity is present or is likely to be present in the chamber being paced.* There are no other known contraindications for ventricular pacing to control heart rate.

Atrial-synchronized ventricular pacing (VDD) is indicated for permanent or intermittent complete heart block with normal atrial rhythm. A-V sequential (DVI) pacing is indicated for permanent sinus bradycardia with or without heart block. Automatic dual-chamber demand pacing (DDD) is indicated when there is an A-V conduction disturbance and/or sinus mode dysfunction (sinus bradycardia with A-V block or bradytachy syndrome). These atrial pacing modes are intended for patients who would benefit from the restoration of atrial contribution to cardiac output.

*Atrial-synchronized ventricular pacing and automatic dual-chamber demand pacing modes are contraindicated for use in the presence of persistent atrial flutter or atrial fibrillation.* VVI mode is recommended for these conditions.

**Precautions**
Cordis Sequicor pacers may respond to programmers of other manufacturers. Because of the unknown nature of such response, use only the Cordis Omnicor Programmer, Model 222C (with the 222C-8 control panel card), the Cordis Programmer III, Model 225A or the Cordis Interactive Programmer, Model 256A for reprogramming.

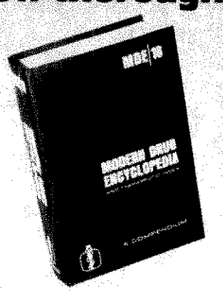
**Warnings**
None

**Adverse Effects**
The following list includes a number of complications related to pacer therapy that have been reported in the medical literature. Noninvasive techniques for assessing and managing such complications are available to the physician. Malfunctions occur randomly and may occur at any time after implant. Complications associated with pacer therapy are listed below.

*Pacer*—battery depletion, component malfunction, electromagnetic interference, decreased sensitivity.

*Lead*—unsatisfactory electrode position, fracture, displacement, penetration/perforation of heart wall, faulty connection with pacer.

*Patient*—reaction, infection/erosion, increase in stimulation threshold.



Before implantation, refer to pacer Instructions for Use supplied with the pacer.

**Caution:** Federal (U.S.A.) law restricts this device to sale by or on the order of a physician.

# How thorough and unbiased is your drug reference?

**If it's not MODERN DRUG ENCYCLOPEDIA, you can't be sure.**

## MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 16th Edition

**Arthur J. Lewis,** MD, Executive Editor
**Gertrude Dittus Gonzales,** R.Ph., B.S. Pharm., Executive Editor
**Charles L. Winek,** Ph.D., Contributing Editor

The all new 16th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

### Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:

- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a-z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension.
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

**The 1,000 page main section** arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

**Three a-z indexes provide** instant access to all the material found in the main section as follows:

- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to read information on prescription drugs.

**Yorke Medical Books**
Box C-757, Brooklyn, New York 11205 AJCB3

Please send me a copy of the all-new 16th Edition of MODERN DRUG ENCYCLOPEDIA. If this new edition is the best drug information reference for practitioners available, I will remit $49.00 plus shipping. Otherwise, I will return it within 30 days and owe nothing.

☐ I am enclosing $49.00 now as full payment.
Publisher pays shipping. Same return guarantee
☐ Charge my credit card: ☐ MasterCard ☐ Visa.

# The angina onslaught

# The angina shield: CORGARD® (nadolol tablets)

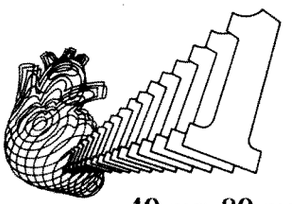
SQUIBB®

# Reliable 24-hour-a-day protection...

Physical exertion, emotional strain, and the unexpected crises of daily life — these can unleash an anginal attack at any time. So it's important to be certain that your patients are protected continuously. Unlike other beta-blockers, Corgard provides this protection around the clock with a once-daily dose — reducing the anginal attack rate, increasing work capacity, and decreasing the dependence on nitroglycerin.

## with convenient once-a-day dosage

A single daily dose of Corgard controls angina all day, every day. And since Corgard is associated with a low incidence of side effects,* your patients can lead more comfortable lives. An added convenience of Corgard is that it can be taken at any time of day, regardless of meals, because its absorption is not affected by food.



*For a full discussion of CONTRAINDICATIONS, PRECAUTIONS, ADVERSE REACTIONS, and WARNINGS, including avoidance of abrupt withdrawal, please see brief summary on next page.

# CORGARD® (nadolol tablets)

## The only once-a-day beta-blocker for both angina pectoris and hypertension

*Please see next page for brief summary.*

# The only once-a-day beta-blocker for both angina pectoris and hypertension

# CORGARD® (nadolol tablets)

**40 mg, 80 mg, 120 mg, and 160 mg scored tablets available in a variety of bottle sizes and in Convenience Packages of 40 mg and 80 mg tablets**

**CORGARD® TABLETS**
**Nadolol Tablets**

**DESCRIPTION:** Corgard (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

**CONTRAINDICATIONS:** Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

**WARNINGS: Cardiac Failure** — Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

**Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal** — Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

**Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)** — PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

**Major Surgery** — Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

**Diabetes and Hypoglycemia** — Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

**Thyrotoxicosis** — Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

**PRECAUTIONS: Impaired Hepatic or Renal Function** — Use nadolol with caution in presence of either of these conditions (see DOSAGE AND ADMINISTRATION section of package insert).

**Information for Patients** — Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign or symptom of impending failure.

**Drug Interactions** — Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. When treating patients with nadolol plus a catecholamine-depleting agent, carefully observe for evidence of hypotension and/or excessive bradycardia which may produce vertigo, syncope, or postural hypotension.

**Carcinogenesis, Mutagenesis, Impairment of Fertility** — In 1 to 2 years' oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

**Pregnancy** — In animal reproduction studies with nadolol, evidence of embryo- and fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times greater (on a mg/kg basis) than maximum indicated human dose; no teratogenic potential was seen in any of these species. There are no well-controlled studies in pregnant women; therefore, use nadolol in pregnant women only if potential benefit justifies potential risk to the fetus.

**Nursing Mothers** — It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when nadolol is administered to a nursing woman. Animal studies showed that nadolol is found in the milk of lactating rats.

**Pediatric Use** — Safety and effectiveness in children have not been established.

**ADVERSE REACTIONS:** Most adverse effects have been mild and transient and have rarely required nadolol withdrawal.

**Cardiovascular** — Bradycardia with heart rates of less than 60 beats per minute occurs commonly, and heart rates below 40 beats per minute and/or symptomatic bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral vascular insufficiency, usually of the Raynaud type, have occurred in approximately 2 of 100 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have each occurred in about 1 of 100 patients. Single instances of first degree and third degree heart block have been reported; intensification of AV block is a known effect of beta-blockers (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS). **Central Nervous System** — Dizziness or fatigue reported in approximately 2 of 100 patients; paresthesias, sedation, and change in behavior reported in approximately 6 of 1000 patients. **Respiratory** — Bronchospasm reported in approximately 1 of 1000 patients (see CONTRAINDICATIONS and WARNINGS). **Gastrointestinal** — Nausea, diarrhea, abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating, and flatulence each reported in 1 to 5 of 1000 patients. **Miscellaneous** — Each of the following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, eyes, or skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; cough; nasal stuffiness; sweating; tinnitus; blurred vision. Although relationship to drug usage is not clear, sleep disturbances have been reported. The oculomucocutaneous syndrome associated with practolol has not been reported with nadolol.

**Potential Adverse Effects:** Although other adverse effects reported with other beta-adrenergic blocking agents have not been reported with nadolol, they should be considered potential adverse effects of nadolol. **Central Nervous System** — reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place; short-term memory loss, emotional lability with slightly clouded sensorium; decreased performance on neuropsychometrics. **Gastrointestinal** — mesenteric arterial thrombosis; ischemic colitis. **Hematologic** — agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura. **Allergic** — fever combined with aching and sore throat; laryngospasm; respiratory distress. **Miscellaneous** — reversible alopecia; Peyronie's disease; erythematous rash.

**OVERDOSAGE:** Nadolol can be removed from the general circulation by hemodialysis. In addition to gastric lavage, employ the following measures as appropriate. In determining duration of corrective therapy, take note of long duration of effect of nadolol.

**Excessive Bradycardia** — Administer atropine (0.25 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.

**Cardiac Failure** — Administer a digitalis glycoside and diuretic. It has been reported that glucagon may also be useful in this situation.

**Hypotension** — Administer vasopressors, e.g., epinephrine or levarterenol. (There is evidence that epinephrine may be the drug of choice.)

**Bronchospasm** — Administer a $beta_2$-stimulating agent and/or a theophylline derivative.

**DOSAGE:** For all patients, DOSAGE MUST BE INDIVIDUALIZED.

For **angina pectoris,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments at 3 to 7 day intervals until optimum clinical response or pronounced slowing of the heart rate; usual maintenance dose is 80 to 240 mg q.d. (most patients respond to 160 mg or less daily). If treatment is to be discontinued, reduce dosage gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments until optimum blood pressure reduction is achieved; usual maintenance dose is 80 to 320 mg q.d. (rarely, doses up to 640 mg may be needed).

Patients with renal failure require adjustment in dosing interval; see package insert for dosage in these patients.

For full prescribing information, consult package insert.

**HOW SUPPLIED:** In scored tablets containing 40, 80, 120, or 160 mg nadolol per tablet in bottles of 100 and 1000 tablets and in Unimatic® unit-dose packs of 100 tablets. The 40 mg and 80 mg tablets are also available in convenience packages containing 4 blister cards of 7 tablets each.

EDITORIAL

# Congestive Heart Failure: A Propitious Time For Intensified Research

EUGENE BRAUNWALD, MD, MICHAEL M. MOCK, MD, and JOHN T. WATSON, PhD

Chronic congestive heart failure is one of the most common serious illnesses, affecting an estimated 3 to 4 million Americans. Because the prognosis in most patients with heart failure is poor, life expectancy being measured in months or a few years, not only the prevalence but also the incidence of this condition is high. Heart failure causes great personal suffering and places enormous economic burdens on the patient, the family, and society at large.

Cognizant of the importance of congestive heart failure as a medical problem, the Cardiology Program of the Division of Heart and Vascular Diseases of the National Heart, Lung and Blood Institute sponsored a Workshop on Congestive Heart Failure in Bethesda, Maryland in April 1981. The objective of the Workshop was to review important recent advances and to identify opportunities for research in this field.

The Workshop was divided into 6 sections: Section I, Clinical Definitions and Current Clinical Studies, chaired by Jay N. Cohn, MD; Section II, Diagnostic Procedures for Evaluating Heart Failure, chaired by Arthur J. Moss, MD; Section III, Etiology, Biochemical, and Structural Changes in Heart Failure, chaired by L. Maximilian Buja, MD; Section IV, Research on the Physiology of Congestive Heart Failure, chaired by A. Clifford Barger, MD; Section V, Assessment of Clinical Treatment, Monitoring, and Surgical Intervention in Advanced Congestive Heart Failure, chaired by Benedict R. Lucchesi, MD; Section VI, Future of Clinical Investigation in Evaluating Treatment of Congestive Heart Failure, chaired by Michael B. Mock, MD. Although the proceedings of this Workshop were recently published,[1] it was considered desirable to summarize some of the major points that emerged.

From the Department of Medicine, Harvard Medical School, and the Division of Heart and Vascular Diseases, National Heart, Lung, and Blood Institute, Bethesda, Maryland. Manuscript received December 9, 1982, accepted January 13, 1982.

Address for reprints: Eugene Braunwald, MD, Brigham and Women's Hospital, 75 Francis Street, Boston, Massachusetts 02115.

It was noted during the Workshop that in the past 2 decades conspicuous advances have been made in our understanding of the pathophysiologic aspects of heart failure, in the ability to assess normal and impaired left ventricular function, in research on drugs that improve cardiac contraction, and in operations designed to treat valvular and coronary heart disease (2 of the most common causes of congestive heart failure). In addition, there have been encouraging developments in the use of mechanical devices to replace the failing heart and in cardiac transplantation in the treatment of irreversible heart failure. Among many important gaps in the field that were identified, several stand out as being particularly ripe for further advances.

**Development of heart failure:** It is well established that many forms of heart failure are the consequence of a deterioration in the ventricle's response to a hemodynamic burden, rather than of an aggravation in the severity of that burden. The ventricle is capable of sustaining an excessive load while its function remains normal for many months (in experimental animals such as the genetically hypertensive rat) or for years (in patients). However, at some point, ventricular function becomes impaired and the chronically stressed ventricle begins to fail. What is responsible for this deterioration of ventricular function? Although there have been many investigations of the biochemical, physiologic, and pathologic changes that occur in the myocardium shortly after the imposition of the stress and in the very late stages of congestive heart failure, far less is known about the conversion of normal ventricular function to early ventricular dysfunction in the hypertrophied heart. The progression from hypertrophy to heart failure should be amenable to precise characterization by combining anatomic, biochemical, physiologic, and pathologic techniques, first in animal models and then in selected clinical situations.

**Animal models of heart failure:** Although a great deal of information has already been obtained from

animal modes of heart disease, this field now appears poised for further important advances. The response of myocardium to identical stress may vary. For example, the left ventricle of some patients with aortic stenosis is capable of sustaining this burden for many years without dilatation or reduction of cardiac output, whereas the left ventricle in others with an identically sized orifice exhibits excessive hypertrophy and dilatation. Similar examples can be cited in the case of other mechanical loads placed on the heart, such as those imposed by regurgitant valvular lesions, systemic hypertension, and congenital pulmonary stenosis. The basis for these widely differing responses is not clear, but carefully controlled studies in animal models of cardiac overload may well provide useful information. Thus, there are great interspecies and interindividual variations in the response to hemodynamic stress in animals with naturally occurring or artificially induced mechanical overloading. Elucidation of the genetic basis for these differences in the myocardium's response to stress appears to offer a particularly fruitful area for research.

**Characterization of the heart's functional reserve:** Although gross dysfunction of the left ventricle can readily be described by both invasive and noninvasive techniques, formidable problems remain in the characterization of early or mild impairment of left ventricular function and in the assessment and even the definition of the functional reserve of the heart. A number of opportunities exist in this field. A variety of methods have been employed, but their precise value is unclear. Thus, 1 group of investigators, a relatively small number in the United States but a larger number in Europe, particularly in Scandinavian countries, assess cardiac function by determining the maximal total body oxygen consumption during exercise ($\dot{V}O_2max$). It is not yet clear whether a reduction of $\dot{V}O_2max$ can serve as a sensitive indicator of mildly impaired function and be useful prognostically in patients with heart disease. The study of exercise tolerance and the measurement of $\dot{V}O_2max$ in patients with cardiovascular disease to identify early dysfunction is indicated.

**"Profiling" patients with heart failure:** The function of a variety of organ systems and control systems is clearly altered in heart failure. These systems include both limbs of the autonomic nervous sytem, that is, the sympathetic, including the adrenal medulla, as well as the parasympathetic; the renin-angiotensin-aldosterone axis, and the posterior pituitary gland, to name only the most obvious. Differences in the extent of activation of these neurohumoral mechanisms result in many differences in the clinical manifestations of heart failure observed among different patients. For example, elevations in systemic vascular resistance induced by adrenergic vasoconstriction are responsible for the maintenance of arterial pressure in the presence of reduced cardiac output, sometimes to the further detriment of the cardiac output; activation of the renin-angiotensin-aldosterone system and renal vasoconstriction result in retention of extracellular fluid and therefore in the symptoms resulting from pulmonary congestion, as well as in hepatomegaly and edema. Abnormalities in function of the sympathetic and parasympathetic systems are responsible for the relatively fixed heart rate characteristic of advanced heart failure.

A variety of agents that can block these various compensatory mechanisms are now available: atropine for blocking the parasympathetic nervous system, beta-adrenergic blocking agents for the cardiac adrenergic receptors, alpha-adrenergic blocking agents for peripheral adrenergic receptors, saralasin for the effects of angiotensin II, a family of converting enzyme inhibitors for blocking the production of angiotensin II, and spironolactone for aldosterone. Examining the responses of these blockades, measurement of circulating renin, angiotensin, and catecholamines and measurement of beta-adrenergic receptor density on circulating white blood cells and sometimes even on cardiac tissue, could be used to "profile" patients with congestive heart failure in an attempt to clarify the existing pathophysiologic abnormalities and to establish the most appropriate therapy.

**Newer inotropic agents:** The treatment of congestive heart failure has become stereotyped; often it commences with diuretics, includes cardiac glycosides, and finally vasodilators are added sequentially. It is not clear whether this treatment is optimal for all or even most patients. It is important to determine whether some modification, such as the treatment with afterload-reducing agents *before* the development of symptoms, could delay the development of congestive heart failure. Although the effectiveness of a number of orally active nonglycoside-positive inotropic agents, including amrinone, and several orally active beta-adrenergic agonists on hemodynamics has been demonstrated, the effect, if any, of these drugs on the survival of patients with heart failure has yet to be established.

**Epidemiology of heart failure:** Surprisingly little is known about the epidemiology of congestive heart failure. The only data available on prevalence are "soft" and come from analysis of the use of cardiac glycosides. In terms of the natural history of heart failure, available information comes from the Framingham data, most of which are now 20 years old. It was of interest how much information on the natural history of heart failure has come from Specialized Centers of Research (SCORs) in Ischemic Heart Disease, underscoring the importance of National Heart, Lung, and Blood Institute support in adding to the body of knowledge about ischemic heart failure. Although information on this subgroup of patients with heart failure is extremely useful, its applicability is obviously limited to patients with this particular cause of heart failure. Extensive prospective surveys of different populations for the incidence and natural history of congestive heart failure are sorely needed. Such studies should examine the influence of sex, age, race, and geographic, social, and regional differences. Also, these surveys should be carried out at regular intervals as diagnostic and therapeutic developments occur (such as the successful treatment of

hypertension and rheumatic valvular heart disease and the prolongation of life in patients with coronary artery disease).

*Conclusions:* It was concluded in the Workshop that great gaps exist in our understanding of the congestive heart failure state, ranging from an elucidation of the most fundamental molecular mechanisms of heart failure to a characterization of the epidemiologic aspects of this condition. Despite the acknowledged importance of congestive heart failure as a clinical problem, and despite its recognition in the national program plan of the National Heart, Lung, and Blood Institute, there is no program of support by the Institute dedicated to the study of this condition. However, the scientific underpinnings for important advances in this field have been established and the research community is now in a good position to capitalize on the wealth of fundamental and clinical observations in heart failure made during the past 2 decades. Thus, the time appears to be propitious for focusing increasing attention on this condition and indeed for launching a major investigative effort in this area.

**Acknowledgment:** The helpful cooperation of the section chairmen listed in the editorial in preparing lucid reviews of their sections of the workshop were invaluable in the preparation of this summary.

# A More Meaningful Scoring System for Determining the Severity of Coronary Heart Disease

GOFFREDO G. GENSINI, MD

Selzer[1] in a recent editorial criticized the classification of the severity of coronary artery disease (CAD) which is currently used in all randomized trials on the surgical versus medical therapy of CAD. He pointed out that the classification of single-, double-, triple-vessel and main left (SDTML) coronary artery disease allows the inclusion in each subgroup of a mixture of patients with both a favorable and an unfavorable prognosis and provides, at best, only marginal differentiation of medically and surgically treated patients. He further suggested that patients with CAD should be identified on the basis of severity of narrowings, cardiac performance, effectiveness of coronary collateral circulation, amount of myocardium jeopardized by ischemia, and possibly other factors as well.

I wholeheartedly share these views, as described in my book in 1975.[2] An updated version of this scoring and stratifying method and a critique of the SDTML disease classification appeared in 1980.[3] There I stated: "A method that assigns a different severity score depending on the degree of luminal narrowing and the geographical importance of its location would be desirable. . . . Several years ago, recognizing these shortcomings, I devised a system that takes into consideration the geometrically increasing severity of lesions, the cumulative effects of multiple obstructions, the significance of their locations, the modifying influence of the collaterals, the size and quality of the distal vessels, and the importance of the status of myocardial function [Fig. 1]. . . . The fundamental concept forming the basis of this system is the hypothesis that the severity of coronary artery disease must be regarded as a consequence of the functional significance of the vascular narrowing and the extent of the area perfused by the involved vessel or vessels; the presence of an effective collateral situation may, on the other hand, modify the functional significance of a severe obstruction or occlusion. . . . Although this method may not be ideal, it provides more useful information than the simple division of patients into single-, double-, and triple-vessel disease. The advantages of this scoring method are as follows: (1) it provides an accurate stratification of patients according to the functional significance of their disease; (2) it lends itself to computer elaboration, storage, retrieval, and analysis; (3) it provides an opportunity to match patients with similar degrees of coronary artery disease who are receiving different forms of treatment; and (4) it allows for continuous, microprocessor-assisted studies of interobserved and intraobserver variability. Computer hardware and software to elaborate and store this type of information are readily available and are inexpensive."

Thus, the challenge of Selzer had already been met several years ago by a classification of patients with CAD, but this classification has not been utilized by others. It is time for cardiologists to adopt a more meaningful measurement of the severity of CAD.

From Msgr. Toomey Cardiovascular Laboratory, St. Joseph's Hospital Health Center, Syracuse, New York.

The right column in this panel indicates the relative severity of these lesions using a score of 1 for 25% obstruction and doubling that number as the severity of the obstructions progresses according to the indicated reduction of lumen diameter (left column). **Right panel,** the principal vascular segments of (from left to right) the right coronary artery, the left anterior descending, and the circumflex. Each segment is followed by a multiplying factor such as X1, X2.5, and so on, depending on the functional significance of the area supplied by that segment.

# Pericardial Windows Are Suboptimal

DAVID H. SPODICK, MD, DSc

Experience with pericardial disease indicates that pericardial "windows" tend to close.[1] For a patient who can tolerate reasonably extensive thoracotomy, as much parietal pericardium as possible should always be resected, particularly in patients with continuing pathologic processes. Even then, pericardial remnants occasionally produce potentially constrictive fibrous tissue or bands of calcium, making the widest excision desirable. The pericardial window therefore has served as a palliative procedure mainly for systemically ill patients, such as those with malignant neoplasms or renal failure, who might not tolerate a more extensive procedure. Subxiphoid pericardiotomy[2] can be done if necessary under local anesthesia and permits the creation of a pericardial window, the resected tissue representing a generous biopsy. It also permits digital and endoscopic inspection of the pericardium, thus avoiding immediate thoracotomy without precluding near-total pericardectomy when the patient is in better condition.

# INSTRUCTIONS TO AUTHORS

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY and they become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. The Publisher assumes no liability for any material published in the *Journal*. All accepted manuscripts are subject to editing to aid understanding and conserve space.

**ADDRESS MANUSCRIPTS TO:** William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 6935 Arlington Road, Suite 406, Bethesda, Maryland 20814. The *covering letter* should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make: for example, the elimination of 1 or more figures or tables or a portion of the text to increase the likelihood of publication of their work in the *Journal*. Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The suggested reviewers will be carefully considered along with other experts in the field. Additionally, the editor would listen if the authors provided the names of any investigators they consider unlikely to give nonbiased reviews of their work.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page consisting of the article's title, the names of the authors, and the institution from which the work originated, (2) a second title page including only the article's title, (3) summary, (4) text, (5) references, (6) acknowledgment, (7) figure legends, and (8) tables. Number all pages in the above sequence, beginning with the title page as 1, the summary as 2, and so on (leave the second title page unnumbered). Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references) with at least 25 mm (1 inch) margins.

The second title page, the one which omits the names of the authors and the institution, will permit the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be obtained. The authors may state which type of review they wish in the covering letter.

**TITLE PAGE, SUMMARY, AND ABSTRACT:** Include the first or middle and last names with other initials of all authors. Provide a short *running title* of 3 to 6 words. Insert at the bottom the name and address of the institution from which the work originated, and information about grant support if necessary. Add at the bottom the phrase "*Address for reprints:*" followed by full name and address with zip code. Limit the **summary** to 250 words. Also, submit an **abstract** of 150 words or less to be used in the Table of Contents. List 2 to 6 **key words** for subject indexing at the end of the summary.

**STYLE:** Use appropriate **subheadings** throughout the body of the text, such as in the Methods, Results, and Comments sections. **Abbreviations** are permitted, but no more than 2 or 3 per manuscript. Spell out the first time they appear in the text followed by the abbreviation in parentheses. Consult the *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* published in the *Annals of Internal Medicine* June 1982; 96: 766–771, and also the *Stylebook/Editorial Manual of the American Medical Association* for current usage. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence.

**REFERENCES:** In references, list **all authors,** inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts if possible, but indicate by the abbreviation (*abstr*) when doing so. Do not use periods after authors' initials. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications do not constitute references. In referring to a manuscript that has been submitted but not yet published, use the phrase "unpublished observations" in parentheses.

**Journal:** Vismara LA, Vera Z, Miller RR, Mason DT. Efficacy of disopyramide phosphate in the treatment of refractory ventricular tachycardia. Am J Cardiol 1977; 39:1027–1034.

**Chapter in Book:** Schiebler GL, Van Mierop LHS, Krovetz LJ. Diseases of the tricuspid valve. In: Moss AJ, Adams F, eds. Heart Disease in Infants, Children and Adolescents. Baltimore: Williams & Wilkins, 1968: 134–139.

**Book:** Berne E. Principles of Group Treatment. New York: Oxford University Press, 1966:26.

**FIGURES:** Submit 3 glossy nonmounted *prints* of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all *charts* (line drawings). Make decimals, broken lines, etc. strong enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by number and title of the article (omit the authors' names so that blinded reviews can be obtained). Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce any previously published figure. Limit figures to the number necessary to present the message clearly. Type each figure legend on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author. If color figures are submitted, identify in the covering letter who should be billed for the color charges.

**TABLES:** Place each table on a separate page, double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate positive or present; a zero (0) for negative or absent, and a dash (—) for "no information available" or "not done."

**REPRINTS:** Price schedules and order cards for reprints will be mailed to the author on publication of the article. Individual reprints must be obtained through the author.

# Dobutamine/Dobutrex®

## Dobutamine HCl

**Description:** Dobutrex is (±)-4-[2-[[3-(*p*-hydroxyphenyl)-1-methylpropyl] amino]ethyl]-pyrocatechol hydrochloride. It is a synthetic catecholamine.

Molecular Formula: $C_{18}H_{23}NO_3 \cdot HCl$ Molecular Weight: 337.84

The clinical formulation is supplied in a sterile lyophilized form for intravenous use only. Each vial contains 250 mg of dobutamine and 250 mg of mannitol. Hydrochloric acid is used to adjust the *p*H. The *p*H of the reconstituted solution is between 2.5 and 5.5.

**Clinical Pharmacology:** Dobutrex is a direct-acting inotropic agent whose primary activity results from stimulation of the beta receptors of the heart while producing comparatively mild chronotropic, hypertensive, arrhythmogenic, and vasodilative effects. It does not cause the release of endogenous norepinephrine, as does dopamine. In animal studies, dobutamine produces less increase in heart rate and less decrease in peripheral vascular resistance for a given inotropic effect than does isoproterenol.

In patients with depressed cardiac function, both dobutamine and isoproterenol increase the cardiac output to a similar degree. In the case of dobutamine, this increase is usually not accompanied by marked increases in heart rate (although tachycardia is occasionally observed), and the cardiac stroke volume is usually increased. In contrast, isoproterenol increases the cardiac index primarily by increasing the heart rate while stroke volume changes little or declines.

Facilitation of atrioventricular conduction has been observed in human electrophysiologic studies and in patients with atrial fibrillation.

Systemic vascular resistance is usually decreased with administration of dobutamine. Occasionally, minimum vasoconstriction has been observed.

Most clinical experience with dobutamine is short-term—up to several hours in duration. In the limited number of patients who were studied for 24, 48, and 72 hours, a persistent increase in cardiac output occurred in some, whereas the output of others returned toward base-line values.

The onset of action of Dobutrex is within one to two minutes; however, as much as ten minutes may be required to obtain the peak effect of a particular infusion rate.

The plasma half-life of dobutamine in humans is two minutes. The principal routes of metabolism are methylation of the catechol and conjugation. In human urine, the major excretion products are the conjugates of dobutamine and 3-O-methyl dobutamine. The 3-O-methyl derivative of dobutamine is inactive.

Alteration of synaptic concentrations of catecholamines with either reserpine or tricyclic antidepressants does not alter the actions of dobutamine in animals, which indicates that the actions of dobutamine are not dependent on presynaptic mechanisms.

**Indications and Usage:** Dobutrex is indicated when parenteral therapy is necessary for inotropic support in the short-term treatment of adults with cardiac decompensation due to depressed contractility resulting either from organic heart disease or from cardiac surgical procedures.

In patients who have atrial fibrillation with rapid ventricular response, a digitalis preparation should be used prior to institution of therapy with Dobutrex.

**Contraindication:** Dobutrex is contraindicated in patients with idiopathic hypertrophic subaortic stenosis.

**Warnings:** 1. *Increase in Heart Rate or Blood Pressure*—Dobutrex may cause a marked increase in heart rate or blood pressure, especially systolic pressure. Approximately 10 percent of patients in clinical studies have had rate increases of 30 beats/minute or more, and about 7.5 percent have had a 50-mm Hg or greater increase in systolic pressure. Reduction of dosage usually reverses these effects promptly. Because dobutamine facilitates atrioventricular conduction, patients with atrial fibrillation are at risk of developing rapid ventricular response. Patients with preexisting hypertension appear to face an increased risk of developing an exaggerated pressor response.

2. *Ectopic Activity*—Dobutrex may precipitate or exacerbate ventricular ectopic activity, but it rarely has caused ventricular tachycardia.

**Precautions: 1. During the administration of Dobutrex, as with any adrenergic agent, ECG and blood pressure should be continuously monitored. In addition, pulmonary wedge pressure and cardiac output should be monitored whenever possible to aid in the safe and effective infusion of Dobutrex.**

2. Hypovolemia should be corrected with suitable volume expanders before treatment with Dobutrex is instituted.

3. Animal studies indicate that Dobutrex may be ineffective if the patient has recently received a beta-blocking drug. In such a case, the peripheral vascular resistance may increase.

4. No improvement may be observed in the presence of marked mechanical obstruction, such as severe valvular aortic stenosis.

*Usage Following Acute Myocardial Infarction*—Clinical experience with Dobutrex following myocardial infarction has been insufficient to establish the safety of the drug for this use. There is concern that any agent which increases contractile force and heart rate may increase the size of an infarction by intensifying ischemia, but it is not known whether dobutamine does so.

*Usage in Pregnancy*—Reproduction studies performed in rats and rabbits have revealed no evidence of impaired fertility, harm to the fetus, or teratogenic effects due to dobutamine. However, the drug has not been administered to pregnant women and should be used only when the expected benefits clearly outweigh the potential risks to the fetus.

*Pediatric Use*—The safety and effectiveness of Dobutrex for use in children have not been studied.

*Drug Interactions*—There was no evidence of drug interactions in clinical studies in which Dobutrex was administered concurrently with other drugs, including digitalis preparations, furosemide, spironolactone, lidocaine, glyceryl trinitrate, isosorbide dinitrate, morphine, atropine, heparin, protamine, potassium chloride, folic acid, and acetaminophen. Preliminary studies indicate that the concomitant use of dobutamine and nitroprusside results in a higher cardiac output and, usually, a lower pulmonary wedge pressure than when either drug is used alone.

**Adverse Reactions:** *Increased Heart Rate, Blood Pressure, and Ventricular Ectopic Activity*—A 10 to 20-mm increase in systolic blood pressure and an increase in heart rate of five to 15 beats per minute have been noted in most patients. (See Warnings regarding exaggerated chronotropic and pressor effects.) Approximately 5 percent of patients have had increased premature ventricular beats during infusions. These effects are dose related.

*Miscellaneous Uncommon Effects*—The following adverse effects have been reported in 1 to 3 percent of patients: nausea, headache, anginal pain, nonspecific chest pain, palpitations, and shortness of breath.

No abnormal laboratory values attributable to Dobutrex have been observed.

*Longer-Term Safety*—Infusions of up to 72 hours have revealed no adverse effects other than those seen with shorter infusions.

**Overdosage:** In case of overdosage, as evidenced by excessive alteration of blood pressure or by tachycardia, reduce the rate of administration or temporarily discontinue Dobutrex until the patient's condition stabilizes. Because the duration of action of Dobutrex is short, usually no additional remedial measures are necessary.

**Administration and Dosage:** *Reconstitution and Stability*—Dobutrex is incompatible with alkaline solutions and should not be mixed with products such as 5% Sodium Bicarbonate Injection.

Dobutrex may be reconstituted with Sterile Water for Injection or 5% Dextrose Injection. To reconstitute, add 10 ml of diluent to Vial No. 7051, Dobutrex, 250 mg. If the material is not completely dissolved, add another 10 ml of diluent. The reconstituted solution may be stored under refrigeration for 48 hours or at room temperature for six hours.

Reconstituted Dobutrex must be further diluted to at least 50 ml prior to administration in 5% Dextrose Injection, 0.9% Sodium Chloride Injection, or Sodium Lactate Injection. Intravenous solutions should be used within 24 hours.

Solutions containing Dobutrex may exhibit a color that, if present, will increase with time. This color change is due to slight oxidation of the drug, but there is no significant loss of potency during the reconstitution time periods stated above.

*Recommended Dosage*—The rate of infusion needed to increase cardiac output usually ranges from 2.5 to 10 mcg/kg/min (see table). On rare occasions, infusion rates up to 40 mcg/kg/min have been required to obtain the desired effect.

Rates of Infusion for Concentrations of 250, 500, and 1000 mcg/ml

| Drug Delivery Rate (mcg/kg/min) | Infusion Delivery Rate | | |
|---|---|---|---|
| | 250 mcg/ml* (ml/kg/min) | 500 mcg/ml† (ml/kg/min) | 1000 mcg/ml‡ (ml/kg/min) |
| 2.5 | 0.01 | 0.005 | 0.0025 |
| 5 | 0.02 | 0.01 | 0.005 |
| 7.5 | 0.03 | 0.015 | 0.0075 |
| 10 | 0.04 | 0.02 | 0.01 |
| 12.5 | 0.05 | 0.025 | 0.0125 |
| 15 | 0.06 | 0.03 | 0.015 |

*250 mg per liter of diluent
†500 mg per liter or 250 mg per 500 ml of diluent
‡1000 mg per liter or 250 mg per 250 ml of diluent

The rate of administration and the duration of therapy should be adjusted according to the patient's response, as determined by heart rate, presence of ectopic activity, blood pressure, urine flow, and, whenever possible, measurement of central venous or pulmonary wedge pressure and cardiac output.

Concentrations up to 5000 mcg/ml have been administered to humans (250 mg/50 ml). The final volume administered should be determined by the fluid requirements of the patient.

**How Supplied:** Vials Dobutrex® (dobutamine hydrochloride, Lilly), for Injection (lyophilized), equivalent to 250 mg dobutamine, 20-ml size, rubber-stoppered, in packages of 1. [121979]

# Cardiac Bioprostheses

## Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982

**The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.**

**To order your copy of this important new book use the order form below.**

**edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD**
**ISBN 0-914316-34-6, 609pp., illus., Nov. 1982., $65.00**

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

## Who are the editors?

**Lawrence H. Cohn, MD,** is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982*.

**Vincenzo Gallucci, MD,** is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

## Table of Contents

**Section 1 CLINICAL ANALYSIS 1.** The Evolution of the Biological Valve **2.** Heart Valve Replacement with the Hancock Bioprosthesis: A 5-11 Year Follow-up **3.** A 14-Year Experience with Valvular Bioprostheses: Valve Survival and Patient Survival **4.** A Thousand Porcine Bioprostheses Revisited. Do They Conform with the Expected Pattern? **5.** Clinical Durability of the Pericardial Xenograft Valve: 11 Years' Experience **6.** Long-term Results of 159 Porcine Valve Implantations **7.** Mid- and Long-term Evaluation of Porcine Bioprosthetic Valves: A 6-Year Experience

**Section 2 HEMODYNAMICS 8.** Hemodynamic Evaluation of the Hancock Bioprosthesis in the Mitral Position: A 1-7 Year Follow-up **9.** Hemodynamic Evaluation of the Carpentier-Edwards Standard and Improved Anulus Bioprostheses **10.** Hemodynamic Evaluation in Valvular Patients Carrying Low Profile Bioprostheses **11.** Noninvasive Scintigraphic Assessment of Left and Right Ventricular Function in Patients with Bioprosthetic Mitral Valves at Long-term Risk **12.** Orifice View Roentgenography for Evaluation of the Orifice Area of Bioprosthetic Valves

**Section 3 THROMBOEMBOLISM 13.** Alterations in Valvular Surgery: Biological Valves **14.** Early and Late Results of Porcine Bioprostheses Versus Mechanical Prostheses in Aortic and Mitral Positions **15.** Mitral Bioprostheses in 202 Patients with Chronic Atrial Fibrillation, Giant Left Atrium, and Atrial Thrombi: Long-term Results with No Anticoagulation **16.** Thromboembolism and Anticoagulation after Isolated Mitral Valve Replacement with Porcine Heterografts **17.** Preoperative Determinants of Return to Sinus Rhythm after Valve Replacement **18.** Porcine Bioprostheses Versus Mechanical Valvular Substitutes: A Retrospective Comparative Analysis

**Section 4 PEDIATRIC VALVE REPLACEMENT 19.** Valved Conduits: A Panacea for Complex Congenital Heart Defects? **20.** Factors Influencing Late Results of Extracardiac Conduit Repair for Congenital Cardiac Defects **21.** Calcification of Porcine Bioprostheses in Children **22.** Valve Replacement in Children: Biological Versus Mechanical Valves **23.** Bioprosthetic Valve Replacement in Children **24.** Aortic Root Replacement **25.** Conduits Containing Antibiotic Preserved Homografts in the Treatment Of Complex Congenital Heart Defects **26.** Dura Mater Bioprosthesis in Young Patients

Pfizer

PHARMACEUTICALS

PFIZER INC., 235 E. 42ND ST., NEW YORK, N.Y. 10017

Dear Doctor:

Scientific progress continues to result in significant new therapeutic advances. As you know, the positive results achieved with these treatments depend in good measure upon effective physician/patient communication. At the same time, there is a growing interest by the general public in becoming better informed on healthcare issues and in assuming a larger role in maintaining their own health. We believe that an informed patient has a better chance of being a healthier patient.

In an effort to help bring needed information to the public, Pfizer is embarking on a health education campaign. This campaign consists of a series of health information messages which will reach patients through newspapers, magazines, television and radio. In these messages, patients are informed of the symptoms of diseases such as hypertension and angina and are advised to seek the advice of their physicians in response to these symptoms. Moreover, the messages stress the need for periodic medical examinations to uncover asymptomatic conditions. A sample message in this series appears on the page opposite this letter.

This campaign is one part of a broad new Pfizer communications program. Another aspect of this effort is our Patient Information Program, which consists of providing comprehensive patient information books, such as Learning to Live with Angina, to physicians for distribution to their patients.

I take pride in this program and invite your participation and response.

Sincerely,

Sheldon G. Gilgore

Sheldon G. Gilgore, M.D.
President

THE PFIZER HEALTHCARE SERIES

# High blood pressure discriminates

## *By age. By sex. By race.*

If you're interested in knowing whether or not you're in a group for which high blood pressure (hypertension) is more common—here is some helpful information.

**Age discrimination**
High blood pressure seems to prefer older people—half of Americans aged 65 and over have it. Yet, hypertension can occur at almost any age.

**Sex discrimination**
Under the age of 50, hypertension is more common in men than in women. After 55 or 60, it is more common in women than in men. But more men die from hypertension complications than do women.

**Race discrimination**
Statistics show that blacks, compared to whites, get high blood pressure earlier in life, at higher levels and twice as often.

Whites as well as blacks have high blood pressure, which may be associated with being overweight. (Your doctor would know if you are.) Hypertension runs in families and it's aggravated by consuming too much salt.

**Why worry about high blood pressure?**
Because in its early stages, high blood pressure is a disease without symptoms. More than 35 million Americans of both sexes and all ages and races have it—yet two out of six afflicted persons don't even know it.

Also, high blood pressure can shorten life. Uncontrolled, it can cause hardening of the arteries and it is the major cause of crippling through heart attacks, strokes and damage to the kidneys.

Yet, high blood pressure is one of the easiest conditions to diagnose and to treat.

**How is high blood pressure diagnosed?**
Hypertension cannot be diagnosed on the basis of one blood pressure reading alone. Only your doctor can accurately diagnose your condition.

**What can be done about high blood pressure?**
High blood pressure can be treated in several ways:

1. Healthier living through modifications in life-style: reduction of weight, salt intake, smoking, stress, anxieties and proper programs of exercise, rest and relaxation.
2. Blood pressure-controlling medicines. These have been among the miracles of modern therapeutics. A whole range of effective medicines can be prescribed by your doctor. The use of antihypertensive medicines, together with improved life-styles, has helped cut one type of stroke death in half and reduce heart attacks by one-third.
3. Watching out for other health conditions that may aggravate the effects of hypertension. For example, the risk of heart disease increases if both high blood pressure and high cholesterol are present. Your doctor can test your cholesterol level and interpret the results.

Obviously, you can't be your own doctor. You need a support system. We call it...

**Partners in Healthcare**

**You are the most important partner.**
Only you can take the first step and seek the advice of your physician. And it's you who must decide to accept the guidance and counseling of your physician, nurse and pharmacist. When medicines are prescribed, only you can take them as directed.

**Your doctor interprets the warning signs, orders your tests, and makes the diagnosis.**
Your physician also prescribes the best medication for you among those available—considering each drug's characteristics—and monitors your progress.

**All those who discover, develop and distribute medicines complete the partnership.**
Pfizer's ongoing research brings you essential medicines for a wide range of diseases. Through our development of these and many other medications, we are fulfilling our responsibility as one of your partners in healthcare.

# THE ALPHA UNIVERSE

## ...is the Catapres® universe of central alpha control* for all kinds of hypertensives

**No contraindications** to Catapres — you can prescribe it for:**

- **Asthmatic hypertensives**
  Does not act directly on beta$_2$ receptors of the lungs (blocking these receptors induces bronchospasm).
- **Diabetic hypertensives**
  Lowers blood pressure without impairing oral antidiabetic effectiveness.
- **Hypertensives with renal insufficiency**
  Lowers blood pressure without long-term reduction of cardiac output. (Does not reduce renal perfusion or GFR.)
- **Hypertensives with congestive heart failure**
  Does not depress myocardial contractility.
- **Stress-induced hypertension**
  Inhibits sympathetic nervous activity centrally and does not elevate plasma catecholamines.
- **Elderly hypertensives**
  Recommended in isolated systolic hypertension in the elderly.[1]

*Central alpha-adrenergic stimulation decreases sympathetic outflow from the brain, as shown in animal studies.

**Like any antihypertensive, use with caution in severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

1. Statement on Hypertension in the Elderly, Revised April, 1980. Approved by the National High Blood Pressure Education Program Coordinating Committee.

Tablets of 0.1, 0.2, 0.3 mg

# Catapres®

## (clonidine HCl)

## Hypertension

Please see brief summary of PI for warnings, precautions, and adverse reactions.

# THE ALPHA UNIVERSE

Tablets of 0.1, 0.2, 0.3 mg

**Catapres®**
(clonidine HCl)
**Hypertension**

## Catapres®

**(clonidine hydrochloride)**

**Tablets of 0.1, 0.2, 0.3 mg**

**Indication:** The drug is indicated in the treatment of hypertension. As an antihypertensive drug, Catapres (clonidine hydrochloride) is mild to moderate in potency. It may be employed in a general treatment program with a diuretic and/or other antihypertensive agents as needed for proper patient response.

**Warnings:** Tolerance may develop in some patients necessitating a reevaluation of therapy.
*Usage in Pregnancy:* In view of embryotoxic findings in animals, and since information on possible adverse effects in pregnant women is limited to uncontrolled clinical data, the drug is not recommended in women who are or may become pregnant unless the potential benefits outweigh the potential risk to mother and fetus.
*Usage in Children:* No clinical experience is available with the use of Catapres (clonidine hydrochloride) in children.

**Precautions:** When discontinuing Catapres (clonidine hydrochloride), reduce the dose gradually over 2 to 4 days to avoid a possible rapid rise in blood pressure and associated subjective symptoms such as nervousness, agitation, and headache. Patients should be instructed not to discontinue therapy without consulting their physician. Rare instances of hypertensive encephalopathy and death have been recorded after cessation of clonidine hydrochloride therapy. A causal relationship has not been established in these cases. It has been demonstrated that an excessive rise in blood pressure, should it occur, can be reversed by resumption of clonidine hydrochloride therapy or by intravenous phentolamine. Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of the sedative effect. This drug may enhance the CNS-depressive effects of alcohol, barbiturates and other sedatives. Like any other agent lowering blood pressure, clonidine hydrochloride should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

As an integral part of their overall long-term care, patients treated with Catapres (clonidine hydrochloride) should receive periodic eye examinations. While, except for some dryness of the eyes, no drug-related abnormal ophthalmologic findings have been recorded with Catapres (clonidine hydrochloride), in several studies the drug produced a dose-dependent increase in the incidence and severity of spontaneously occurring retinal degeneration in albino rats treated for 6 months or longer.

**Adverse Reactions:** The most common reactions are dry mouth, drowsiness and sedation. Constipation, dizziness, headache, and fatigue have been reported. Generally these effects tend to diminish with continued therapy. The following reactions have been associated with the drug, some of them rarely. (In some instances an exact causal relationship has not been established.) These include: Anorexia, malaise, nausea, vomiting, parotid pain, mild transient abnormalities in liver function tests; one report of possible drug-induced hepatitis without icterus and hyperbilirubinemia in a patient receiving clonidine hydrochloride, chlorthalidone and papaverine hydrochloride. Weight gain, transient elevation of blood glucose, or serum creatine phosphokinase; congestive heart failure, Raynaud's phenomenon; vivid dreams or nightmares, insomnia, other behavioral changes, nervousness, restlessness, anxiety and mental depression. Also rash, angioneurotic edema, hives, urticaria, thinning of the hair, pruritus not associated with a rash, impotence, urinary retention, increased sensitivity to alcohol, dryness, itching or burning of the eyes, dryness of the nasal mucosa, pallor, gynecomastia, weakly positive Coombs' test, asymptomatic electrocardiographic abnormalities manifested as Wenckebach period or ventricular trigeminy.

**Overdosage:** Profound hypotension, weakness, somnolence, diminished or absent reflexes and vomiting followed the accidental ingestion of Catapres (clonidine hydrochloride) by several children from 19 months to 5 years of age. Gastric lavage and administration of an analeptic and vasopressor led to complete recovery within 24 hours. Tolazoline in intravenous doses of 10 mg at 30-minute intervals usually abolishes all effects of Catapres (clonidine hydrochloride) overdosage.

**How Supplied:** Catapres, brand of clonidine hydrochloride, is available as 0.1 mg (tan) and 0.2 mg (orange) oval, single-scored tablets in bottles of 100 and 1000 and unit dose package of 100.. Also available as 0.3 mg (peach) oval, single-scored tablets in bottles of 100.

For complete details, please see full prescribing information.

# Ventricular Flutter During Treatment With Amiodarone

GUANGGENG CUI, MD, WEIMIN HUANG, MD, and FERDINAND URTHALER, MD

Amiodarone is a widely used antiarrhythmic drug with long-lasting efficacy, minimal side effects, and few contraindications. However, amiodarone is not absolutely safe because it can itself trigger ventricular tachyarrhythmias[1,2] or cause sinus arrest,[3] as demonstrated in the patient to be described.

*A 48-year-old woman with known rheumatic mitral valve disease and recent onset of atrial fibrillation (Fig. 1-1) was started on digoxin (0.25 mg daily) and amiodarone (600 mg daily) on December 17, 1980. On January 5, 1981, the ventricular rate was about 80 beats/min and the dose of digoxin was decreased to 0.125 mg/day. Because of persisting atrial fibrillation, the dosage of amiodarone was increased to 800 mg/day on January 12, 1981. Ten days later sinus rhythm was restored, but the Q-T interval was prolonged to 0.48 second (Fig. 1-2). Digoxin was withdrawn and the dosage of amiodarone was reduced to 400 mg/day. The following day, Stokes-Adams attacks occurred. The electrocardiogram showed an atrioventricular (AV) junctional rhythm with ventricular bigeminy (Fig. 1-3), followed a few moments later by ventricular flutter (VF) (200 beats/min) (Fig. 1-4). At the time, the plasma level of digoxin, determined by radioimmunologic assay, was 0.92 ng/ml. Serum potassium, measured twice, was 3.5 and 4.0 mEq/liter, respectively. Lidocaine (200 mg) given intravenously was ineffective. Direct current shock with 100 W-s converted the VF to a slow[4] (Fig. 1-5) and then to a normal AV junctional rhythm[4] (Fig. 1-6) before restoring sinus rhythm with giant U wave alternans (Fig. 1-7). The next day VF recurred but was stopped by cardioversion, and by February 3 the electrocardiogram was normal (Fig. 1-8) and remained so for at least 6 months.*

Amiodarone prolongs the duration of the action potential in both atrial and ventricular cells.[5,6] It is not known whether amiodarone selectively inhibits potassium ion conductance or increases the slow inward current inactivation time constant, or both.[6] However, it is likely that a generalized prolongation of the action potentials will be reflected in a lengthening of the Q-T interval. Our patient had a prolonged Q-T interval that returned to normal 11 days after amiodarone therapy was discontinued. Others have made the same observation, but few adverse effects have been associated with amiodarone-induced lengthening of the Q-T interval.

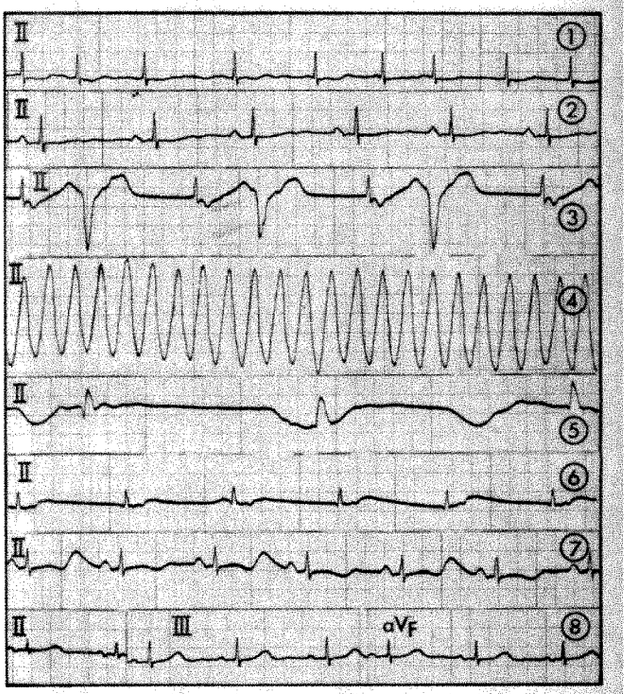

**FIGURE 1.** Lead II electrocardiograms (except for bottom strip with leads II, III, and aVF) illustrating episodes of (1) atrial fibrillation, (2) sinus rhythm, (3) AV junctional rhythm with retrograde atrial capture and ventricular premature beats (bigeminy), (4) ventricular flutter, (5) slow AV junctional rhythm, and (6) normal AV junctional rhythm. Paper speed 25 mm/s.

Our patient had a transient sinus arrest immediately before and after electroconversion of VF; however, in contrast to 2 cases of a previous report[3] in which the automaticity of the escape foci also was depressed, our patient had a normal substitute AV junctional escape rhythm.[4] Such depressions of automaticity could be due to an amiodarone-induced inhibition of the slow channel. Calcium entry blocking drugs are more effective in depressing sinus node automaticity than AV junctional automaticity.[7]

A profound decrease in heart rate coupled with an amiodarone-induced rate-independent prolongation of the Q-T interval will enhance the temporal dispersion of the refractory period[8] and favor the development of ventricular premature beats. Our patient had several

From the Shanghai Sixth People's Hospital, Shanghai, People's Republic of China; and the Department of Medicine, University of Alabama Medical Center, Birmingham, Alabama. This study was supported by the National Heart, Lung, and Blood Institute (Program Project Grant HL 11310 and SCOR on Ischemic Heart Disease HL 17667) and was conducted while Dr. Huang was on sabbatical leave in Birmingham, Alabama. Manuscript received September 1, 1982, accepted September 16, 1982.

premature beats immediately before the onset of VF. Although digitalis levels reportedly increase after administration of amiodarone,[9] our patient's digoxin level was normal. Thus, amiodarone can elicit dysrhythmias, and the simultaneous occurrence of depressed automaticity, a prolonged Q-T interval, and ventricular premature beats is an ominous premonitory sign.

# Myocardial Ischemia in Anomalous Origin of the Right Coronary Artery From the Pulmonary Trunk

## Proof of a Coronary Steal

GARY S. MINTZ, MD, ABDULMASSIH S. ISKANDRIAN, MD, CHARLES E. BEMIS, MD, ELDRED D. MUNDTH, MD, and JOHN S. OWENS, MD

Anomalous origin of the right coronary artery from the pulmonary artery is considered a benign entity. At least 22 patients with this condition have been reported. Two patients, both young, died suddenly.[1,2] This report describes another consequence of an anomalous right coronary artery.

*A 47-year-old man presented after having angina pectoris for 2 months. Findings on physicial examination, resting electrocardiography and chest roentgenography were normal. A multistage, graded treadmill exercise test was performed. After 9 minutes of exercise (at a heart rate of 160 beats/min), the patient described angina, and the electrocardiographic monitor showed 3 mm downsloping S-T segment depression in the anterior precordial leads (Fig. 1). A thallium-201 myocardial perfusion scan showed a decrease in perfusion of the anterior surface during exercise with normal perfusion in the 4-hour delayed study. On selective coronary arteriography the left anterior descending and left circumflex coronary arteries were normal. The right coronary artery (RCA) originated from the pulmonary trunk; it filled retrogradely by way of collaterals from the left coronary artery and emptied into the pulmonary trunk (Fig. 2). Myocardial perfusion scintigraphy using intracoronary injection of labelled particles was performed after coronary arteriography. Three mCi of technetium-99m human albumin microspheres were injected selectively into the left coronary artery. Total lung counts were 19,314 (84%); heart counts were 3,963 (16%) (Fig. 3).*

*The coronary artery anomaly was operatively corrected. The RCA was isolated; its origin was excised from the anterior surface of the pulmonary trunk and reimplanted into the aorta. Before excision, blood flow through the anomalous artery was 1,200 to 1,400 ml/min toward the pulmonary artery. After reimplantation, blood flow into the RCA was normal in direction. The postoperative course was uneventful. Findings were normal on exercise thallium-201 myocardial scintigraphy 3 months after operation. Arteriography showed that anastomosis of the RCA was normal.*

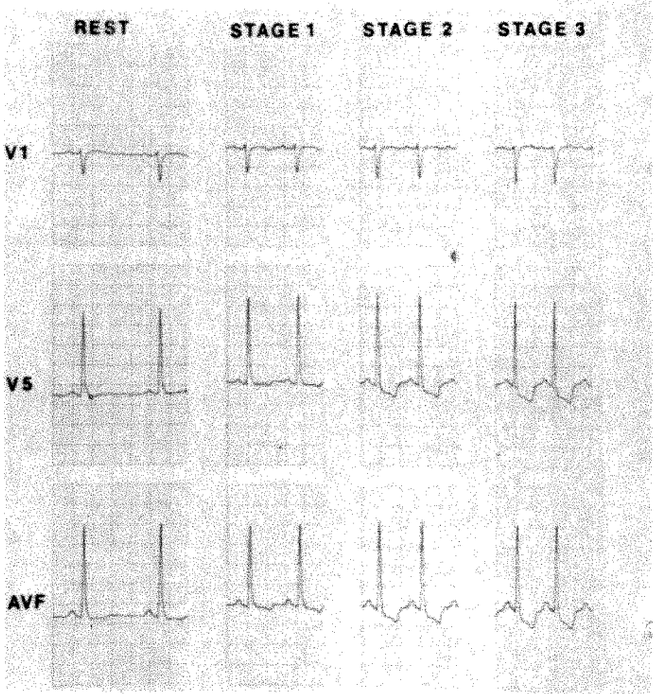

**FIGURE 1.** At stage 3 of the Bruce protocol, the treadmill exercise tests shows 3 mm downsloping S-T depression in the anterior precordial ($V_5$) and inferior (aVF) leads.

Coronary arterial steal may result from shunting of blood from 1 coronary artery to another (*intercoronary*), from 1 location in a coronary to another in the

From the Likoff Cardiovascular Institute, Hahnemann University and Hospital, Philadelphia, Pennsylvania. Manuscript received July 15, 1982; revised manuscript received August 10, 1982; accepted August 13, 1982.

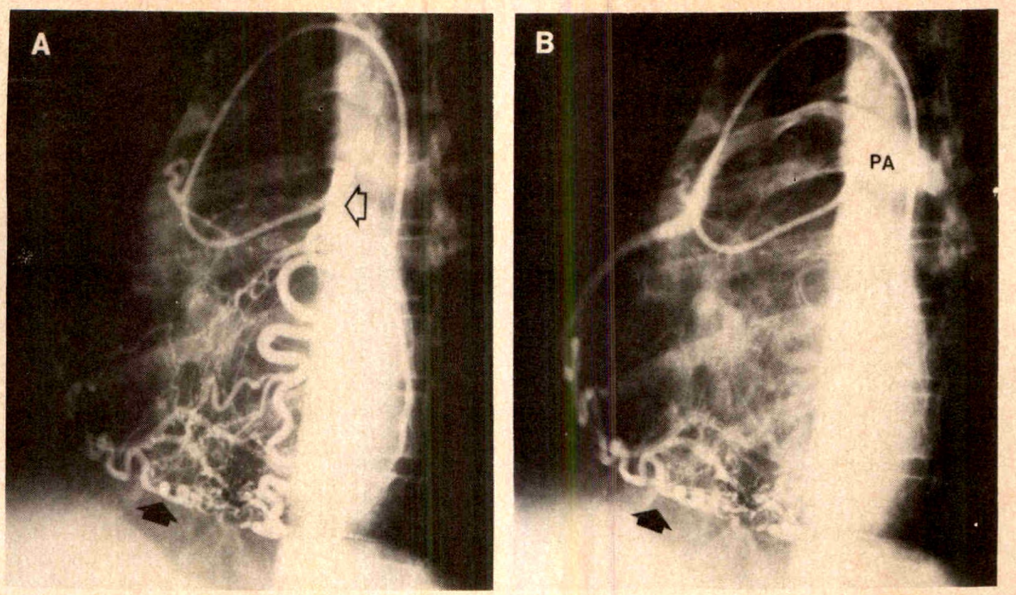

**FIGURE 2.** Selective coronary arteriograms demonstrating the anomalous origin of the right coronary artery from the pulmonary artery. **A**, contrast material is injected into the left coronary artery (**open arrow**); the right coronary artery (**solid arrow**) begins to opacify faintly. **B**, a later frame from the same injection shows denser opacification of the right coronary artery (**solid arrow**) as well as visualization of the anomalous artery originating from the pulmonary artery (PA).

same coronary through collateral flow (*intracoronary*), and from a coronary artery to a venous connection (*arteriovenous*). There are 3 potential causes: congenital or acquired anatomic malformations, obstructive coronary artery disease, and vasoactive pharmacologic interventions.

The most common congenital cause of a coronary steal is anomalous origin of the left coronary artery from the pulmonary trunk. After birth, the pulmonary arterial pressure falls, and survival depends on the acute development of collateral blood flow from the right to the left coronary artery. The collateral flow causes a large arteriovenous shunt, and the coronary steal embarasses left ventricular myocardial function.[3,4] It has been postulated that intercoronary shunting may exist in patients with obstructive coronary artery disease. Blood may be "stolen" from the less diseased artery by way of collateral flow to the more diseased artery.[5] Pharmacologic experiments have shown that vasodilators can cause "shunting" of blood from ischemic to nonischemic (or from subendocardial to subepicardial) myocardium. Alpha-adrenergic stimulation and vasoconstriction will reverse this phenomenon. It can be argued that these changes do not represent a true coronary steal, but rather a decrease in the effective perfusion pressure needed to maintain maximal collateral blood flow to the ischemic zone.[6,7]

Our patient with an anomalous origin of the RCA has an unusual proof of a true coronary artery steal. Of the technetium-99m labeled microspheres injected into the left coronary artery, 84% passed through the collaterals to the RCA to lodge in the pulmonary artery; thus, there was a 5 to 1, resting left-to-right shunt through the collateral circulation of the coronary vascular bed. (Because approximately 95% of these microspheres are

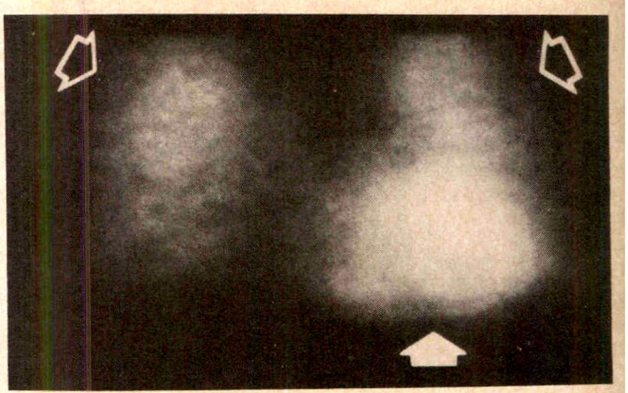

**FIGURE 3.** Three mCi of technetium-99m human albumin microspheres were injected selectively into the left coronary artery. Scintigraphic images of the heart and lungs show total lung counts of 19,314 (**open arrows**) and total heart counts of 3,963 (**solid arrows**). The left-to-right shunt through the coronary circulation is approximately 5 to 1.

10 to 30 $\mu$m in diameter, their presence in the lungs in such magnitude indicates large diameter collateral vessels.) During exercise, angina developed; myocardial scintigraphy showed decreased anterior wall perfusion; and the exercise electrocardiogram showed marked anterior precordial S-T segment depression. After reimplantation of the anomalous RCA, the patient became asymptomatic; and both the exercise scintigraphic and electrocardiographic results became normal.

Two explanations are possible. First, intercoronary steal from the anterior myocardial circulation caused anterior ischemia. Second, because the coronary circulation was maximally dilated, there was no ability to

increase blood flow to the anterior myocardium to meet the increased demand of exercise. Because the zone of ischemic myocardium was in the distribution of the left anterior descending artery, a steal was likely.

At surgery, coronary blood flow was 1,200 to 1,400 ml/min toward the pulmonary artery. Thus (by inference from the 5 to 1 intercoronary shunt), total anterograde left coronary blood flow was 1,440 to 1,680 ml/min, but only 240 to 280 ml/min supplied myocardium. Normal myocardial blood flow is approximately 85 ml/min/100 g of left ventricular myocardium at rest.[8,9] During maximal exercise, myocardial blood flow increased 4 times; during maximal pharmacologic coronary vasodilatation with dipyrimadole, myocardial blood flow increases 5 times. In our patient at rest before surgery, anterograde left coronary blood flow was greater than the maximal expected flow after maximal coronary vasodilatation. The ability to augment total flow during exercise was limited. A steal and myocardial ischemia resulted.

Thus, anomalous origin of the RCA is not benign. A coronary steal may cause exercise-induced myocardial ischemia. This may be the mechanism of sudden death reported in this disorder. If exercise-induced myocardial scintigraphy documents a steal, surgical correction appears warranted.

# Blood Cyst of the Papillary Muscle

## Clinical, Echocardiographic and Anatomic Observations

ANDREW M. HAUSER, MD, KAMALSINGH RATHOD, MD, JANET McGILL, MD, BARBARA F. ROSENBERG, MD, SEYMOUR GORDON, MD, and GERALD C. TIMMIS, MD

We describe the echocardiographic and anatomic features of an intraventricular cardiac blood cyst which was diagnosed after an embolic stroke.

*A 27-year-old man was admitted with acute right-sided hemiparesis and expressive aphasia. The cardiac sounds were normal and a grade 1/6 apical systolic murmur was heard. Findings on chest radiography, electrocardiography, and brain scan were normal. The hemiparesis and aphasia disappeared in 48 hours. A 2-dimensional echocardiogram (Fig. 1) demonstrated mild left atrial enlargement and systolic mitral valve prolapse. A 2.5 cm echolucent mass attached to the tip of the anterolateral papillary muscle moved in synchrony with adjacent chordae tendineae. In systole, anterior motion of the mass toward the left ventricular outflow tract was observed.*

From the Noninvasive Laboratory, the Division of Cardiovascular Diseases, the Department of Internal Medicine, the Department of Anatomic Pathology, the Division of Cardiovascular Diseases, and the Cardiac Laboratories, William Beaumont Hospital, Royal Oak, Michigan. Manuscript received September 3, 1982; revised manuscript received September 14, 1982, accepted September 17, 1982.

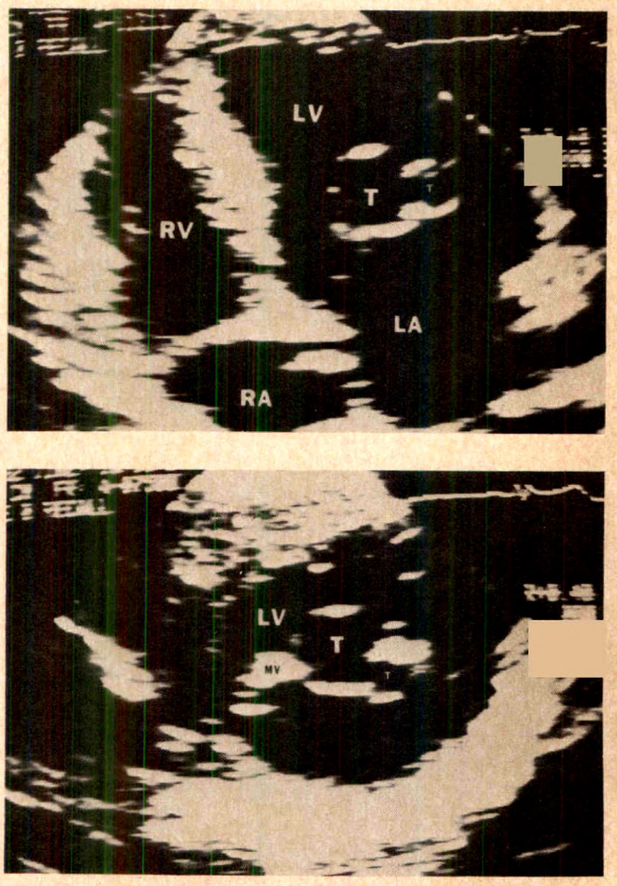

**FIGURE 1.** Apical 4-chamber view (**top**) and parasternal short-axis view (**bottom**) demonstrating the bilobed and cystic appearance of a mobile mass attached to the tip of the anterolateral papillary muscle and adjacent chordae tendineae. The left atrium (LA) is mildly enlarged. LV = left ventricle; RA = right atrium; RV = right ventricle; T = tumor.

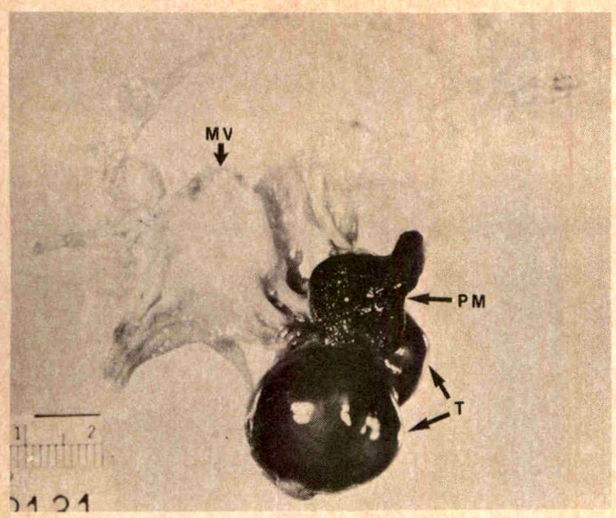

**FIGURE 2.** The 2.5 cm bilobed cyst attached to the papillary muscle. MV = normal mitral valve; PM = papillary muscle; T = tumor.

*Through a left atrial incision, a bilobed 2.5 cm cystic mass was found attached to the anterolateral papillary muscle and adjacent chordae tendineae. Complete removal necessitated replacement of the mitral valve also. The mass was formed of 2 contiguous cysts with trabeculated inner linings and contained dark red blood (Fig. 2). The cyst wall extended from the tip of the papillary muscle, adhered to adjacent chordae tendineae, and consisted of relatively dense collagenous fibrous tissue containing elastic fibers, lymphocytes, and a few plasma cells and eosinophils. The cyst was lined by endothelial-like cells. The mitral leaflets were normal.*

Since cystic cardiac masses are rare, there have been few echocardiographic descriptions. Farooki et al[1] noted an echo-free appearance on M-mode examination of an intramural fluid-filled hydatid cyst in a child with echinococcosis. The angiographic and pathologic appearance of a nonendothelialized cyst involving the mitral valve has been described by Leatherman et al.[2] Blood-filled cysts also may involve the pulmonic valve and can result in obstruction.[3–5] Our case differs from these in several respects: papilllary muscle attachment is unique, and to date, it is the only blood cyst detected by echocardiography. The echocardiogram provided the only clinical clue to the etiology of our patient's embolic event and obviated the need for cardiac catheterization.

# Transmural Ischemia During Preexercise Hyperventilation

BERNHARD H. LISKER, MD and
SANFORD E. LEFF, MD

Hyperventilation is performed in many laboratories as an adjunct to stress testing. Its purpose is to identify an abnormal electrocardiographic response that may occur from the hyperventilation associated with exercise rather than the exercise itself. There have been no reported complications of this procedure. We were recently involved in the care of a patient in whom profound myocardial ischemia developed during routine hyperventilation.

*The patient (LW) was a 69-year-old white man with systemic hypertension and exertional angina. His medications were hydrochlorothiazide and captopril. The 12-lead electrocardiogram, heart rate, and blood pressure were recorded supine, standing, and after 30 seconds of hyperventilation. With hyperventilation the heart rate increased from 76 to 122 beats/min and the blood pressure increased from 180/80 to 200/110 mm Hg. S-T segment elevations of 3 mm appeared in leads I and aVL and S-T segment depressions of 2 mm in the inferior leads (Fig. 1). The patient was dyspneic but without chest pain. The electrocardiogram returned to baseline after several minutes (Fig. 2). The patient was hospitalized. Serial cardiac enzyme levels were normal, but the electrocardiogram evolved T-wave inversions across the precordium lasting 4 days, consistent with nontransmural injury. Cardiac catheterization revealed 90% diameter narrowing of the left main coronary artery and multiple high grade narrowings in the proximal and mid right and left coronary arteries. The patient was treated with long-acting nitrates in addition to the antihypertensive medications and was referred for coronary bypass surgery.*

From the Division of Cardiology, Department of Medicine, Jewish Hospital and Medical Center of Brooklyn, Brooklyn, New York. Manuscript received September 27, 1982, accepted October 16, 1982.

Patients with angiographically proven normal coronary arteries have a propensity to electrocardiographic changes induced by hyperventilation. It has been suggested that subjects be routinely studied with at least 25 seconds of hyperventilation before exercise testing to rule out false-positive results.[1] However, there are reports that hyperventilation may induce changes in patients with angiographically proven coronary artery disease, demonstrating that these entities do coexist.[2] During hyperventilation a 20 to 30% increase in resting heart rate is expected, possibly because of stimulation of sympathetic activity.[3] Additionally, an analysis of coronary vascular dynamics after 6 minutes of hyper-

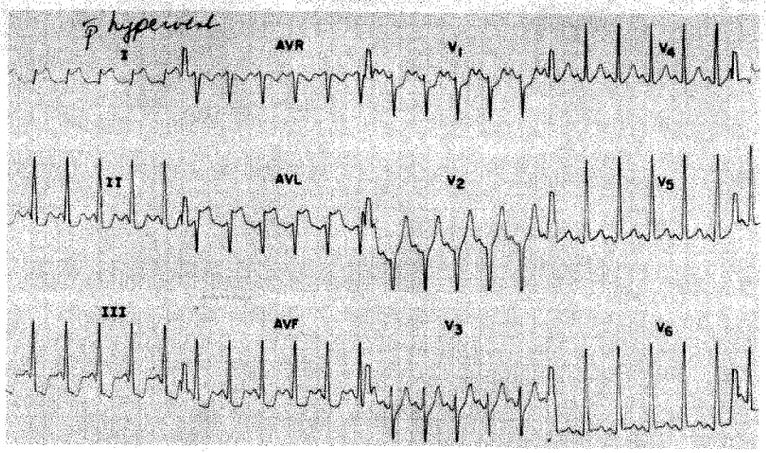

**FIGURE 1.** Electrocardiogram of patient LW immediately after hyperventilation, showing S-T segment elevations and depressions and pseudonormalization of T waves.

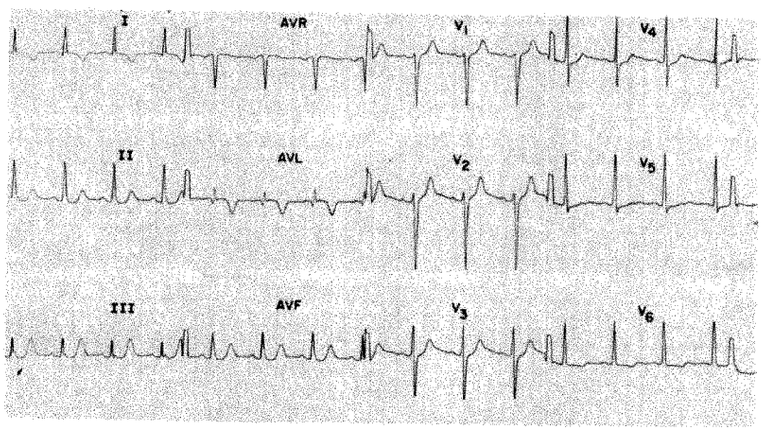

**FIGURE 2.** Three minutes after hyperventilation the electrocardiogram had returned to baseline.

ventilation showed an increase in myocardial oxygen uptake independent of the rate-pressure product, without reduction in coronary sinus blood flow, suggesting that hyperventilation can increase myocardial oxygen extraction but does not cause significant coronary vasoconstriction.[4] Coronary spasm has been elicited by respiratory alkalosis in a patient known to have variant angina[5] and in a recent series of 10 patients also with variant angina.[6] However, in all cases, more than 4 minutes of hyperventilation was required; the onset of electrocardiographic changes was usually delayed by several minutes; S-T segment elevations were rarely more than 1 mV.

Our patient had transmural ischemia that could be explained by a doubling of the rate-pressure product and a possible secondary or independent increase in myocardial oxygen extraction in a high risk setting. We cannot exclude spasm, but it is unlikely to have been provoked by such brief hyperventilation; we chose not to challenge with ergonovine during catheterization in view of the recent injury and severe obstructive coronary disease. The response to hyperventilation that we encountered, regardless of the exact cause, confirms that the responses to hyperventilation are complex, and the routine use of this procedure before exercise testing may yield unpredictable information that is not necessarily false-positive.

# Two-Dimensional Echocardiographic Detection of Right Atrial Thrombi

BRUNO V. MANNO, MD, IOANNIS P. PANIDIS, MD, MORRIS N. KOTLER, MD, GARY S. MINTZ, MD, and JOHN ROSS, RCPT

Right atrial thrombi are rarely diagnosed antemortem.[1,2] We describe 2 cases of right atrial thrombi detected by 2-dimensional echocardiography. A 62-year-old man with amyloid heart disease and congestive heart failure underwent 2-dimensional echocardiography, which revealed 4-chamber enlargement, especially of the right atrium. A dense echogenic band was reproducibly visualized coursing the right atrium only in an off-axis apical view while not seen in standard views (Fig. 1). This was confirmed as thrombus in the right atrial appendage at autopsy. A 34-year-old man underwent uneventful repair of a secundum atrial septal defect. Echocardiography performed postoperatively revealed an enlarged right atrium and ventricle. An irregular, immobile speckled mass was visualized posterolaterally in the right atrium in apical 4-chamber, right ventricular inflow, and right-sided apical 2-chamber views (Fig. 2). Angiography later confirmed this mass as thrombus.

Right atrial thrombus formation is uncommon; it is found in patients with an enlarged right atrium, reduced cardiac output, and relative stasis of blood, such as congestive cardiomyopathy,[3] idiopathic dilation of the right atrium[4] with foreign bodies,[5] or after endocardial damage.[6] Several of these factors were present in both of our cases.

The typical 2-dimensional echocardiographic appearance of atrial thrombus is a nonhomogeneous, immobile mass with a broad base of attachment to the atrial wall and a distinct intracavitary margin, as seen in our second patient (Fig. 2). However, the other pathologically confirmed thrombus was visualized as a curvilinear echodense band with a distal echo-free area seen only in an off-axis view (Fig. 1). The distal echo-free zone may be explained pathologically by the lack of organization or fibrosis; the band represented the interface between the blood and the thrombus. A previous report emphasized the necessity of visualizing right atrial masses in multiple standard planes to eliminate artifactual echoes.[1] The reproducibility and persistence of the band with varying transducer angulation and gain settings make artifact an unlikely cause. This suggests that nonstandard views may be necessary to detect right atrial thrombi, especially those in the right atrial appendage, and that thrombus may have an atypical echocardiographic appearance. Right atrial thrombus must be differentiated from other causes of a right atrial mass such as myxomas, sarcomas, and other neoplasms, primary or secondary. Secondary neoplasms can extend into the right atrium by way of the inferior vena cava, especially in patients with hypernephromas.[1,2] Differentiation from thrombus may be difficult; however, the site of attachment of the mass is useful. In myxomas, the site of attachment is the atrial septum, and in secondary tumors extension from the inferior vena may assist in the differentiation of right atrial masses. Triscuspid valve vegetation also may present as a right atrial mass; however, the attachment to the tricuspid leaflet and mobility during the cardiac cycle often help in the differentiation from thrombus. Several intrinsic right atrial structures such as Chiari network, aneurysm of the atrial septum, and Eustachian valves may appear as atrial masses. However, their location and mobility again help differentiate these structures from thrombus.

From the Likoff Cardiovascular Institute, Hahnemann University, Philadelphia, Pennsylvania. Manuscript received October 14, 1982; revised manuscript received October 24, 1982, accepted October 27, 1982.

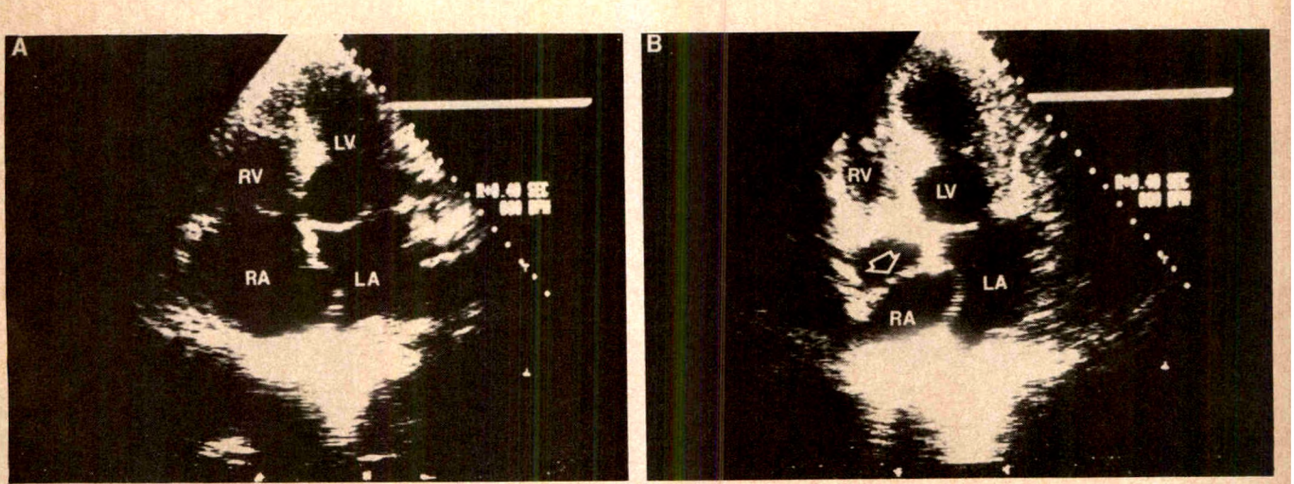

**FIGURE 1. A,** a 2-dimensional 4-chamber apical view. The right atrium (RA) is enlarged. No thrombus is seen. **B,** off-axis apical 4-chamber view. An echodense band is seen coursing the right atrium (**arrow**). LA = left atrium; LV = left ventricle; RV = right ventricle.

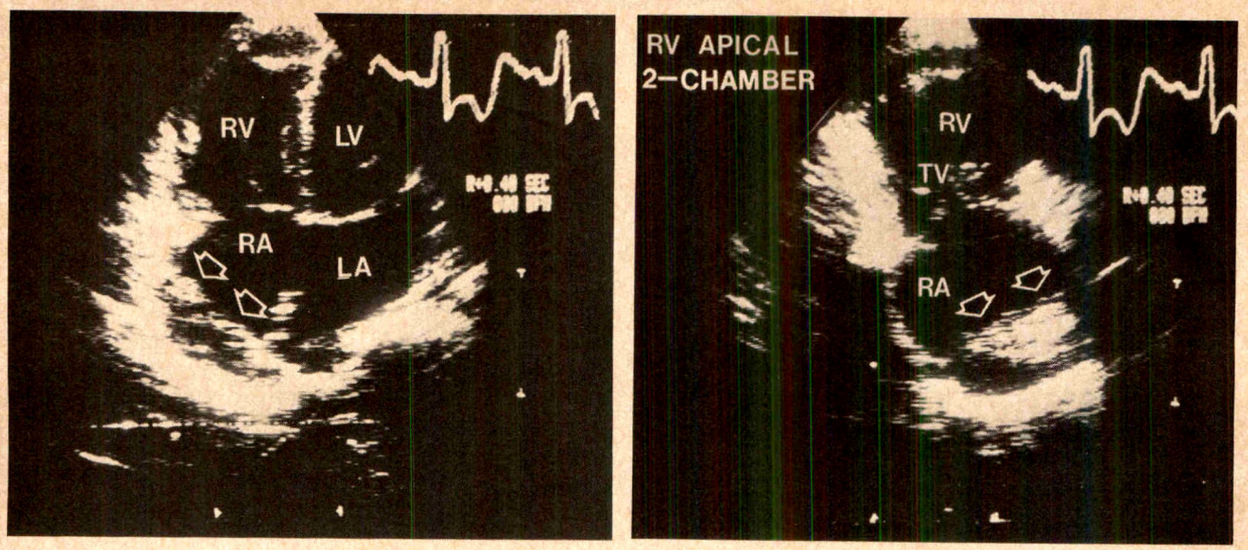

**FIGURE 2. Left,** 2-dimensional 4-chamber apical view demonstrating thrombus in posterolateral right atrium (RA) (**arrows**). **Right,** right ventricular apical 2-chamber view again demonstrates thrombus in right atrium (**arrow**). LA = left atrium; LV = left ventricle; RV = right ventricle; TV = tricuspid valve.

*In conclusion*, right atrial thrombus, although an uncommon finding, can be reliably diagnosed and differentiated from other atrial masses using 2-dimensional echocardiography. Use of off-axis as well as standard views may be necessary to visualize the thrombus.

# BASIC THERAPY FOR THE PREVENTION OF ANGINA PECTORIS*

Report from "Step-Care Therapy for Ischemic Heart Disease"
—a special symposium preceding the annual meeting
of the American College of Cardiology, April 24, 1982.

## Synopsis of the Symposium

### Step 1: Nitrates

Since nitrates both reduce myocardial oxygen demand and increase myocardial oxygen supply, their use is warranted as initial therapy for the control of angina pectoris. Dosage needs often vary significantly from patient to patient, and attention should be given to ensure that an adequate dosage level has been established.

### Step 2: Nitrates and beta blockers

For angina refractory to maximum-dose nitrate therapy, the complementary actions of beta blockers and nitrates provide a rational therapeutic modality. At this point a beta blocker should be added to the nitrate regimen.

### Step 3: Nitrates and calcium antagonists

Calcium antagonists have special usefulness in controlling cases where the myocardial oxygen supply is diminished by coronary vasospasm; their use in combination with nitrates is recommended if Step 2 therapy is unsatisfactory (or if the patient has variant or vasospastic angina).

Consensus of the Symposium

**Nitrates are basic in step-care therapy for ischemic heart disease**

**Step 1**
Stable or unstable angina: Nitrates

**Step 2**
If not controlled: Nitrates + beta blockers

**Step 3**
If still not controlled (or in variant angina): Nitrates + calcium antagonists

**The basic antianginal agent in these basic dosage forms**

*In angina pectoris...*

# ISORDIL® (ISOSORBIDE DINITRATE)

*is basic*

*ISORDIL has been evaluated as probably effective when taken by the sublingual or chewable route and possibly effective when taken orally for this indication. See Brief Summary on following page.

Ives®

© 1982 Ives Laboratories Inc.

# ISORDIL®
# (ISOSORBIDE DINITRATE) IS BASIC

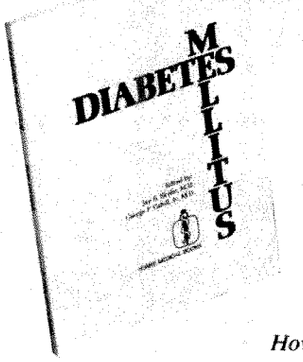
***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: When taken by the sublingual or chewable route, Isordil Sublingual and Chewable Tablets are indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.

"Possibly" effective: When taken by the oral route, Isordil is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded as useful in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indications requires further investigation.

**Contraindication:** Idiosyncrasy to this drug.
**Warnings:** Data supporting the use of nitrites and nitrates during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.
**Precautions:** Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.
**Adverse Reactions:** Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.



Consult direction circular before prescribing.

# INFECTIONS IN THE ABNORMAL HOST

**Edited by Michael H. Grieco, M.D.**
Prof. Clinical Medicine, Columbia Univ. College Physicians and Surgeons, Director R.A. Cooke Institute of Allergy, St. Luke's-Roosevelt Hosp., N.Y.

**Text by 47 specialists, 1,035 pages, 147 illus., 78 full-color photos. Completely indexed. $79.95.**

In 36 revealing chapters are reviewed the mechanics of host defenses. . .the various underlying disorders and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation. INFECTIONS IN THE ABNORMAL HOST will help you understand, diagnose, and manage the many infections which strike patients whose defense mechanisms are down.

## Check this list of chapters

### PART I HOST DEFENSES

• Introduction to the Abnormal Host and Complicating Infections • The Neutrophil in Host Defense: Congenital, Acquired and Drug-induced Abnormalities • The Complement System in Human Disease • Structure and Function of Immunoglobulins • Human Lymphocyte Subpopulations: Surface, Intracellular, Enzymatic Markers and Functions • Congenital and Acquired Primary Disorders of B and T Lymphocyte Function • Drug-induced B and T Lymphocyte and Monocyte Dysfunction • Cutaneous, Pulmonary, Gastrointestinal and Genitourinary Defense Mechanisms and Relationship to Nosocomial Infections • The Effects of Malnutrition on Host Responses and the Metabolic Sequelae of Infections • Humoral and Cellular Responses to Infection

### PART II INFECTIONS ASSOCIATED WITH THE ABNORMAL HOST

• Pyogenic Bacterial Infections • Higher Bacterial and Fungal Infections • Mycobacterial Infections • Viral and Chlamydial Infections • Protozoal and Helminthic Infections • Infections Complicating the Transfusion of Blood, Blood Products, Animal Exposure and Animal Products • Infections Complicating the Alcoholic Host • Infections in Parenteral Narcotic and Drug Abusers • Infections Complicating Uremia and Organ Transplantation • Infections in Patients with Neoplastic Diseases • Infections Complicating Diabetes Mellitus • Diagnosis and Treatment of Diffuse Pneumonias • Host Deficiency States and Central Nervous System Infections • Genitourinary Infections • Infections Complicating the Rheumatic Diseases • Endovascular and Prosthetic Implant Infections • Intraocular Manifestations of Systemic Infections • Selected Histopathologic Responses • The Microbiology Laboratory in Diagnosis and Therapy • Infections Complicating Surgical or Functional Splenectomy and Gastrectomy

### PART III MANAGEMENT

• Antimicrobial Therapy in the Compromised Host: Resistance, Pharmacology and Toxicity • Chemotherapy for Viral and Chlamydial Infections • Chemotherapy for Protozoal and Helminthic Infections • Infection Prevention in Patients with Cancer and Granulocytopenia • Immunologic Reconstitution • Gamma Globulin and Vaccine Therapy

• Index

1 "With this comprehensive work, Grieco has clearly filled a marked gap in the infectious disease literature. Various sections should be of interest to a broad range of practitioners. . . should serve as an important starting point and a useful reference source for any physician concerned with the complicated but increasingly important patient, the compromised host."
Philip A. Pizzo, MD, National Cancer Institute, **NEW ENGLAND JOURNAL OF MEDICINE**, Jan. 8, 1981

"This work will serve the physician well in caring for patients with serious infections. It is well organized and easy to use for quick reference. It also serves as an extensive review of infections in the defective host for specialists in infectious disease, pulmonary medicine, and cancer."
W. Lee Fanning, MD, **JOURNAL AMERICAN MEDICAL ASSOCIATION**, Jan. 2, 1981

"This important text should play a valuable role in the understanding and management of infections in the abnormal host and shows how clinical microbiologists, immunologists, and infectious disease clinicians can work together in the diagnosis and management of patients."
D.M. Weir, Dept. Bacteriology, Univ. of Edinburgh, **LANCET**, July 19, 1980

2 "This book is expertly edited. . .an outstanding feature is the thoroughness in which the book is indexed. . . As a comprehensive text for the academician and as a sound guide for the clinician in every field, the book is highly recommended. Immunologists, microbiologists, oncologists, internists, and specialists in infectious diseases should either purchase the book or have a copy readily available as a reference. Medical and graduate school libraries should own copies."
E.A. Gorzynski, **IMMUNOLOGICAL COMMUNICATIONS**, Sept. 7, 1980

3 "And so we must not only choose the correct antibiotic but also overcome the infection in this compromised, immunosuppressed patient or what we commonly term the person with poor resistance. This clearly calls for a book of guidance and this is it, all 1,035 pages of it, beautifully edited, lavishly produced, and with the experience and wisdom of 47 contributors."
D. Geraint James, FRCP, Dean Royal Northern Hospital, London, **MILAN DAILY MEDICAL NEWSPAPER**, May 1980

COMP SCAN
HOLTER ANALYSIS...
RESULTS THAT SPEAK FOR THEMSELVES
compu-scan
Medical Systems

**Comp-scan uses modern computer technology to accurately locate and classify each irregular heartbeat that occurs in a 24 hour Holter ECG procedure. Comp-scan then compiles and presents that information in a format that enables rapid verification and interpretation of scanned results...so, the cardiologist can concentrate on patient diagnosis and treatment.**

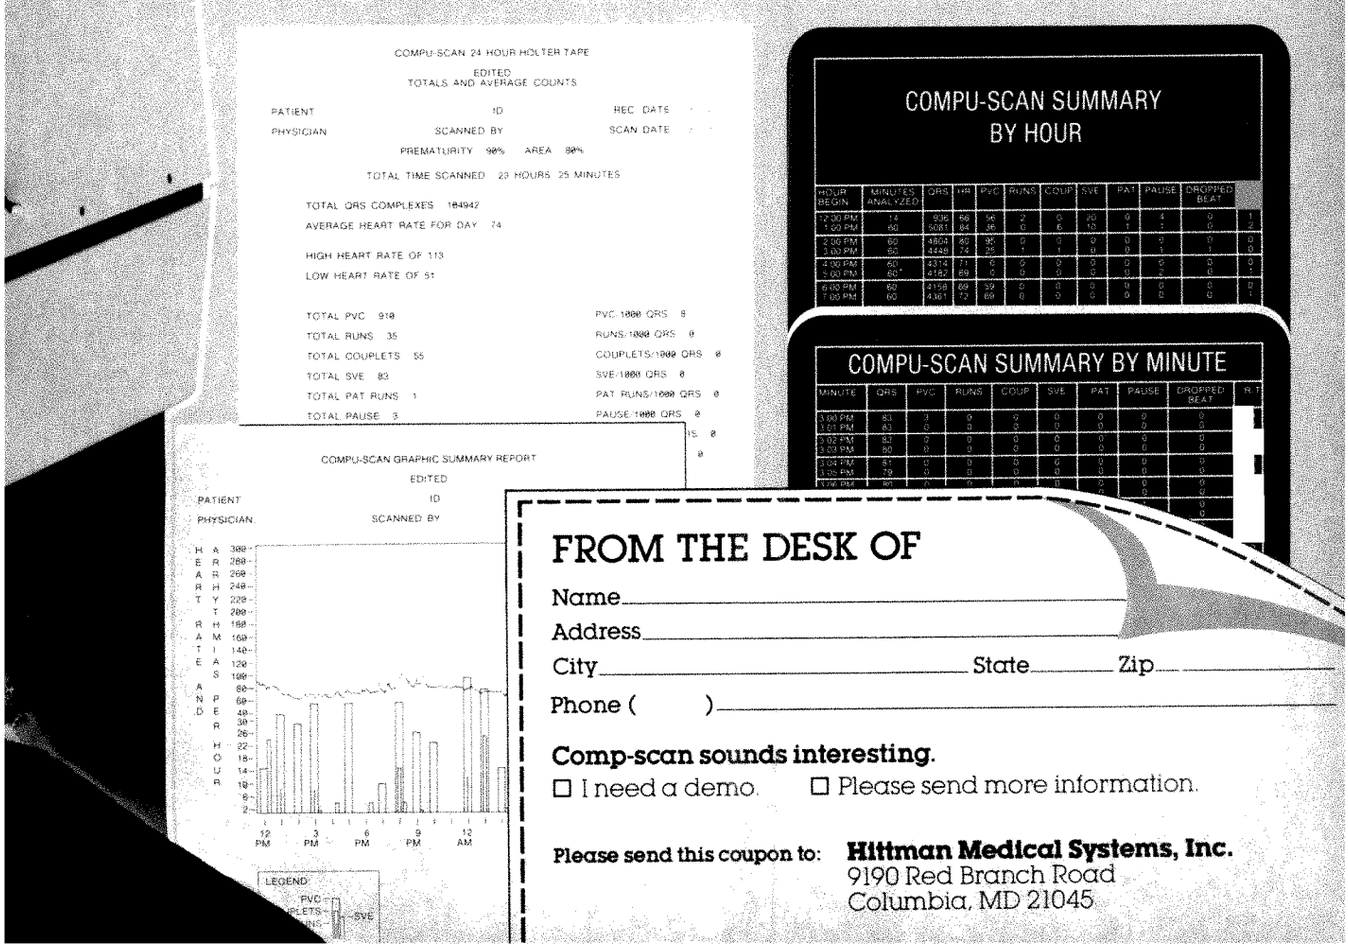
Comp-scan's rapidly available and precise reports are presented in the format needed by the technician and the cardiologist. Comprehensive summaries list all major events with ectopics classified by type and by the hour of occurrence. Classified events can be quickly and easily verified using the minute by minute breakdown of any selected hour. Or, the user can verify results by specific arrhythmia type using Comp-scan's exclusive automated arrhythmia search feature. Summary reports are presented on the color screen for immediate review, with permanent records provided by the high speed printer. ECG complexes are presented on a separate large display screen with permanent printout available from the 2-channel chart recorder.

## ACCURATE RESULTS

Comp-scan's computer has been programmed to recognize ectopic events. Once the operator has defined a patient's normal ECG, Comp-scan works by itself to locate and classify each ectopic event. Advanced hardware and software design allows Comp-scan to reject artifact while accommodating normal physiological changes.

## CONSISTENT RESULTS

Comp-scan's computer never gets tired or looks away. Every heartbeat of every Holter tape is analyzed with precisely the same criteria. While the system is automatically scanning, the operator can perform other tasks. And when analysis is complete, the operator's expertise is focused on verification and interpretation of results.



## VERIFIABLE RESULTS

Comp-scan can recall every heartbeat by the minute in which it occurred. So, each ectopic event that was detected by Comp-scan can be quickly displayed on the ECG screen for rapid verification. And those results can be edited and documented with patient ID for permanent record.

capsules

(temazepam)

## RESTORIL®
(temazepam)
## has an appropriate half-life

A half-life (mean of 10 hours) that parallels normal sleep time:

- patient gets 7-8 hours sleep
- most medication gone by morning
- patient awakes alert and refreshed
- minimal side effects
- insignificant accumulation

Please see brief summary of prescribing information on next page.

# Restful sleep, alert awakening

# RESTORIL®

15 mg
30 mg
capsules

(temazepam)

## A more appropriate half-life

One 30-mg capsule, h.s.—*usual adult dosage.*
One 15-mg capsule, h.s.—*recommended initial dosage for elderly and/or debilitated patients.*

**INDICATIONS AND USAGE:** Restoril® (temazepam) is indicated for the relief of insomnia associated with complaints of difficulty in falling asleep, frequent nocturnal awakenings, and/or early morning awakenings. Since insomnia is often transient and intermittent, the prolonged administration of Restoril is generally not necessary or recommended. Restoril has been employed for sleep maintenance for up to 35 consecutive nights of drug administration in sleep laboratory studies.

The possibility that the insomnia may be related to a condition for which there is more specific treatment should be considered.

**CONTRAINDICATIONS:** Benzodiazepines may cause fetal damage when administered during pregnancy. An increased risk of congenital malformations associated with the use of diazepam and chlordiazepoxide during the first trimester of pregnancy has been suggested in several studies. Also, ingestion of therapeutic doses of benzodiazepine hypnotics during the last weeks of pregnancy has resulted in neonatal CNS depression. Restoril is contraindicated in pregnant women. Consider a possibility of pregnancy when instituting therapy or whether patient intends to become pregnant.

**WARNINGS:** Patients receiving Restoril (temazepam) should be cautioned about possible combined effects with alcohol and other CNS depressants.

**PRECAUTIONS:** In elderly and/or debilitated patients, it is recommended that initial dosage be limited to 15 mg. The usual precautions are indicated for severely depressed patients or those in whom there is any evidence of latent depression; it should be recognized that suicidal tendencies may be present and protective measures may be necessary.

If Restoril is to be combined with other drugs having known hypnotic properties or CNS-depressant effects, due consideration should be given to potential additive effects.

*Information for Patients:* Patients receiving Restoril should be cautioned about possible combined effects with alcohol and other CNS depressants. Patients should be cautioned not to operate machinery or drive a motor vehicle. They should be advised of the possibility of disturbed nocturnal sleep for the first or second night after discontinuing the drug.

*Laboratory Tests:* The usual precautions should be observed in patients with impaired renal or hepatic function. Abnormal liver function tests as well as blood dyscrasias have been reported with benzodiazepines.

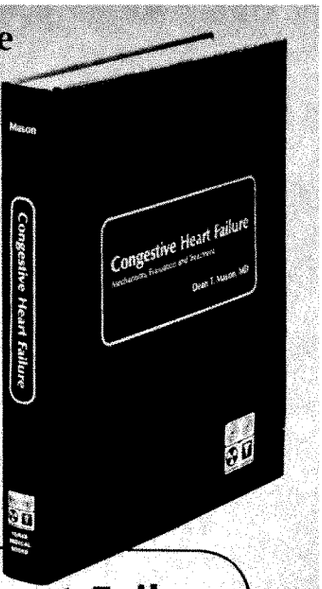
*Pregnancy:* Pregnancy Category X. See Contraindications.

*Pediatric Use:* Safety and effectiveness in children below the age of 18 years have not been established.

**ADVERSE REACTIONS:** The most common adverse reactions were drowsiness, dizziness and lethargy. Other side effects include confusion, euphoria and relaxed feeling. Less commonly reported were weakness, anorexia and diarrhea. Rarely reported were tremor, ataxia, lack of concentration, loss of equilibrium, falling and palpitations. And rarely reported were hallucinations, horizontal nystagmus and paradoxical reactions, including excitement, stimulation and hyperactivity.

Restoril is a controlled substance in Schedule IV. Caution must be exercised in addiction-prone individuals or those who might increase dosage.

**DOSAGE AND ADMINISTRATION:** *Adults:* 30 mg usual dosage before retiring; 15 mg may suffice in some. *Elderly and/or debilitated:* 15 mg recommended initially until individual response is determined.



**SUPPLIED:** Restoril (temazepam) capsules—15 mg maroon and pink, imprinted "RESTORIL 15 mg"; 30 mg, maroon and blue, imprinted "RESTORIL 30 mg". Packages of 100, 500 and ControlPak® packages of 25 capsules (continuous reverse-numbered roll of sealed blisters). (RES-Z2 11/1/81)

*Before prescribing, see package insert for full product information.*

# Brings you up-to-date on basic research and clinical progress

448 PAGES, 250 ILLUS./1976

## Congestive Heart Failure

Mechanisms, Evaluation and Treatment
Dean T. Mason, M.D.

This rare treatment of such a multifaceted subject provides an unusual opportunity for the busy clinician to add to his knowledge in a minimum amount of time. Any area of immediate interest can be rapidly located and as much data as needed can be quickly extracted. The concentration on improved clinical management will be appreciated by every internist, cardiologist, generalist, and any professional involved in cardiovascular medicine.

Dean Mason, President of the American College of Cardiology, has organized this monograph within the three areas relevant to an understanding of congestive heart failure: *mechanisms, evaluation* and *treatment*. Fifty-six recognized authorities have been assembled by Dr. Mason, each contributing their expertise to make this book the foremost text covering the highly important and common disorders of abnormal heart function.

This presentation of recent advances in basic research and clinical progress has been highly acclaimed for its major contribution to the improvement of patient care. We invite you to see if you don't agree. Order and take 30 days to look over the book. If you're not totally satisfied, return it.

### About the author . . . Dean T. Mason, M.D.

Professor of Medicine, Professor Physiology, Chief of Cardiovascular Medicine, University of California, School of Medicine, Davis.

President, American College of Cardiology; President, Western Society for Clinical Research.

Member of the American Board of Internal Medicine Cardiovascular Diseases.

Has authored more than 400 original articles on cardiovascular science and clinical cardiology.

Serves on the editorial boards of The American Journal of Cardiology, The Journal of Clinical Investigation, Circulation, Chest, Clinical Pharmacology and Therapeutics, Catheterization and Cardiovascular Diagnosis, and Heart and Lung.

Recipient of Experimental Therapeutics Award in 1973 from the American Society of Pharmacology and Experimental Therapeutics, the Research Awards in 1965 from the American Therapeutic Society, and the Theodore and Susan B. Cummings Humanitarian Awards in 1972, 1973, and 1975 from the U.S. State Department and the American College of Cardiology.

**YORKE MEDICAL BOOKS Box C-757, Brooklyn, N.Y. 11205**

Please send me a copy of CONGESTIVE HEART FAILURE for 30 days free examination and use. If I decide to keep it, your invoice will be honored ($40.00 plus shipping cost). Otherwise, the book will be returned for full credit or refund.

☐ Full payment enclosed, publisher absorbs shipping cost.
☐ Send invoice (U.S. and Canada only)
Countries outside Western Hemisphere: $40.00 prepaid in U.S. funds.

SIEMENS

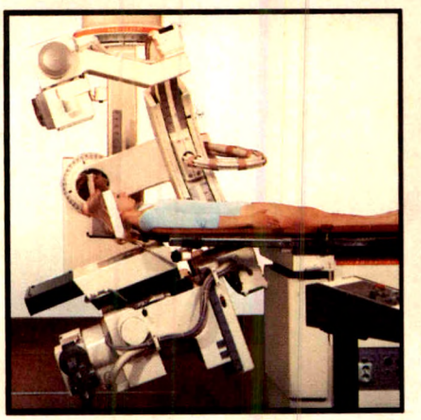
# ANGIOSKOP takes the compromise

Siemens...
an investment in diagnostic confidence.

# out of angiography.

When you invest in angiography equipment, there's no need for compromise. You can select an imaging system designed to optimize operator efficiency and clinical versatility. The ANGIOSKOP overcomes the typical limitations of other systems. That's why it's the "no-compromise" system. See for yourself. Compare the facts and discover the ANGIOSKOP advantage.

**A.P./P.A. Studies**



The typical compromise: True a.p. projection is not possible.
The ANGIOSKOP advantage: A C-arm system that easily positions to a.p. for classic peripheral studies including leg arteriography.

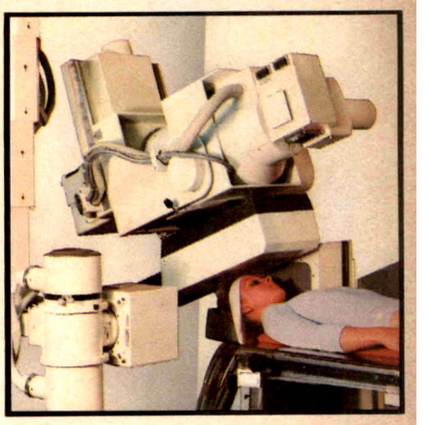
**Oblique Studies**

The typical compromise: Restricted patient access.
The ANGIOSKOP advantage: An imaging system that doesn't get in the way between clinician and patient. Our C-arm design eliminates the usual hinderances and provides easy access.

**Contact Studies**

The typical compromise: Inadequate working height.
The ANGIOSKOP advantage: Vertical adjustment of the isocenter to maintain an efficient and comfortable working height at all times.

**Cine Studies**



The typical compromise: Limited imaging applications.
The ANGIOSKOP advantage: A universal system that is well suited for cine technique and adaptable to perform all imaging modalities.

**Focal Spot Selection**

The typical compromise: Double focus tubes.
The ANGIOSKOP advantage: A unique triple focus tube for full range performance, minimizing geometric or motion unsharpness.

**X-Ray Generator System**

The typical compromise: Complex technique selection.
The ANGIOSKOP advantage: A new special procedure D.C. generator—the PANDOROS 1200A. Features convenient anatomic program selection from a single control desk for all modalities.

**...And Digital Subtraction Angiography**

The ANGIOSKOP allows all projection capabilities essential for optimum digital subtraction angiography. And Siemens offers a choice of digital imaging systems to match your clinical requirement.

To learn more about how the ANGIOSKOP can help uncomplicate your angiographic procedures, contact your local representative or

# The Pacekeeper™

## For steady maintenance following cardioversion of supraventricular, ventricular, and atrial tachyarrhythmias

- Maintains normal sinus rhythm
- Full quinidine cardiodynamics
- Greater gastrointestinal tolerance than with quinidine sulfate*
- Convenient b.i.d. or t.i.d. dosage

*Bibliography available upon request.

# CARDIOQUIN®
## TABLETS
## (quinidine polygalacturonate)

INDICATIONS AND USAGE: CARDIOQUIN Tablets are indicated as maintenance therapy after spontaneous and electrical conversion of atrial tachycardia, flutter or fibrillation and in the treatment of premature atrial and ventricular contractions, paroxysmal atrial tachycardia, paroxysmal A-V junctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when therapy is appropriate, and paroxysmal ventricular tachycardia when not associated with complete heartblock. CONTRAINDICATIONS: History of hypersensitivity to quinidine, complete A-V block, complete bundle branch block or other severe intraventricular conduction defects, myasthenia gravis, arrhythmias associated with digitalis toxicity. WARNINGS: In the treatment of atrial fibrillation with rapid ventricular response, use digitalis to control ventricular rate prior to administration of quinidine. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely high ventricular rate. This potential hazard may be reduced by digitalization prior to administration of quinidine. *Potentially toxic digoxin plasma levels may occur when quinidine is administered concurrently. Consider reducing digoxin dosage and monitoring for digitalis toxicity.* Evidence of quinidine cardiotoxicity (increased P-R and Q-T intervals, 50% widening of QRS, and/or ventricular ectopic beats or tachycardia) mandates immediate discontinuation of the drug, and/or close clinical and electrocardiographic monitoring. NOTE: Quinidine effect is enhanced by potassium and reduced in the presence of hypokalemia. Quinidine should be used with extreme caution in the presence of incomplete A-V block, since complete block and asystole may result. Quinidine may cause abnormalities of rhythm in digitalized patients; therefore, it should be used with caution in the presence of digitalis intoxication. Caution is also called for in patients exhibiting renal, cardiac or hepatic insufficiency because of potential toxic accumulation of quinidine in plasma. PRECAUTIONS: A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncracy to quinidine. ECG monitoring and determination of plasma quinidine levels are recommended when doses greater than 2.5 g/day are administered. Periodic blood counts and liver and kidney function tests should be performed during long-term therapy.

DRUG INTERACTIONS OF QUINIDINE:

| DRUG | EFFECT |
|---|---|
| With anticholinergic drugs | Additive vagolytic effect. |
| With cholinergic drugs | Antagonism of cholinergic effects. |
| With carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics | Alkalinization of urine resulting in decreased excretion of quinidine. |
| With coumarin anticoagulants | Reduction of clotting factor concentrations. |
| With tubocurare, succinylcholine and decamethonium | Potentiation of neuromuscular blockade. |
| With phenothiazines and reserpine | Additive cardiac depressive effects. |
| With hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin) | Decreased plasma half-life of quinidine. |
| With digoxin | Increased plasma concentrations of digoxin (see WARNINGS). |

PREGNANCY: The use of quinidine in pregnancy should be reserved only for those cases where the benefits outweigh the possible hazards to the patient and fetus. NURSING MOTHERS: The drug should be used with caution due to excretion of the quinidine in breast milk. ADVERSE REACTIONS: SYMPTOMS OF CINCHONISM (ringing in the ears, nausea, headaches, and/or disturbed vision) may appear in sensitive patients after a single dose of the drug. GASTROINTESTINAL: Diarrhea, nausea, vomiting, abdominal pain. CARDIOVASCULAR: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms (including ventricular tachycardia and fibrillation), paradoxical tachycardia, arterial embolism, and hypotension. HEMATOLOGIC: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranulocytosis. CNS: Headache, fever, vertigo, apprehension, excitement, confusion, delirium, and syncope; disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis. DERMATOLOGIC: Rash, cutaneous flushing with intense pruritus, urticaria. HYPERSENSITIVITY REACTIONS: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity. See package insert for Full Prescribing Information.

## Proceedings of a Symposium:
## INITIAL THERAPY IN HYPERTENSION

**619 Introduction**
NORMAN M. KAPLAN

**621 New Approaches to the Therapy of Mild Hypertension**
NORMAN M. KAPLAN

Despite widespread acceptance of the diuretic-first, stepped-care approach to the treatment of hypertension, the extensive broadening of antihypertensive therapy to many millions more who are at relatively low risk from mild hypertension should bring about a reassessment of current practice. The use of other alternatives to a diuretic as initial therapy and the substitution of another single agent rather than the sequential addition of drugs should be given careful consideration in order to provide the most benefit at the least risk.

**628 Effect of Antihypertensive Agents on Lipid Metabolism**
RALPH CUTLER

Recent studies have shown that thiazides and chlorthalidone have an adverse effect on lipid metabolism by increasing plasma triglycerides, total cholesterol, and low density lipoprotein (LDL) cholesterol in mildly hypertensive patients. Loop diuretics also affected lipid metabolism adversely, but by lowering high density lipoprotein (HDL) cholesterol instead. Methyldopa has also been found to decrease HDL, while reserpine appears to be lipid neutral. Beta-adrenergic blocking agents generally increase triglycerides—with the exception of nadolol, which decreases them—or decrease HDL. Prazosin has no adverse effect on lipids.

**632 Negative Effects of Diuretic Drugs on Metabolic Risk Factors for Coronary Heart Disease: Possible Alternative Drug Therapies**
RICHARD P. AMES

Results of 8 major hypertension treatment trials, all using diuretic drugs as first-line drug therapy, indicate a uniform reduction in stroke and congestive heart failure (CHD) but no convincing benefit to CHD. The reason for this unexpected failure to control CHD is unclear, but metabolic studies indicate that other risk factors for CHD, including serum lipids and glucose intolerance, are negatively affected during therapy, to the point of offsetting the benefit from the lowering of blood pressure. A link between the disturbed glucose and lipid pathways is suggested by evidence that they are reversed proportionally after the discontinuance of diuretic-based therapy. Replacement of diuretic drugs as first-line therapy for mild and moderate hypertension may be appropriate.

**639 New Developments in Alpha-Adrenergic Receptor Pharmacology: Implications for the Initial Treatment of Hypertension**
WILSON S. COLUCCI

Recent advances in our understanding of alpha-adrenergic receptor subtypes has resulted in the development of alpha$_1$ selective antagonists which demonstrate important advantages over both non-subtype-selective alpha

blockers and non–receptor-blocking sympatholytic agents which globally disrupt sympathetic function. In contrast, alpha$_1$ selective blockade results in a nearly specific reduction in vascular tone, and hence blood pressure. Prazosin, the first of these agents to become clinically available, has proved of value in the treatment of patients with hypertension. In contrast to non–subtype-selective alpha-adrenergic antagonists and direct-acting vasodilators, prazosin's hypotensive action is accompanied by little or no increase in heart rate, plasma renin activity, or plasma norepinephrine level. Prazosin may be used alone or in combination with a diuretic to treat mild, moderate, or severe hypertension, and the antihypertensive effect is sustained during long-term therapy. The major side effect, postural hypotension after the first drug administration, is related to drug dose and intravascular volume depletion, and can be effectively prevented. Because of the adverse effects of diuretics and beta-adrenergic antagonists, as well as the growing evidence that these drugs adversely affect serum lipids, the role of alpha-adrenergic receptor blockade with prazosin as initial therapy of hypertension, particularly in young adults, should be seriously considered.

**644 Effectiveness of Prazosin as Initial Antihypertensive Therapy**

RONALD OKUN

In a substantial number of studies dating back to 1973 and earlier, prazosin has been shown to be an effective and well-tolerated agent when used as initial therapy in all degrees of hypertension. Prazosin lowers blood pressure by reducing total peripheral resistance, which is the underlying hemodynamic abnormality in most essential hypertension. It minimally affects heart rate, cardiac output, renal function, plasma renin activity, circulating catecholamines, and plasma electrolytes. It has no adverse effect on lipid, glucose, or uric acid metabolism. Its most potentially serious side effect, the so-called first-dose phenomenon, is rare; its occurrence can be further diminished and in many cases abolished by giving it as initial therapy before a diuretic, avoiding volume depletion, and giving a minimal initial dose at bedtime.

**651 Treating the Patient With Mild Hypertension and Renal Insufficiency**

J. CAULIE GUNNELLS, Jr.

Patients with impaired renal function are particularly susceptible to potential damage from hypertension even if mild. The aims of therapy in such patients are (1) protection of renal function and (2) prevention or delay of accelerated atherosclerosis. To this end, antihypertensive therapy is required that does not adversely affect the lipid profile and does not further impair renal function. Diuretic and beta-blocking drugs fail to meet these basic criteria fully. Central- and peripheral-acting drugs also fall short of achieving the therapeutic objective because of symptomatic side effects leading, in some patients, to poor compliance. The alpha$_1$-adrenergic blocking agent prazosin meets the 2 requirements and therefore may be particularly useful as initial therapy in these patients.

**657 Roundtable Discussion**

# Introduction

NORMAN M. KAPLAN, MD

Over the past 25 years since orally effective drugs have become available, we have witnessed a steady and significant increase both in the number of persons found to be hypertensive and in the proportion who are being treated. According to the most recent National Health Survey, more than half of all persons with hypertension in the United States had their condition diagnosed, treated, and controlled in the late 1970s, versus less than 1 of 8 in the early 1960s.

Despite this widespread attention over the last 25 years, the therapy of hypertension now seems to be in a state of uncertainty. The reasons for this uncertainty are multiple. First, as more and more patients with milder forms of hypertension are being identified, the evidence for the value of active drug therapy for these 30 million or more persons in the United States remains in question. Second, even less definitive information is known about the long-term adherence to and effectiveness from nondrug therapies. Although many believe that these therapies should be used, particularly in individuals with mild hypertension, their use in part must be based on faith—and the realization that they will do no harm. On the other hand, the potential for long-term harm from currently used drug therapies has surfaced, as they are given to more patients at relatively lower risk. This applies particularly to the widely used diuretic-first, stepped-care approach.

This Symposium was put together in order to examine these issues and to offer additional evidence in favor of alternative approaches to the treatment of hypertension in the future. The first report reviews the evidence that current approaches may not provide the maximal balance between benefits and risks.

Initiation of therapy with drugs other than diuretics is advocated in my review. Dr. Cutler reviews the now-extensive literature about disturbances in lipid metabolism which may be seen with a variety of antihypertensive agents, and then Dr. Ames takes particular aim at the negative effects of diuretics on risk factors for coronary heart disease.

As additional support for the rationale of alpha-receptor blockade for the initial therapy of hypertension, Dr. Colucci provides some new information about alpha-receptor pharmacology. Dr. Okun next examines the evidence concerning the appropriateness of prazosin as an alternative choice. Last, Dr. Gunnells considers the therapy of patients with varying degrees of renal insufficiency.

All in all, these reports should be a useful source of information about alternative approaches to the initial therapy of hypertension, an area of present uncertainty that may find new solutions in the near future.

●

# New Approaches to the Therapy of Mild Hypertension

NORMAN M. KAPLAN, MD

**Concern about the initial use of diuretic agents under the stepped-care approach to the treatment of hypertension has been voiced before. Recently, however, the level of concern has risen as the results of various trials have questioned the safety of these agents in mild hypertension. Diuretic-induced hypokalemia has been reported in 10 to 30% of patients on long-term treatment. Recent studies show that hypokalemia may lead to previously unsuspected and potentially fatal arrhythmias, particularly after infarction. Increases in plasma cholesterol of 10 to 20 mg/dl may occur with diuretic therapy. Diuretics are also known to decrease glucose tolerance. Beta-adrenergic blocking drugs, although useful in many situations, are contraindicated in about 25% of the hypertensive population. These agents may also pose a long-term atherogenic risk because of their adverse effect on lipid and glucose metabolism.**

**If all these effects have the potential to increase the risk of coronary heart disease over the long term, then first-line administration of diuretic therapy and, to a lesser extent, beta-blocking therapy, to the 25 to 30 million Americans with diastolic pressure in the 90 to 100 mm Hg range must obviously be reassessed. Various alternative therapies, including withholding drugs for 6 months in patients with diastolic pressure of 90 to 100 mm Hg, using hygienic measures in patients not otherwise at high risk, and using other drugs such as the alpha$_1$-adrenergic inhibitor prazosin for initial therapy are discussed and evaluated.**

Recently, the stepwise addition of drugs, starting with a diuretic (Table I), has become the most widely used approach to the treatment of hypertension. The choice of a diuretic as the first drug has been advocated by expert clinicians, either as individuals or as members of committees, in the United States,[1] Canada,[2] England,[3] Sweden,[4] West Germany,[5] and Australia.[6] Every published large-scale clinical trial of the therapy of hypertension has used this approach.[7–11]

Objections have been raised to the uniform use of a diuretic as the first drug, mainly on the basis of the observed side effects and potential hazards of diuretics.[12] Laragh[13] was among the first to advocate the use initially of a beta-blocking drug in most patients, the choice to be based preferably on a renin profile. Some advocate a combination of a diuretic and a beta-blocking drug as ideal initial therapy,[14] whereas others suggest a beta-blocking agent for borderline and early hypertension and the combination of a thiazide-type diuretic and an adrenergic inhibitor, such as reserpine and guanethidine, for most with established essential hypertension.[15]

Currently, there are no large-scale, definitive data to document a substantial advantage in either efficacy or patient acceptance of any specific type of drug therapy. Two such trials are now underway, both comparing a diuretic with a beta-blocking drug, one involving 5,000 Swedish men,[16] the other 18,000 English patients.[17] It will likely be another 3 to 5 years before the results of these 2 trials are available.

In the meantime, the rationale for the use of a diuretic as the first and the combination of a diuretic and an adrenergic inhibitor as the second step in therapy needs reassessment. At least 2 other choices seem to be plausible: the first is the alternative of using a beta-blocking agent or another adrenergic inhibitor as the first drug; the second is the substitution of another single drug for the first one used if an inadequate response is obtained with the first, rather than the addition of the second drug to the first.

From the Department of Internal Medicine, University of Texas Southwestern Medical School, Dallas, Texas. This study was supported in part by Grant 5K07 HL00596 from the National Heart, Lung, and Blood Institute, Bethesda, Maryland.

## Alternatives to a Diuretic First

The widespread use of diuretics as the first drug to treat hypertension arose empirically: they were effective, relatively well-accepted by patients, and capable of sustaining their antihypertensive action indefinitely. Other types of drugs (Table II) were tried as initial agents, but a tendency for fluid retention to blunt their effectiveness was recognized[18] and documented[19] (Table III). These increases in plasma volume were observed after only short-term use of the 4 drugs and presumably reflect a tendency by the kidneys of hypertensive patients to retain sodium and water whenever the blood pressure is decreased by nondiuretic agents (Fig. 1). This reactive fluid retention should not be looked upon as a side effect of these agents but rather as a "natural" counteraction to decreasing the blood pressure by kidneys that have their pressure-sodium excretion relation reset at a higher level. With vasodilators, an additional mechanism is involved, the activation of the renin-angiotensin system with secondary increases in aldosterone. Therefore, the use of a diuretic as initial therapy seemed logical: up to half the patients could be controlled on it alone, and if another drug were needed, the diuretic was usually required to obtain maximal effectiveness.

**TABLE II Antihypertensive Drugs Available in the United States**

| Volume Depleting Agents | Sympathetic Blocking Drugs | Vasodilators | Converting Enzyme Inhibitors |
|---|---|---|---|
| (Sodium restriction) | Peripheral | Hydralazine | Captopril |
| | Reserpine | Minoxidil | |
| Diuretics | Guanethidine | | |
| Thiazides and related drugs | | | |
| Chlorthalidone | Central | | |
| Metolazone | Methyldopa | Diazoxide | |
| | Clonidine | Nitroprusside | |
| Loop diuretics | Guanabenz | | |
| Furosemide | Beta-receptor | | |
| Potassium savers | Atenolol | | |
| Spironolactone | Metoprolol | | |
| Triamterene | Nadolol | | |
| Amiloride | Pindolol | | |
| | Propanolol | | |
| | Timolol | | |
| | Alpha-receptor | | |
| | Prazosin | | |

**TABLE III Hemodynamic Effects of Antihypertensive Drugs (Given for 7 Days While Patients Were Taking 110 mmol of Sodium per Day)**

| Drug (Approximate Dose) | Arterial Pressure (mm Hg) | | Plasma Volume (ml/kg) |
|---|---|---|---|
| Methyldopa | Before | 148 ± 7 | 38 ± 2 |
| (840 mg) | After | 118 ± 7 | 42 ± 2 |
| Guanethidine | Before | 143 ± 6 | 36 ± 4 |
| (30 mg) | After | 119 ± 5 | 44 ± 3 |
| Reserpine | Before | 149 ± 8 | 39 ± 2 |
| (1.4 mg) | After | 122 ± 5 | 43 ± 2 |
| Clonidine | Before | 156 ± 9 | 42 ± 3 |
| (0.5 mg) | After | 127 ± 9 | 48 ± 3 |

From Safar et al.[19]

At least 4 issues concerning the routine use of diuretics as the initial choice of therapy have arisen in the past few years. Two are related to doubts about the efficacy and safety of diuretics, one concerns the nature of the hypertensive patients being treated, and the fourth involves the availability of newer antihypertensive agents.

## Questions Concerning the Safety of Diuretic Agents

Numerous side effects are known to follow the continuous use of diuretics in the therapy of hypertension (Fig. 2). Some, such as postural hypotension, hyponatremia, and prerenal azotemia, are unusual or of little apparent consequence. Others, such as hyperuricemia and hypercalcemia, are common but seldom harmful. However, others may increase the risk of cardiovascular complications, reducing or blunting the protection provided by decreasing the blood pressure. These include hypokalemia, decreases in glucose tolerance, and increases in plasma cholesterol, a complication not shown in Figure 2 because its pathogenesis is not understood.

*Hypokalemia* appears in 10 to 30% of patients re-

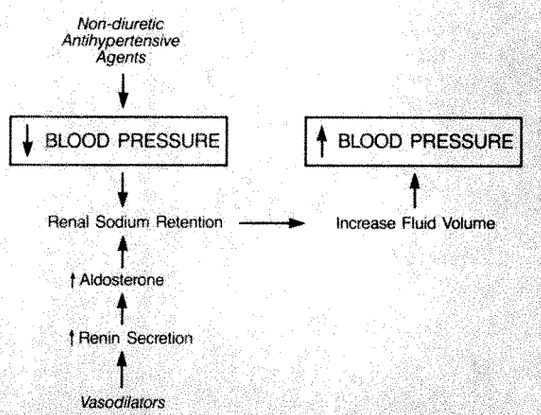

**FIGURE 1.** The manner by which nondiuretic antihypertensive agents may lose their effectiveness by renal sodium retention. (Reprinted, with permission, from Kaplan.[28])

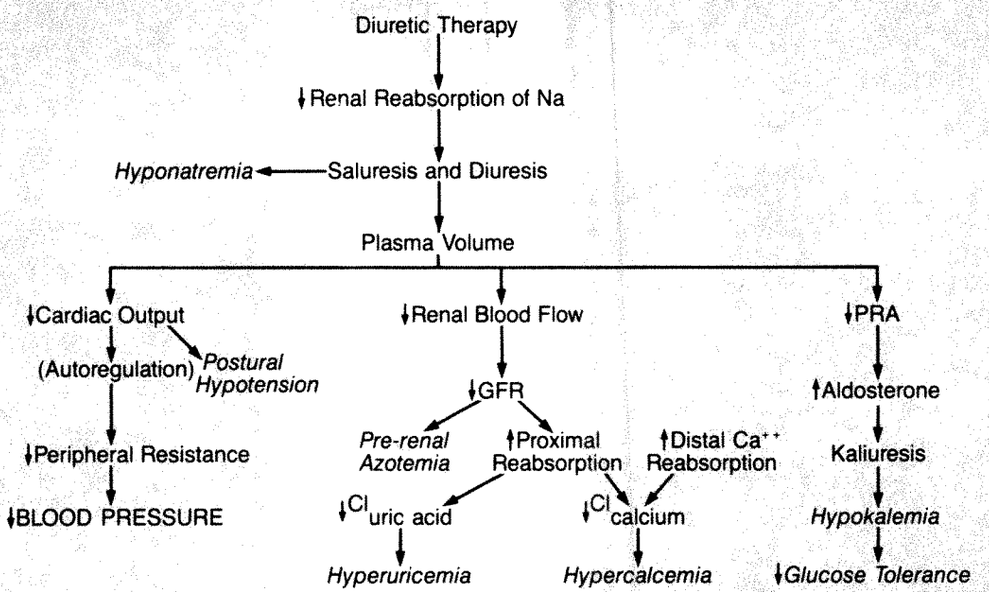

**FIGURE 2.** The mechanism by which chronic diuretic therapy may lead to various complications. (Reprinted, with permission, from Kaplan.[28])

ceiving long-term diuretic therapy[20] (Table IV). The 158 patients in this study were typical mildly hypertensive, middle-class, middle-aged English men and women who were on good diets and, therefore, likely representative of the majority of hypertensive subjects given diuretics.

The primary hazard of diuretic-induced hypokalemia is its tendency to increase myocardial irritability, inciting ventricular ectopic activity.[21] This change may become clinically apparent only when the myocardium experiences acute ischemia, as after acute myocardial infarction (Table V). The high frequency of ventricular fibrillation in hypokalemic patients is of concern because coronary artery disease is by far the most common cause of death among hypertensive individuals. The danger is known to be greater in those who are taking digitalis.

It may take acute stress such as acute myocardial infarction to expose this hazard from hypokalemia. With severe stress, plasma catecholamine levels increase to concentrations that have been shown to reduce plasma potassium levels by 0.5 to 0.6 mmol/liter[12] by accelerating the movement of potassium into cells. Moreover, catecholamines facilitate delayed postdepolarization[22] so that arrhythmias may arise during stress from both the direct effect of the catecholamines and the more intense hypokalemia in those already made susceptible by previous potassium losses.

**TABLE IV Effects on Plasma Potassium of Diuretic Agents in 158 Hypertensive English Patients**

| | Initial | 3 Months | 1 Year | 2 Years |
|---|---|---|---|---|
| Mean (mmol/liter) | 3.89 | 3.74 | 3.69 | 3.69 |
| % of patients 3.0–3.3 | 6 | 17 | 18 | 29 |
| % of patients 2.6–2.9 | 2 | 4 | 5 | 7 |

From Sandor et al.[20]

Thus, the usual diuretic-induced decrease in plasma potassium concentration of 0.6 mmol/liter[23] may be more hazardous than has been assumed. At least, these potential risks should serve to justify those steps that reduce diuretic wastage of potassium, namely, the use of the smallest effective dose of a diuretic, a reduced dietary sodium intake, and the concomitant use of potassium-sparing agents.

*Glucose intolerance* may accompany prolonged diuretic therapy. In the first 3 years of the Medical Research Council (MRC) trial, the incidence of impaired glucose tolerance was significantly higher in both men and women taking bendroflumethiazide than in those taking either a placebo or propranolol, but no differences in the mean random blood glucose levels were noted among the 3 groups.[17] The atherogenic potential of relatively small changes in glucose tolerance is unknown, but it poses another concern about the long-term safety of diuretic therapy.

In Figure 2, the decrease in glucose tolerance is shown to be caused by hypokalemia and there is some evidence

**TABLE V Ventricular Fibrillation (VF) After Acute Myocardial Infarction in Relation to Serum Potassium**

| Initial Serum Potassium | Patients (n) | Frequency of VF (%) per Population |
|---|---|---|
| ≤3.0 | 23 | 25 |
| 3.1–3.5 | 94 | 13 |
| 3.6–4.0 | 357 | 9 |
| 4.1–4.5 | 393 | 5 |
| 4.6–5.1 | 144 | 6 |
| ≥5.2 | 24 | 12 |

Data from Nordrehaug JD. Malignant arrhythmias in relation to serum potassium values in patients with an acute myocardial infarction. Acta Med Scand (Suppl) 1980;647:101–107.

for this causal connection.[24] Insulin resistance may also play a role because elevations in blood glucose have been closely correlated with higher plasma insulin levels.[25]

*Increases in plasma cholesterol* of 10 to 20 mg% frequently occur with diuretic therapy and are also correlated with higher plasma-insulin levels.[25] The atherogenic potential of a 20 mg/100 ml increase in plasma cholesterol can be shown by use of the Framingham data of the risks for coronary heart disease to completely reverse the reduction in risk provided by the 10 to 15 mm Hg decrease in systolic blood pressure that might be expected with chronic diuretic therapy.

## Questions Concerning the Efficacy of Diuretic Agents

All 3 of these biochemical aberrations may be responsible for increasing the cardiovascular risk. Separately or collectively they may be involved in the lesser protection from coronary artery disease that has been noted in most trials of therapy of hypertension, all of which used a diuretic as the first step in treatment. In all of these trials, antihypertensive therapy has been more effective in preventing strokes, congestive heart failure, aortic dissection, and progression of renal damage than in preventing coronary artery disease. In the Oslo study[10] *more* myocardial infarctions occurred in the treated patients. In both the Veterans Administration[7] and the Australian trials,[9] fewer fatal coronary events occurred in those given drug therapy, but the numbers were so small as not to reach statistical significance, whereas *more* nonfatal myocardial infarctions were noted in the treated patients, but did not reach statistical significance. Among those with mild hypertension in the Hypertension Detection and Follow-Up Program (HDFP) trial who were given more intensive therapy, that is, the stepped-care patients, there were 45% fewer deaths from myocardial infarction but 9% more deaths from "ischemic heart disease," giving an overall 20% decrease in deaths from coronary disease. Interpretation of the HDFP data is clouded by numerous problems, including the more intensive overall medical care provided stepped-care patients.[26]

The results of data on mortality from the massive Multiple Risk Factor Intervention Trial (MRFIT) cause further concern about the efficacy of treatment with the diuretic-first, stepped-care approach.[11] Almost 90% of the hypertensive men in the special intervention group were given antihypertensive drugs, 33% a diuretic drug alone, and 40% a diuretic plus an antiadrenergic drug (reserpine, methyldopa, or propranolol).[27] Among the less intensively treated patients, that is, the usual care half, fewer were given drug therapy and the mean decrease in diastolic blood pressure was 3.1 mm Hg less than that in the special intervention group. Among those who started with a diastolic pressure between 90 and 94 mm Hg, *more* coronary deaths occurred in the more intensively treated special intervention group, whereas those with a diastolic pressure >100 mm Hg were protected by more intensive therapy (Table VI). The same differential was noted in the Australian trial.[9]

**TABLE VI Multiple Risk Factor Intervention Trial: Mortality in Hypertensive Subjects Given Therapy**

| Initial Blood Pressure | Number | | CHD Deaths per 1,000 | | Total Deaths per 1,000 | |
|---|---|---|---|---|---|---|
| | SI | UC | SI | UC | SI | UC |
| 90–94 | 1,157 | 1,181 | 14.7 | 10.2 | 40.6 | 26.2 |
| 95–99 | 830 | 846 | 22.9 | 22.5 | 51.8 | 46.1 |
| ≥100 | 771 | 739 | 20.8 | 29.8 | 32.4 | 60.9 |
| Normal ECG | 2,785 | 2,808 | 15.8 | 20.7 | 35.9 | 43.4 |
| Abnormal ECG | 1,233 | 1,185 | 29.2 | 17.7 | 60.0 | 39.7 |

From Multiple Risk Factor Intervention Trial Research Group.[11]
CHD = coronary heart disease; ECG = electrocardiogram; SI = special intervention; UC = usual care.

Another disturbing set of figures from the MRFIT study is shown at the bottom of Table VI. Among all hypertensive subjects whose initial resting electrocardiogram was abnormal, those given more intensive therapy had significantly *more* coronary deaths. As of now, analyses relating coronary events to specific drugs and to specific laboratory data are not available, but the possibility that hypertensive subjects who start with an abnormal electrocardiogram would be even more susceptible to mischief from diuretic-induced hypokalemia must be considered.

Taken together, these data suggest that diuretics may provide less protection from the progression of coronary artery disease than their antihypertensive potency should offer. The antihypertensive potency of usual doses of a diuretic is comparable to that of moderate doses of a beta-blocking agent[4] or other adrenergic inhibitors.[28] Therefore, the biochemical aberrations that accompany the diuretic may detract from the protection they provide by reducing the blood pressure. Definitive evidence comparing the protection from coronary disease provided by diuretics versus beta-blocking agents will hopefully be forthcoming from the 2 ongoing European trials.[16,17]

## The Changing Hypertensive Population

The preceding litany of side effects and potential dangers from diuretics should not detract from their proven antihypertensive potency and the overall protection from cardiovascular diseases they provide in hypertensive subjects with diastolic pressure >100 mm Hg. However, we in the United States and likely practitioners everywhere are treating more and more patients with less elevated pressure, including many whose diastolic blood pressure is in the 90 to 100 mm Hg range. In the HDFP population, two thirds of all those with a diastolic pressure >90 mm Hg were in the 90 to 104 mm Hg range.[8] Such patients are at less risk from hypertension. Therefore, they can be provided less protection from a reduction in the blood pressure than can patients with higher pressures. As a result, any additional risk, no matter how small, from the therapy used to decrease the blood pressure must be weighed on a balance with correspondingly less counterweight. As an example, for

those with a level of blood pressure high enough to impose an additional 50% risk, the use of therapy that removes the excess risk while in itself adding a 10% risk can easily be defended as beneficial. However, for those with a lower level of blood pressure which in itself increases risk by only 10%, the use of such a therapy cannot be defended.

The treatment of mild asymptomatic hypertension is properly considered preventive medicine. The British epidemiologist Geoffrey Rose[29] emphasized the need for great caution in applying preventive measures to large groups of people: "If a preventive measure exposes many people to a small risk, then the harm it does may readily—as in the case of clofibrate—outweigh the benefits, since these are received by relatively few . . . . We may thus be unable to identify that small level of harm to individuals from long-term intervention that would be sufficient to make that line of prevention unprofitable or even harmful. Consequently we cannot accept long-term mass preventive medication."

If we accept the fact that there is some, albeit small, risk from the long-term use of diuretics, the administration of diuretic therapy to the 25 to 30 million Americans with diastolic pressure in the 90 to 100 mm Hg range must obviously be reconsidered. As I[30] and others[26,31] have suggested, the overall relative risk status of individual patients can be determined, using the Framingham data. Considering the potential risks and discomforts of drug therapy, a reasonable course might be to withhold drugs from those with diastolic pressure in the 90 to 100 mm Hg range who are otherwise at relatively low risk for at least 6 months while they are encouraged to follow nondrug therapy including weight reduction for the obese, moderate sodium restriction for all, and relaxation therapy for those who are willing. According to this view, only if the diastolic pressure remains >100 mm Hg is there a definite indication for drug therapy.

## Availability of Other Drugs

The fourth issue relates to the preceding 3: if diuretics pose various problems, are other drugs available that pose fewer problems and that therefore are alternative choices to the initial drug therapy of hypertension? One point alluded to before should be reiterated: there is little to distinguish the various available drugs listed in Table II as to antihypertensive efficacy in the majority of hypertensive subjects. Therefore, the choice of the initial drug should be based mainly on safety and side effects. Unfortunately, there are few controlled studies to document the differences among them. In the ongoing MRC trial, the percentage of patients who withdrew from treatment "owing to suspected adverse reactions" during the first 5 years totaled about 5% of those on placebo and about 15% of those on either bendroflumethiazide or propranolol.

Without firm data on which to base a decision, a review of the evidence on the major groups of currently available drugs is in order to come to some reasonable conclusions (Table VII).

*Beta-blocking drugs* are generally considered the most logical alternative, advocated most persistently by Laragh .[13] One major drawback of the use of nondiuretic antihypertensive drugs, their tendency to cause retention of sodium and water, which counteracts their effectiveness (Fig. 1), is less common with beta-blocking drugs. This decreased tendency to cause fluid retention is likely related to the greater inhibition of the renin-angiotensin-aldosterone system by beta-blocking drugs.[32] Patients whose renin system is "naturally" suppressed obtain a lesser antihypertensive effect from beta-blocking drugs.[13] A paradoxical increase in blood pressure was seen in 11% of 187 patients given propranolol alone, and these patients had the lowest levels of plasma renin activity.[32] However, in the majority of hypertensive subjects, less reactive fluid retention is likely to occur with administration of beta-blocking drugs than with other adrenergic inhibitors or vasodilators.

When the various side effects of beta-blocking drugs have been tallied, about 25% of hypertensive subjects should not receive them or will stop taking them. As monotherapy, they likely work less well in the elderly[33] and in blacks,[34] groups that generally start with lower renin levels, and groups in which the incidence of hypertension is relatively high.

Two disadvantages listed in Table VII deserve further comment. One, the increase in plasma triglycerides and the decrease in plasma HDL-cholesterol, although less marked with the more cardioselective agents,[35] may present as much of a long-range stimulus to atherogenesis as the increase in total cholesterol that accompanies diuretic therapy. The second disadvantage, the increase in peripheral resistance[36] related to blockade of vasodilatory peripheral vascular beta-receptors, is clinically a bother in colder climates where cold extremities are frequently observed, but also poses a more theoretic objection. Increased peripheral resistance is the underlying hemodynamic fault of hypertension. Drugs that lower peripheral resistance as they lower the blood pressure, such as diuretic agents, prazosin, and vasodilators, have an advantage over beta-blocking drugs because they relieve the underlying fault, whereas beta-blocking drugs increase the resistance further. Careful, controlled, long-term comparisons of these various agents are necessary to determine the clinical consequences of the mode of action of various agents.

One very important, but still unproved, advantage of beta-blocking drugs is their potential to prevent coronary events. Such prevention was amply shown in secondary trials involving patients who survived recent myocardial infarction.[37] However, primary prevention in patients with hypertension, who obviously are quite different from survivors of recent myocardial infarction, has not been shown. Hopefully, the 2 trials using beta-blocking drugs[16,17] will provide such evidence.

*Reserpine*, the first of the orally effective antihypertensive drugs to be widely used, has steadily lost ground in the face of unfounded accusations about its carcinogenicity and in the absence of any strong endorsement. It was the first of the second-step drugs in most clinical trials and apparently was somewhat mo

**TABLE VII Characteristics of Nondiuretic Antihypertensive Drugs**

| Drug | Advantages | Disadvantages |
|---|---|---|
| Beta-blocking agents | Lack of sedation, dry mouth<br>One a day<br>Relief from anxiety-related symptoms<br>Less volume retention<br>Possible protection from coronary heart disease | Serious side effects<br>Bronchospasm<br>Prolongation of insulin-induced hypoglycemia<br>Other side effects<br>Peripheral vasoconstriction<br>Reduced exercise tolerance<br>Fatigue, depression<br>Increased triglycerides<br>Decreased HDL-cholesterol<br>Increase in peripheral resistance<br>Less effect in elderly and blacks |
| Reserpine | Once a day | Serious side effects<br>Depression<br>Other side effects<br>Sedation<br>Nasal stuffiness |
| Methyldopa | . . . | Serious side effects<br>Hepatotoxicity<br>Other "autoimmune" reactions<br>Other side effects<br>Sedation, mental slowness<br>Impotence |
| Clonidine | . . . | Serious side effects<br>More frequent rebound if abruptly stopped<br>Other side effects<br>Sedation<br>Dry mouth |
| Prazosin | Lack of sedation, dry mouth<br>Decrease in peripheral resistance<br>No alterations in plasma lipids<br>No reduction in cardiac output<br>Low incidence of impotence<br>Kidney perfusion is maintained | First-dose hypotension (occurs rarely and is associated with patients who have been taking a diuretic drug)<br>Lassitude, headache, drowsiness |

effective than methyldopa or propranolol in the MRFIT study.[27] Regardless, it seems unable to compete with the newer drugs.

*Methyldopa* was by far the most widely used antihypertensive drug after diuretics, before the advent of beta-blocking drugs. Many practitioners continue to prefer it to all others, but much of that preference likely reflects the tenacity of prescribing habits. For those who are not bothered by sedation or mental dullness, the long-term safety of the drug remains reassuring despite the occasional development of serious "autoimmune" reactions.

*Clonidine* does everything that methyldopa does without the autoimmune reactions. Because of its shorter duration of action, its abrupt discontinuation may more frequently be followed by a rebound of the blood pressure or withdrawal symptoms, but those may occur when most antihypertensive drugs are abruptly stopped.[38]

*Prazosin* is an attractive alternative choice for initial therapy of hypertension. As a postsynaptic alpha$_1$-receptor blocking agent, prazosin acts as a vasodilator, relaxing the vascular smooth muscle. Because the alpha$_2$-receptors on the neuronal surface are not blocked, further release of norepinephrine is inhibited and neither tachycardia nor renin release occurs as with the use of direct-acting vasodilators. Furthermore, prazosin does not act on the heart, so cardiac output is not reduced and normal organ perfusion is well maintained. In specific studies, glomerular filtration rate and renal blood flow were maintained in patients on prazosin.[18,19]

Beyond the favorable hemodynamic effect, that is, a decrease in peripheral resistance, prazosin does not induce the other side effects related to beta-blockade, particularly alterations in plasma lipids.[39] However, administration of the first doses of prazosin may cause postural hypotension. Because this complication occurs mainly when the drug is given to patients who are volume-depleted from previous diuretic therapy,[40] it should be less common if the drug is used as initial treatment in hypertension.

*Guanabenz*, recently approved for use in the United States, was introduced as a centrally acting alpha-agonist similar to clonidine, with evidence that it causes no fluid retention,[41] so that it could be an appropriate drug to be used without a diuretic. However, the side effects of the drug may limit its use.

*Other drugs* not now available in the United States may serve as safe and effective alternatives when and if they are released. These include labetolol, which is a less likely candidate for initial therapy in most cases of mild hypertension because it causes rather frequent postural hypotension.[42]

## Substitution Therapy

Beyond the use of a drug other than a diuretic as initial therapy, the other major change that should be considered is the substitution of another agent as sole

therapy when the first is inadequate or intolerable. The "traditional" stepped-care concept is based on the sequential addition of drugs until the goal of therapy is achieved.

One rationale for substitution therapy is that some patients respond better to 1 class than to another. Despite the earlier generalization that all drugs have comparable antihypertensive potency, some patients respond differently to different drugs. As noted, the elderly and blacks seem to respond less well to beta-blocking agents. The reverse may also be true: young, white patients may respond better to beta-blocking drugs than to diuretics.[34] Without having ways to predetermine the likelihood of a good response, the clinician may logically try a different type of drug when the first is inadequate.

Part of this difference in response may be caused by differences in adherence to therapy with different drugs. If a patient develops such intolerable side effects as to require the discontinuance of the drug, the problem is usually obvious and a second agent can routinely be substituted. However, patients may not volunteer or admit problems with their drugs; rather, they may just not take them. For whatever reason, when a patient does not have the desired effect from the initial drug, a logical next step might be to stop the drug and try one from another category. Thereby, the patient may be more successfully treated with fewer medications.

**Conclusion:** Despite widespread acceptance of the diuretic-first, stepped-care approach, extensive broadening of antihypertensive therapy to many millions more who are at relatively low overall risk from mild hypertension should bring about a reassessment of current practice. The use of other alternatives to a diuretic as initial therapy and the substitution of another single agent rather than the sequential addition of drugs should be given careful consideration in order to provide the most benefit at the least risk.

# Effect of Antihypertensive Agents on Lipid Metabolism

RALPH CUTLER, MD

**Diuretics and adrenergic blocking agents have been used extensively in the treatment of hypertension. Recent studies have indicated that the thiazides and chlorthalidone have an adverse effect on lipid metabolism, by increasing plasma triglycerides, total cholesterol, and low density lipoprotein cholesterol in mildly hypertensive patients. These same agents produced little change in high density lipoprotein cholesterol. On the other hand, the loop diuretic furosemide adversely affected the cholesterol ratio by lowering high density lipoproteins (HDL) instead of increasing very low density lipoproteins (VLDL) or low density lipoproteins (LDL). The centrally acting drug methyldopa has also been reported to lower HDL, while another centrally acting drug, reserpine, appears to be lipid-neutral. Practically all the beta blocking agents increase triglycerides or decrease HDL, thus yielding an adverse cholesterol ratio. The alpha$_1$-adrenergic blocking agent prazosin has been shown in several studies to have no adverse effect on the lipid profile.**

Among major risk factors for coronary heart disease (CHD), hypertension is perhaps the most readily treatable, either by hygienic measures or, when these are not enough, by drug therapy. Although not the soundest therapeutic practice, the use of diuretic agents has eliminated the need for sodium restriction in many mild, asymptomatic patients who were not willing to limit their dietary salt intake. On the other hand, cessation of smoking and lowering of high blood lipids, the other 2 major CHD risk factors, usually demand greater sacrifices in life-style. Nevertheless, Americans as a whole have achieved considerable changes in this regard, as shown by their lowered consumption of cigarettes, eggs, butter, cream, and other items potentially detrimental to their health.

In the past decade or two, antihypertensive agents have been increasingly used as first-line drugs in controlling moderate to severe hypertension. Lately, the use of these agents has been recommended also for the treatment of the mildest forms of hypertension, with a view to avoiding the complications that may develop later on in the course of the disease. Yet a number of large intervention trials have failed to show any substantial benefit of blood pressure-lowering on CHD mortality. In fact, according to the recent Multiple Risk Factor Intervention Trial (MRFIT), CHD mortality did not decrease after stepped-care treatment of hypertension, counseling for cigarette smoking and dietary advice for lowering blood cholesterol levels as compared with a similar population who received only their usual sources of health care in the community. This is in marked contrast to the significant improvements in stroke, heart failure, and renal failure that have been reported as a result of controlling high blood pressure.

The lack of impact of blood pressure-lowering on CHD mortality has raised the question of whether the antihypertensive agents commonly used may be offsetting the potential benefits of such a reduction. The effects of these agents on hemodynamics and metabolism have been cited as probable causes. Some antihypertensive agents may impair perfusion and function of certain organs by reducing cardiac output; others by creating hyperdynamic states which may be detrimental to the patient; and still others by increasing peripheral resistance instead of lowering it. Furthermore, some agents are known to cause potentially hazardous potassium depletion, increase serum levels of lipids, glucose, and uric acid, or increase plasma renin activity. Taken singly, some of these effects may not pose a significant risk, but together they add up to what could be a serious threat to the hypertensive patient.

## A Brief Look at Lipid Metabolism

Dietary lipids are absorbed through the small intestine and reach the blood mainly in the form of chylomicrons. Other lipid fractions are synthesized within the liver and gut from primitive metabolites such as acetate. High density lipoproteins (HDL) and very low density

**TABLE I Correlation of HDL, LDL, and Blood Pressure With Risk of CHD in 4 Years**

| | Years | | | |
|---|---|---|---|---|
| | 1 | 2 | 3 | 4 |
| Mortality risk ratio | 0.5 | 1.0 | 2.0 | 3.0 |
| LDL/HDL ratio* | 1.0 | 3.6 | 6.3 | 8.0 |
| Total cholesterol/HDL cholesterol* | 3.4 | 5.0 | 9.6 | 23.4 |

From Gordon et al.[3]
* Both the LDL/HDL ratio and the total cholesterol/HDL ratio are expressed here so that an increase in either is detrimental while a decrease would be favorable. Other investigators have used the reverse ratios (HDL/LDL and HDL/total cholesterol) so that an increased ratio would be favorable and a decreased ratio detrimental.

lipoproteins (VLDL) are both synthesized in the liver. LDL and triglycerides result from the splitting of VLDL by an enzyme. LDL is the lipoprotein which carries most of the serum cholesterol. Borne by the bloodstream, the cholesterol-rich LDL fraction from the liver apparently enters the coronary artery wall and deposits its cholesterol load in the intima, where it may initiate or perpetuate the process of atherosclerotic plaque formation. The HDL fraction, also carried by the blood stream, reaches the arterial wall, where it seems to play a protective role against the formation or progression of atherosclerosis by removing the cholesterol deposited by LDL and returning it to the liver for further metabolism and excretion through the hepatobiliary system.

Levy,[1] after many years of gathering data about lipid profiles from major clinical centers throughout the United States, reported a definite correlation between increased serum LDL cholesterol concentrations and the prevalence of CHD, whether manifested as angina pectoris, myocardial infarction, or simply as angiographic evidence of coronary vessel disease. Miller et al[2] were among the first to note an inverse correlation between HDL cholesterol and CHD prevalence. Data generated from the Framingham study[3] showed that the cholesterol ratio (total cholesterol to HDL cholesterol) was higher among men and women with clinical evidence of CHD than among those at standard risk. Total cholesterol is made up of VLDL, LDL, and HDL. Increases in both the ratio of total cholesterol to HDL and the ratio of LDL to HDL were found to be associated with an increased risk of mortality (Table I).

## Effect of Antihypertensive Drugs on Lipids

Several studies have examined the effects of diuretics and adrenergic inhibitors commonly used in the treatment of hypertension on the cholesterol ratio and on the various lipoproteins.

**Diuretic agents:** Grimm et al[4] recently showed that hydrochlorothiazide and chlorthalidone increase plasma triglycerides, and total cholesterol in mildly hypertensive patients, and that this effect can be countered or modulated by a diet low in saturated fats and high in polyunsaturated fats (Table II). Chlorthalidone increased LDL cholesterol also. These particular agents produced very little change in HDL cholesterol levels. However, various types of diuretics appear to differ significantly in this respect. In a study comparing the lipid effects of chlorthalidone, hydrochlorothiazide, and furosemide, Ames and Hill[5] showed that furosemide had no significant effect on the lipid profile by lowering HDL rather than by increasing LDL or VLDL (Table III). The ratio of total cholesterol to HDL cholesterol was significantly elevated in the furosemide group, and this effect occurred at comparatively lower antihypertensive doses of this drug than of the other 2 agents.

**Adrenergic inhibitors:** The second major group of drugs used in the treatment of hypertension are the adrenergic inhibiting or blocking agents. This class of drugs is made up of agents that act centrally—methyldopa and clonidine—and agents that act peripherally—guanethidine, reserpine, alpha blockers, and beta blockers. Beta-blocking agents, it should be noted, also may have some central action that has not been clearly defined.

*Reserpine and methyldopa:* In the study cited earlier, Ames and Hill[5] also compared the lipid effects of reserpine and methyldopa and showed variable changes (Table IV). The ratio of total cholesterol to HDL cholesterol was increased by both agents,* but the increase reached statistical significance only in the group treated with methyldopa. While HDL cholesterol levels were decreased by both drugs, only methyldopa produced a

* It should be noted that under the definition of the cholesterol ratio used here, an increase in the ratio would be detrimental and a decrease beneficial. Other investigators use a different definition of the cholesterol ratio (HDL/LDL + VLDL), and in such a case an increased ratio would be beneficial and a decreased ratio detrimental.

From Ames and Hill.[5]
* $p < 0.05$.

statistically significant change. However, the lipid effects of these 2 agents await further confirmation because this was a very small study.

*Alpha and beta blocking agents:* There are many differences among the beta-blocking agents. Not only are they variously selective with respect to their beta-receptor activity—some affect the heart more specifically, while others have a general effect on receptors over the whole body—but they may also possess intrinsic sympathomimetic activity (alprenolol, oxprenolol, and pindolol), or lack this property (propranolol, nadolol, metoprolol, and timolol). Such differences may account for the divergent findings reported by various investigators concerning the lipid effects of these agents.

The one consistent finding is that all beta-blocking agents appear to produce remarkable increases in triglyceride levels—with the exception of nadolol, which causes a dramatic decrease—and a decrease in HDL cholesterol with the exception of pindolol (Table V). However, triglycerides are believed to have a much less significant correlation with atherogenesis than the other lipids and lipoproteins. Few data are available about the effects of beta-blocking agents on HDL, LDL, and VLDL cholesterol values. Studies that have examined these lipid fractions report quite variable results, and these may be explainable on the basis of differences in the population studies, lipid assays used, and the type, dosage, and duration of drugs given. All beta blockers appear to lower HDL cholesterol, except possibly pindolol.

Using a three-way crossover design, the Oslo Study[6] compared the commonly used beta-blocking agent, propranolol, with the only available selective $alpha_1$-blocking agent, prazosin, in the same group of patients to determine the effects of these drugs on serum lipids and on blood pressure when administered singly or in combination. The effects on blood pressure were comparable when the drugs were used as monotherapy, but lower pressures were achieved under combined therapy, and this may be attributable to the additive effects of the different blocking mechanisms of these 2 agents. Prazosin had no adverse effect on blood lipids. On the other hand, propranolol alone resulted in a reduction in HDL, an increase in triglycerides, and a reduction in the ratio of HDL to LDL + VLDL.

The results of this study appear to indicate that prazosin does not adversely affect the lipid profile.

## Clinical Implications

For many years diuretic agents have constituted the standard initial drug therapy for hypertension. Numerous short- and long-acting diuretic agents became available to the physician, and very few were associated with obvious clinical problems, except for hypokalemia, hyperglycemia, and hyperuricemia, all of which were considered either inconsequential or readily correctable. Because of the effectiveness of diuretics and the ease of treatment with these agents, many clinicians today still use them as first-step therapy for hypertensive patients. However, in view of recent findings with regard to metabolic effects, including newer hazards caused by hypokalemia, and the adverse effects of these drugs on the cholesterol ratio, we must ask ourselves whether the same results could not be obtained from other drugs without incurring the risks posed by the diuretics.[7]

As for the adrenergic inhibitors, the lipid effects of propranolol and some of the other beta-blocking agents also seem to be pointing in the same adverse direction. Beta-blocking agents, in addition, are contraindicated for various reasons in a sizable percentage (20 to 25%) of the hypertensive population. Furthermore, they may adversely affect renal function (especially propranolol), and all beta blockers reduce cardiac output and may increase peripheral resistance. Beta-blocking agents have a number of less serious but bothersome effects, such as fatigue, depression, and hallucinations, which may impinge on the quality of life.

As for some of the other adrenergic blockers, the centrally acting agents (methyldopa, clonidine) not only affect lipid metabolism, but also have other side effects such as dry mouth, depression, and impotence, which make them less than ideal from the standpoint of patient compliance.

Side effects of prazosin are mild and transient. The major one is postural hypotension (dizziness, weakness, and so on), which is most pronounced after initial administration and then declines markedly during long-term therapy. Rarely is discontinuation of the drug necessary.

Hydralazine and minoxidil also have serious side effects, mainly the production of a hyperdynamic circulation and tachycardia in patients with a normal baroreceptor reflex, and the triggering of angina or myocardial infarction in predisposed patients. These drugs usually require the concomitant use of a beta-blocking

**TABLE V Effects of Beta-Blocking Agents (Other Than Propranolol) Over Various Periods of Treatment**

| Drug (Dose, mg/day) | Duration (mo) | TC (mg/dl) | TG (mg/dl) | LDL-C (mg/dl) | VLDL-C (mg/dl) | HDL-C (mg/dl) |
|---|---|---|---|---|---|---|
| Atenolol (100–200) | 6 | +1.5 | +24.5 | – | – | – |
| Atenolol (100) | 3 | 0 | 0 | – | – | −10 |
| Nadolol (50–200) | 2.5 | +1.5 | −14.5 | −2 | +29 | −3 |
| Metoprolol (50–400) | 3 | – | +9 | – | – | −13 |
| Metoprolol (100–200) | 4 | −6.5 | +11 | −7 | −6 | −6 |
| Pindolol (10–20) | 6 | −4.0 | +1 | – | – | +4 |

TC = total cholesterol; TG = triglycerides; LDL-C = low density lipoprotein cholesterol; VLDL-C = very low density lipoprotein cholesterol; HDL-C = high density lipoprotein cholesterol.

agent, which to some extent redresses their adverse effects. But while the addition of a beta-blocking agent reduces the elevated heart rate, it does not entirely correct the hyperdynamic condition, since neither the beta blocker nor hydralazine nor minoxidil affects the venous side of the circulation. Therefore, vasoconstriction prevails in the capacitance vessels, venous return remains high, and the high cardiac output is only partly reduced, if at all.

## Discussion

Given the many new antihypertensive agents introduced in recent years, the 1980s seem to be the decade in which it is not only possible but appropriate to move away from a standardized approach toward a more individualized therapy to meet specific treatment objectives. Certainly, in young patients with hypertension who may be facing a lifelong prospect of drug therapy, consideration of the lipid profile and other side effects of conventional agents becomes quite important. If the physician continues to be inclined to give diuretics, today's evidence strongly suggests that he should monitor lipid levels. If the lipid profile does not change after a few weeks of therapy, it is probably safe to continue treatment, at least from the standpoint of lipids.

On the other hand, if the patient's cholesterol ratio is abnormal to begin with, another type of antihypertensive agent that does not adversely affect lipids should certainly be tried. Other considerations regarding the use of diuretics, including hypokalemia, hyperglycemia, and hyperuricemia, should be kept in mind in specific patients, and this may require frequent monitoring of serum potassium, glucose, and uric acid levels.

**Conclusion:** In looking for other possible initial therapies, prazosin appears to offer a very attractive alternative. Prazosin effectively lowers blood pressure by reducing total peripheral resistance; it does not significantly affect heart rate or cardiac output; it has no adverse effect on lipids, glucose, uric acid, or renin; it does not adversely affect renal function; and it rarely produces sexual disturbances. Its main adverse reaction—postural hypotension, which may on rare occasions lead to syncope—can frequently be avoided by careful administration of the first dose, as has been pointed out by other participants. Other side effects are generally mild and transient, and the drug is usually well accepted by the patients.

# Negative Effects of Diuretic Drugs on Metabolic Risk Factors for Coronary Heart Disease: Possible Alternative Drug Therapies

RICHARD P. AMES, MD

**The results of 8 major hypertension treatment trials, all using diuretics as first-line therapy, show a clear-cut reduction in stroke and congestive heart failure, but coronary heart disease (CHD) is not consistently benefited. It is unclear why CHD is not controlled, but diuretics can subtly upset metabolic risk factors for CHD, among which are lipid and glucose concentrations. Although these metabolic disturbances appear clinically unimpressive, risk table analysis reveals that they can offset or even reverse the benefits of reducing blood pressure. A link between glucose intolerance and increased serum lipid concentrations during diuretic-based therapy is suggested by multiple correlations between them. Replacement of diuretics as first-line therapy for mild and moderate hypertension should therefore be considered. Spironolactone seems to counter the adverse metabolic effects, but its effect on lipoproteins needs more study. A drug that does not disturb glucose and lipid metabolism would seem preferable. Thus prazosin is a promising candidate.**

The many hypertension treatment trials performed worldwide have conclusively demonstrated that control of hypertension reduces the incidence of stroke and congestive heart failure.[1–5] One might also expect a reduction in coronary heart disease (CHD) because hypertension is one of the major risk factors for CHD, according to epidemiologic studies.[6,7] However, this expectation of improvement has not been borne out.[5,8] Because CHD is responsible for the largest number of deaths among patients with cardiovascular disease, its lack of response in hypertension to conventional therapy based mainly on diuretic drugs constitutes a major problem in cardiovascular care. To date, efforts to solve this problem have been largely unsuccessful. However, potentially useful alternative approaches should be considered, particularly as a result of the data recently published from the Multiple Risk Factor Intervention Trial (MRFIT).[8]

MRFIT presents perhaps the strongest case against the proposition that drug treatment of hypertension—at least in its mildest forms—protects against CHD. Moreover, some of the results of this trial lead to the hypothesis to be put forth here: The breakdown in the link between treatment of hypertension and improvement in CHD may be due to metabolic disturbances induced by conventional diuretic therapy. Diuretic drugs, although highly effective in reducing blood pressure, have a detrimental effect on other risk factors for CHD, thereby offsetting the positive influence of hypertension control.

Commissioned by the National Heart, Lung, and Blood Institute (NHLBI) specifically to ascertain whether reduction in severity of risk factors would result in a lowering of coronary death rates, this massive MRFIT study was performed over a 7-year period by 250 investigators in 22 institutions and involved nearly 13,000 high-risk men aged 35 to 57 years who had no clinical evidence of CHD at entry.[8] The highly surprising results that were obtained may have been due in part to the fact that the study design did not include a placebo control group. Instead, subjects were classified into special intervention (SI) and usual care (UC) groups for test and control, respectively.

The SI group received intensive sessions in smoking cessation, cholesterol-lowering by dietary changes and weight control, and treatment of hypertension. Hypertension was treated when diastolic blood pressure was >89 mm Hg on 3 consecutive clinic visits. Treatment started with an attempt at weight reduction if indicated, followed by thiazide-type diuretic drugs given according to the well-known stepped care sequence. The

**TABLE I Hypertension Trials and CHD Mortality**

| Trial | Cases (n) | Duration (yr) | CHD Mortality |
|---|---|---|---|
| Freis—VA (1967) | 143 | 1.5 | P-1, T-0 |
| Freis—VA (1970) | 380 | 3 | P-11, T-6 |
| Smith—PHS (1977) | 389 | 7 | P-2, T-2 |
| Morgan (1978) | 192 | 1–5 | U-1, T-9 |
| HDFP (1979) | 10,940 | 5 | RC-69, SC-51 |
| Oslo (1980) | 785 | 5 | U-2, T-6 |
| Australia (1980) | 3,427 | 4 | P-8, T-2 |
| MRFIT (1982) | 8,011* | 6 | UC-79, SI-80 |

* The MRFIT study included a total of 12,866 and the average follow-up lasted 7 years. The results shown here represent the 8,011 participants who had hypertension. The 4,855 men who did not have hypertension are not considered in this report because the focus of this discussion is on hypertension.

HDFP = Hypertension Detection and Follow-Up Program; MRFIT = Multiple Risk Factor Intervention Trial; P = placebo group; PHS = Public Health Service; RC = referred care group; SC = stepped care group; SI = special intervention; T = treatment group; U = untreated group; UC = usual care group; VA = Veterans Administration.

goal of treatment was to lower diastolic pressure by 10 mm Hg or below 85 mm Hg, whichever was lower. Diuretic dosage was increased to 100 mg/day, if tolerated, before a second drug was added. Reserpine and methyldopa were the preferred second step drugs. Later in the trial, propranolol became available, but it was used in fewer than half of the hypertensive patients.

UC men were referred with the MRFIT risk factor report to their personal physicians for advice. The UC men were examined annually by the MRFIT staff, and a report of the findings was always sent to the personal physicians.

A relatively high mortality was predicted in the UC group because of the high CHD risk status and a belief a decade ago that community physicians were slighting risk factors. This situation would allow the UC group to serve as a control group without denying them standard care. However, this expectation proved wrong. Instead, there was a startling equivalence in the number of deaths from CHD for both groups: 124 in the UC group and 115 in the SI group. Among the 8,000 patients with hypertension (4,000 in each group), which is the focus of our interest in this discussion, there was also an equivalence of CHD deaths: 79 in the UC group and 80 in the SI group. The overall mortality was substantially lower than anticipated in the UC group, thus diminishing the statistical power of the comparison.

Notwithstanding flaws in the design, 2 valuable pieces of information can be gleaned from this study. First, considerable treatment for hypertension was administered to both groups, although the SI group did receive somewhat more. Smoking and cholesterol levels were reduced for both groups, again a little more in the SI group. Thus, risk factors were improved in *both* groups, and overall death rates from CHD were reduced in both groups compared with predictions based on Framingham results. This finding supports the concept that risk factors are important in the causation of CHD and that control of these factors does indeed reduce the incidence of CHD.

The second important point to be brought out in this trial is that the 2 groups showed equivalent mortality rates, even though vigorous drug treatment dropped blood pressure lower in the (stepped care) SC group. This result suggests that intensifying treatment of hypertension with the traditional mode of diuretic therapy produces no extra protection against CHD.

In view of the foregoing observations and the known metabolic side effects of diuretic drugs, the question arose whether it is the diuretic therapy itself that might be causing detrimental changes in other risk factors for CHD aside from hypertension.

## Comparison of Results From Various Trials

Table I compares the results of MRFIT with those from other studies utilizing diuretic drugs as first-line treatment.

There is only 1 study that reports findings in direct opposition to those obtained in MRFIT. This study, the Hypertension Detection and Follow-Up Program (HDFP), was also sponsored by the NHLBI.[10,11] In 14 communities scattered throughout the United States, 10,940 subjects with high blood pressure were randomly assigned to either SC or referred care (RC [control]) groups. At the end of the 5-year period, control of blood pressure was consistently better for the SC than for the RC group. Furthermore, mortality from all causes was 17% lower in the SC group relative to the RC group (6.4 versus 7.7%, $p < 0.01$). Overall, there were 69 deaths from myocardial infarction in the RC group and 51 in the SC group. On the face of it, these findings suggest that management of hypertension is important for reducing mortality in the population with high blood pressure. However, there was no placebo control group in this trial, and placebo control is generally the most reliable paradigm for a study of this nature. The double blind placebo control study design is important because it obligates the investigators to treat all patients similarly, thereby equalizing all aspects of medical care other than the drug regimen. Referring control patients to other physicians causes unequal medical surveillance between control and experimental groups. Because the experimental group received free, enthusiastic, and close supervision, illness may have been detected early and converted from a fatal to a nonfatal outcome (formally published results to date report only mortality data). Thus, it is not clear, because of the several differences in management between control and experimental groups, that the small difference in blood pressure control between groups accounts for the lower coronary mortality. This point must be emphasized because none of the placebo controlled clinical trials using diuretics as first-line therapy reported improvement in CHD with treatment.[1,2,4,12]

A second cautionary note about HDFP results is that mortality from a category termed "other ischemic heart disease" was equal in the step-care and referred care groups, that is, 80 and 79 cases, respectively. Therefore, the total number of deaths from myocardial infarction plus other ischemic heart disease would be 131 and 148 for the step care and referred care groups, respectively. This represents a difference in CHD mortality between groups of 11.6%. Thus, even in HDFP the improvement in CHD mortality may not be as great as publicized.

**TABLE II Effects of Chlorthalidone on Serum Lipids (n = 17)**

| | Control | Treatment | p |
|---|---|---|---|
| Total cholesterol (mg/dl) | 217 | 237 | 0.01 |
| Triglycerides (mg/dl) | 96 | 114 | 0.01 |

| Serum Lipids | During Therapy | After Cessation of Therapy |
|---|---|---|
| Total cholesterol (mg/dl) | 235 ± 8 | 217 ± 6* |
| Triglycerides (mg/dl) | 127 ± 11 | 100 ± 8* |
| HDL cholesterol (mg/dl) | 48 ± 2 | 49 ± 2 |
| Total cholesterol/HDL cholesterol ratio | 5.1 ± 0.3 | 4.5 ± 0.2* |

* $p < 0.01$.

There is 1 other study with results that might be construed as somewhat supportive of the HDFP findings: the Australian national trial, reported on in 1980.[4] This was a controlled therapeutic treatment trial involving 3,427 men and women with mild hypertension who were followed up for an average of 4 years. The number of deaths from CHD was small in this study but amounted to 8 in the control group and 2 in the treatment group. This difference fell just short of the usual $p < 0.05$ level of significance.

The mortality data in the Australian study are in harmony with the HDFP findings, but the total number of CHD events, i.e., both fatal and nonfatal coronary disease, was not significantly different between groups. There were 109 coronary events in the placebo group and 98 in the treatment group. As suggested previously,[13] a possible explanation for this discrepancy is that coronary disease was not actually prevented by treatment, but rather that potentially fatal events were rendered nonfatal by the pharmacologic lowering of cardiac afterload. Thus, the more favorable hemodynamic status of the treatment group may explain the reduced number of deaths, while CHD was not reduced overall.

In opposition to the findings of the HDFP and the Australian national trial are the results obtained in the 1978 Morgan study, which was also derived from the Australian population.[14] This was a small study involving 192 elderly men with mild hypertension observed over a variable period of 1 to 5 years. In the untreated and the sodium-restricted groups combined, 1 death occurred from myocardial infarction whereas in the group given a thiazide diuretic as initial therapy 9 deaths were observed. CHD deaths were significantly higher in the thiazide group.

Thus, a large disparity exists between the results reported in the HDFP and Australian national studies, and those obtained in the Morgan study. Four other major trials that utilized diuretic drugs as first-line therapy reported outcomes somewhere between these extremes.

The most interesting of these trials was the Oslo Study.[5] In this study, designed to evaluate the effect of therapy on cardiovascular complications, 785 patients treatment (406) and nontreatment (379) groups and were followed up for 5 years. Treatment consisted of hydrochlorothiazide as initial drug and methyldopa or propranolol as second step therapy. Although no difference between groups was seen in total mortality or cardiovascular mortality, the number of CHD deaths was higher in the treatment group (Table I). In analyzing total cardiovascular events, i.e., fatal and nonfatal endpoints, the expected reduction in cerebrovascular episodes was offset by an increase in CHD events (13 in control, 20 in treated patients). While not statistically significant, this difference certainly constitutes an unfavorable trend, and one that was not anticipated at the outset of the study.[5]

As did MRFIT and the Australian national trial, the 3 remaining major hypertension studies that should be mentioned showed essentially no difference in the incidence of CHD between their treatment and control groups. The first of these was the Veterans Administration trial, directed by Freis, which was published in 1967.[1] In comparison with later studies, this was a small trial involving only 143 patients with severe hypertension. Over a period of 18 months, 1 sudden death and 2 nonfatal heart attacks were reported in the placebo-treated group and none in the treatment group, a statistically insignificant result.

This study was followed by a second Veterans Administration trial in 1970, in which 380 patients with mild or moderate hypertension were observed for an average of 3 years.[2] On analysis, 3 fatal myocardial infarctions and 8 sudden deaths occurred in the placebo group; in the drug-treated group 2 fatal myocardial infarctions and 4 sudden deaths were observed. The difference between groups again was insignificant.

The third study, performed in 1977 by Smith from the Public Health Service (PHS) Group,[12] included approximately 400 patients with mild hypertension, who were followed up for a relatively long period of time. The average follow-up was 7 years, with some patients being observed for 9 years. Despite this long follow-up, only 2 CHD deaths were reported in the placebo group and 2 in the drug-treated group. Examination of the total number of myocardial infarctions, both fatal and nonfatal, revealed 6 occurrences in the control group and 7 in the treatment group—essentially no difference at all.

Summing up the results of these 8 major trials, all of which employed diuretic drugs as first-line therapy, only 1 study (HDFP) supported the premise that the incidence of CHD could be lowered by treatment of hypertension.[9,10] The Morgan Study and the Oslo Study actually showed a worsening of CHD with antihyper-

**TABLE VI Probability of CHD in 6 Years During Diuretic-Based Therapy and After Therapy Was Stopped***

| | During Therapy | After Cessation of Therapy |
|---|---|---|
| Cholesterol (mg/dl) | 235 | 217 |
| Systolic blood pressure (mm Hg) | 133 | 151 |
| Glucose intolerance | Yes | No |
| Probability | 8.8% | 7.6% |

* Probability table for a 55-year-old man was used.[15] This table was closest to the average age of our patients.

know to what extent the changes could offset the beneficial effect of decreasing blood pressure on CHD risk in patients with hypertension. We used the coronary probability table developed from the Framingham study[15] and employed data from the patients studied during and after cessation of therapy.[9] Table VI shows that the probability of CHD was actually somewhat increased during therapy with diuretic drugs.

Although this analysis seems to overstate the case, it does provide a clue as to why it has proved so difficult to reduce the incidence of CHD with conventional diuretic therapy: Risk factors other than hypertension are negatively influenced and may therefore neutralize or even eliminate the benefits of reducing blood pressure.

## Possible Alternatives

Beta-blocking drugs have been suggested as first-line therapy for hypertension because of their antirenin and cardioprotective effects.[24,25] Indeed, an uncontrolled study in which beta blockers served as initial therapy for hypertension reported a reduction in CHD.[26] However, the cardioprotective effect has been demonstrated in relatively short-term studies.[25,27,28] A long-term study of oxyprenolol showed an increased incidence of CHD in some groups of patients.[29] Several beta blockers have an adverse influence on serum lipids and lipoproteins, an effect most evident in long-term study.[30–32] Thus, it is possible that an early benefit resulting from improved electrical stability might become reversed as the adverse lipid alteration exerts its slowly developing effect.

To determine whether potassium-sparing diuretic drugs might have a role in this context, we studied 23 hypertensive patients exhibiting raised total cholesterol during treatment with chlorthalidone. As shown in Table VII, when spironolactone was substituted for chlorthalidone in randomized fashion, total cholesterol decreased. When these patients resumed taking chlorthalidone, total cholesterol increased again. In contrast, a control group that continued taking chlorthalidone throughout the same interval of time showed no noteworthy change in total cholesterol. Whereas this information is promising, data are needed on lipoprotein fractions. Further study of potassium-sparing diuretic drugs used alone and in combination with thiazide agents seems warranted.

Several short-term studies indicate that prazosin, an alpha$_1$-adrenergic blocking agent, has no adverse effects on serum lipids and lipoproteins.[32–38] If long-term trials clearly prove its sustained antihypertensive efficacy and lack of adverse lipid effects, prazosin could well become the drug of choice in the initial treatment of mild and moderate hypertension. However, considering the widespread acceptance and applicability of diuretic therapy,[31] a clinical trial may be needed to test a diuretic-based regimen (of proved efficacy against stroke and congestive heart failure) against an alternative regimen (of presumed efficacy against CHD based on lipid effects but unproved in the prevention of stroke and congestive heart failure). Before even considering such a trial, the best alternative regimen would need to be identified. Drug selection would rest on the net effect on CHD probability (estimated from risk tables[15] or coefficients[16]) based on long-term changes in blood pressure, glucose tolerance, lipids and lipoproteins.

**TABLE VII Serum Cholesterol and Triglyceride Levels During Randomized Substitution of Spironolactone for Chlorthalidone: Comparison With Patients Continuing on Chlorthalidone**

| Group | Total Cholesterol (mg/dl) | Triglycerides (mg/dl) |
|---|---|---|
| Spironolactone group (n = 11) | | |
| Initial chlorthalidone period | 261 | 210 |
| Spironolactone period | 237* | 152 |
| Final chlorthalidone period | 254 | 150 |
| Chlorthalidone group (n = 12) | | |
| Initial chlorthalidone period | 265 | 167 |
| Middle chlorthalidone period | 263 | 155 |
| Final chlorthalidone period | 252 | 150 |

* $p < 0.05$ versus the initial and final chlorthalidone periods for this group. Also $p < 0.05$ versus the middle period in the chlorthalidone group. Cholesterol did not differ between groups in the initial and final chlorthalidone periods.

**Conclusions:** Diuretic-based antihypertensive therapy has been shown to cause an increase in total cholesterol and triglycerides. It can also lead to glucose intolerance and insulin resistance, in addition to other adverse effects reported earlier on potassium, chlorides, uric acid, and renin levels. The fact that lipid alterations correlate with glucose intolerance suggests there is a link between these pathways or that a common mechanism may be involved. This may prove to be the reason that diuretic therapy did not reduce mortality greatly in the MRFIT study and other major CHD studies.

Quantitatively, the changes in coronary risk factors, including glucose, lipids, and systolic blood pressure, during diuretic-based antihypertensive therapy may even increase the probability of developing CHD.

Prazosin, an agent that does not have an adverse effect on lipids, glucose, potassium, uric acid or renin, may be a preferable choice for initial therapy in hypertension. It is effective alone or it can be added for enhanced effectiveness. It needs to be tested against diuretic drugs in a long-term study to document its superiority, using the results of all risk factor changes during therapy as the index of relative merit.

# New Developments in Alpha-Adrenergic Receptor Pharmacology: Implications for the Initial Treatment of Hypertension

WILSON S. COLUCCI, MD

**The vascular postsynaptic alpha$_1$ receptor is the major locus through which adrenergically determined vascular tone is mediated. Therefore, blockade of this receptor is a particularly specific approach to the major pathophysiologic defect in hypertension—an elevation of peripheral vascular resistance. Although the mechanism responsible for this increase in peripheral vascular resistance in hypertension is not known, it is apparent that the sympathetic nervous system plays a key role. In addition, considerable evidence suggests that a common abnormality in hypertension is an increase in the sensitivity of vessels to alpha-adrenergic stimulation, a defect potentially located at the alpha-receptor level. Basic radioligand binding studies of vascular alpha$_1$ receptors, in fact, demonstrate that the affinity, or avidity, of binding of these sites is under the regulation of both neural and humoral factors.**

**Although diuretics, and more recently, beta-adrenergic blocking agents, have been utilized for the initial treatment of hypertension, recent information about the adverse effects of these agents has led to a reappraisal of the role of alpha-receptor blockade as a rational approach to the initial treatment of hypertension.**

The central role of the adrenergic nervous system in the development and maintenance of hypertension has long been appreciated. Not surprisingly, adrenergic blocking agents of many different types have been widely utilized in the therapy of hypertension. Agents such as reserpine, alpha-methyldopa, clonidine, and guanethidine result in a *nonspecific* suppression of sympathetic nervous system activity. Therefore, although these agents are effective in lowering blood pressure, they also cause a number of side effects which often make them unacceptable as "first-line" antihypertensive therapeutic agents. More recently, beta-blocking agents have proven effective in the lowering of blood pressure, and have been suggested as initial therapy of hypertension. Paradoxically, most beta-adrenergic blockers may result in an *increase* in peripheral vascular resistance due to blockade of vascular beta$_2$ receptors, stimulation of which results in vasodilation. Nevertheless, beta-blockers work because other indirect effects act to overcome the direct vasoconstriction resulting from beta blockade.

During the last 10 years, information in the field of alpha-adrenergic receptor pharmacology has greatly expanded. Understanding of how the two alpha-receptor subtypes mediate distinct physiologic functions has provided us with a sound basis for the development of alpha$_1$ selective antagonists that inhibit only that portion of adrenergic function involved in the maintenance of vascular tone, thereby bypassing many of the adverse effects of nonspecific sympatholytic agents. In particular, the alpha$_1$ selective antagonist, prazosin, has proved to be an effective antihypertensive agent. In view of these advances, it is appropriate to reevaluate the traditional "stepped" care of the hypertensive patient.

## New Concepts in Alpha-Adrenergic Receptor Pharmacology

For many years, it has been known that the actions of the sympathetic nervous system on the tissues under its control are mediated by either of 2 receptor types, designated alpha and beta.[1] These receptor types are defined by their response patterns to stimulation by a series of catecholamines. *Alpha*-receptor sites respond maximally to epinephrine and norepinephrine, and much less so to isoproterenol. Conversely, *beta*-receptor sites respond maximally to isoproterenol and less so to norepinephrine and epinephrine. Beta-receptors are subdivided into $beta_1$ and $beta_2$ receptors. $Beta_1$ receptors primarily mediate cardiac responses, while $beta_2$ receptors mediate vascular and bronchial smooth muscle relaxation.

More recently it has also been appreciated that there are 2 subtypes of alpha-receptors, designated $alpha_1$ and $alpha_2$ (Fig. 1).[2–4] In general, alpha-receptors located *postsynaptically* on the vascular smooth muscle cell are the $alpha_1$ subtype, whereas receptors which are located *presynaptically* on the sympathetic nerve ending are of the $alpha_2$ subtype. Blockade of the postsynaptic $alpha_1$ receptor results in relaxation of vascular smooth muscle, and a fall in blood pressure. It is only recently that the physiologic function of the presynaptic $alpha_2$ receptor has been appreciated. Based on many types of information, it now appears that stimulation of the presynaptic $alpha_2$ receptor by norepinephrine, which has been released from the nerve ending, results in a reduction of further release of norepinephrine from that nerve ending.[4] In addition, norepinephrine or epinephrine which enters the synaptic cleft from the circulation may also result in a reduction in norepinephrine release. Thus, the presynaptic $alpha_2$ receptor forms part of a feedback loop which maintains the local level of sympathetic activity, and hence, vascular tone.

$Alpha_1$ and $alpha_2$ receptors are distinguishable by their pharmacologic specificities for various antagonist drugs.[3] Thus, $alpha_1$ receptors have a particularly high affinity (avidity of binding) for drugs such as prazosin, and a very low affinity for drugs such as clonidine or yohimbine, a drug that has been of particular value in the pharmacologic study of $alpha_2$ receptors. Conversely, $alpha_2$ receptors show very high affinity for clonidine or yohimbine, and extremely low affinity for prazosin. These types of pharmacologic specificity can be demonstrated by several techniques including physiologic experiments and, as will be discussed later, radioligand binding assay methods.

A more recent development is the understanding that postsynaptic alpha-receptors may be of either the $alpha_1$ subtype, the $alpha_2$ subtype, or a mixture of both subtypes. Although it previously was assumed that all postsynaptic alpha-receptors in blood vessels were of the $alpha_1$ subtype, it now is apparent that at least in certain blood vessels, some of the postsynaptic receptors may be of the $alpha_2$ subtype.[5,6] Interestingly, it appears that these $alpha_2$ receptors are located away from the sympathetic nerve endings, whereas $alpha_1$ receptors

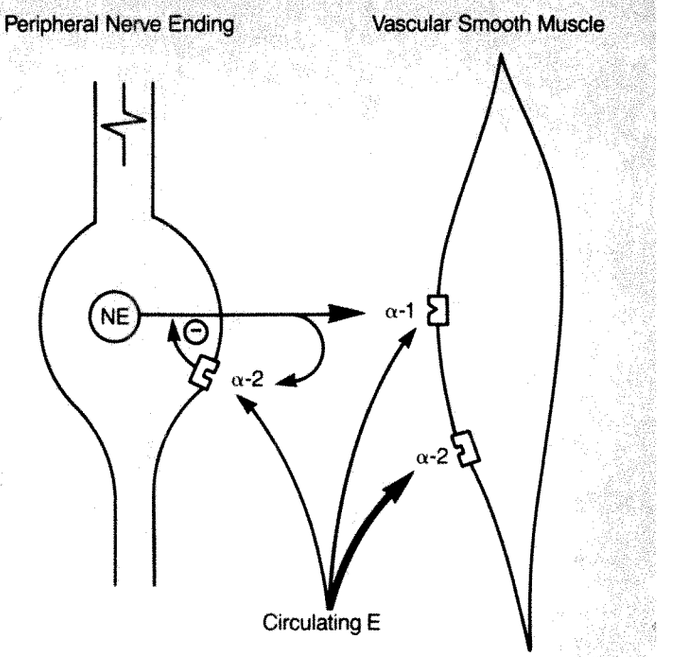

**FIGURE 1.** Schematic representation of the alpha-adrenergic receptor subtypes on peripheral nerve endings (presynaptic) and vascular smooth muscle (postsynaptic). Contraction of vascular smooth muscle is mediated primarily by $alpha_1$ receptors, whereas $alpha_2$ receptors located on peripheral nerve endings inhibit norepinephrine (NE) release, thereby providing local feedback control of sympathetic vasoconstriction. Recent data indicate that some vascular postsynaptic receptors are of the $alpha_2$ subtype. (Reprinted with permission, from Colucci WS, Braunwald E. Adrenergic receptors: new concepts and implications for cardiovascular therapeutics. In: Conti CR, Brest A, eds. Cardiovas Clin, in press, 1983.)

appear to be located within close proximity to the nerve ending.[5] A consequence of this fact is that the concentration of released norepinephrine is very high at $alpha_1$ receptors, and extremely low by the time it has diffused to the extrasynaptic $alpha_2$ receptors. Based on these observations, it is possible that $alpha_2$ receptors in blood vessels represent primarily a back-up system which gains importance in times of stress when circulating catecholamines are elevated to levels adequate to stimulate extrasynaptic $alpha_2$ receptors.

## Physiologic Significance of Alpha-Receptor Subtypes

Administration of phentolamine or phenoxybenzamine results in a *nonselective* blockade of alpha-adrenergic receptors. Thus, both the postsynaptic receptor on the vascular smooth muscle cell and the *presynaptic* receptor on the peripheral nerve ending are blocked. As discussed earlier, blockade of the presynaptic $alpha_2$ receptor results in an increased release of neuronal norepinephrine which then may result in attenuation of the desired postsynaptic blockade, and, in addition, may circulate systemically to result in such undesirable side effects as tachycardia and tremulousness. Blockade with an $alpha_1$ selective agent such as prazosin, on the other hand, does not affect the presynaptic $alpha_2$ re-

ceptor, thus leaving the negative feedback loop for norepinephrine *intact*, and circumventing the undesirable cardiac and systemic effects of increased norepinephrine release. Consequently, the use of an alpha$_1$ selective blocker makes physiologic and pharmacologic sense in the therapy of hypertension.

The differential physiologic effects of alpha$_1$ selective versus nonselective alpha blockade are illustrated in Figure 2. In this study, prazosin and phentolamine were administered to dogs in doses which lowered mean arterial pressure to the same degree.[7] When pressure was lowered with prazosin, there was a negligible effect on circulating plasma norepinephrine levels, whereas an equal lowering of blood pressure with phentolamine produced a marked increase in plasma norepinephrine. A similar elevation of circulating norepinephrine in humans might be seen during states of stress or strenuous exercise.

## A Potential Role of Vascular Alpha-Receptors in Hypertension

Although the fundamental cause of essential hypertension still is not known, it is clear that increased vascular tone is a primary hemodynamic derangement. Some of the possible causes of this increase in vascular tone include increased sympathetic nervous system activity, an increase in vascular *sensitivity* to catecholamines or to other vasoactive substances, increased activity of the renin-angiotensin-aldosterone system, or decreased local or circulating vasodilator substances.

Evidence of an increased sympathetic nervous system outflow in patients with essential hypertension has been inconclusive. Circulating levels of norepinephrine, which are thought to represent neuronal activity are, in general, not elevated in hypertensive patients.[8] Recently, however, there has been evidence that hypertensives may have elevated levels of epinephrine which is derived primarily from the adrenal medulla.[9]

Another potential cause of hypertension is an *increased sensitivity* to vasoconstrictor stimuli. In fact, a large literature suggests that increased vascular sensitivity in hypertension, and in many cases this hypersensitivity is demonstrable for norepinephrine.[10,11] However, it has previously been impossible to specifically implicate the alpha-receptor as the *site* of this abnormality. Recently, it has been possible to use direct radioligand binding studies of vascular alpha$_1$ receptors in order to begin approaching this question. These studies utilize a radioactive probe such as tritium-labeled prazosin to quantify both the *number* and *affinity* (avidity of binding) of alpha$_1$ receptors in vascular smooth muscle.

Under normal assay conditions, the alpha$_1$ receptors are occupied by the radioactive probe (Fig. 3). As varying concentrations of alpha-agonists or antagonists are competed with the radioligand, displacement curves can be obtained which indicate the affinity of the receptor for each of the compounds tested. A shift of the binding curve to the left indicates an increase in receptor affinity, whereas a shift of the curve to the right indicates a decrease in affinity.

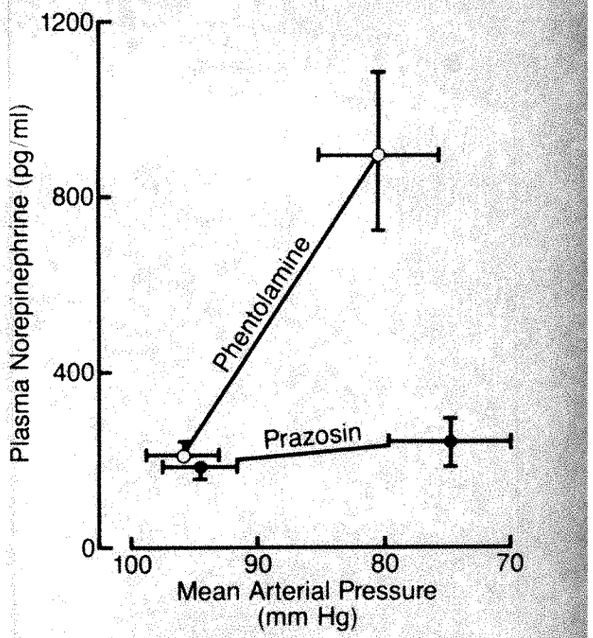

**FIGURE 2.** Relative effects of equihypotensive doses of phentolamine and prazosin on the plasma norepinephrine concentration in conscious dogs. The postphentolamine concentration of norepinephrine is significantly elevated ($p < 0.05$), whereas there is no significant change in norepinephrine concentration after prazosin. (Modified from Saeed M, et al.[7])

Using this approach, we recently have been able to demonstrate that the affinity of the vascular alpha$_1$ receptor is regulated by (among other things) the estrogen sex hormones.[13] As shown in Figure 4, the effect of estrogens is to increase vascular alpha$_1$ receptor affinity, as signified by a leftward shift in the binding curve in females as compared to males. After ovarectomy, this difference is abolished further implicating the role of estrogens. Likewise, the administration of estrogens to male rats results in a leftward shift in the binding curve, or an increase in affinity.

These observations may be relevant to the mechanism of birth-control-pill–induced hypertension. Perhaps more important, though, these data demonstrate that the affinity of the vascular alpha$_1$ receptor is in a dynamic state; the absolute affinity being regulated by various neural and humoral influences. Potentially, an abnormally high affinity of vascular alpha$_1$ receptors could be a basic underlying defect in essential hypertension. Although we do not yet know the answer to this question, it is an area of active investigation.

## Treatment of Hypertension With Prazosin

Prazosin is a versatile antihypertensive agent which is effective alone or with other types of antihypertensives in the therapy of mild, moderate, or severe hypertension.[14] Prazosin's antihypertensive action is due to a decrease in peripheral vascular resistance as a result of blockade of vascular alpha$_1$ receptors. However, unlike other vasodilators such as hydralazine and minoxidil which require concomitant beta-adrenergic

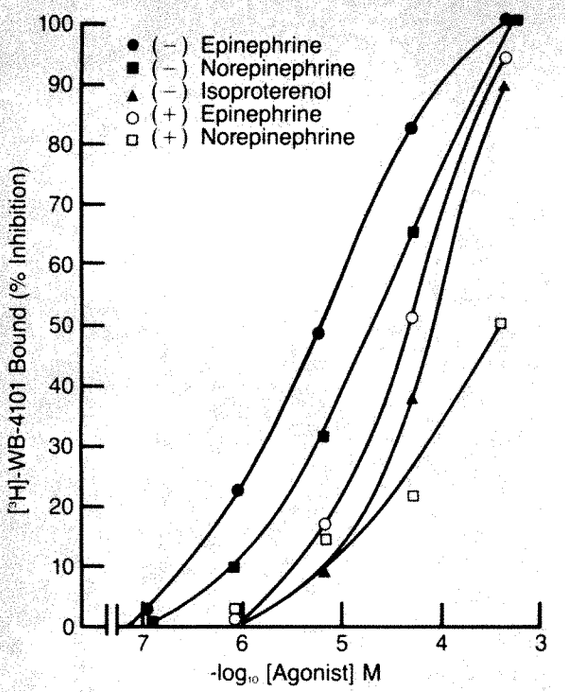

**FIGURE 3.** Inhibition of the binding of an alpha$_1$ selective radioligand ($^3$H-WB-4101) to vascular alpha$_1$ receptors by various catecholamines. The location of each curve represents the *affinity* of the alpha$_1$ receptor for that compound. (Reprinted from Colucci WS et al,[12] with permission of the American Heart Association.)

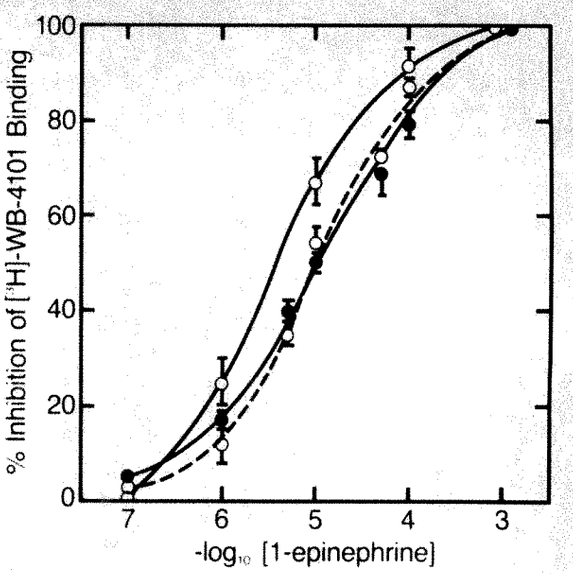

**FIGURE 4.** As in Figure 3, the location of the l-epinephrine curve indicates the affinity of the alpha$_1$ receptor. The affinity of binding is higher in female rats (**open circles**) than in male rats (**closed circles**), whereas the difference is no longer evident after ovarectomy (**open circles separated by broken line**). (Reprinted from Colucci et al,[13] with permission of the American Heart Association.)

blockade in order to be effective (and therefore are generally reserved for Step 3 use), prazosin may be used as a Step 1, Step 2, or Step 3 agent without beta-adrenergic blockade. This is because prazosin's antihypertensive effect is accompanied by little or no increase in heart rate, plasma renin activity, or circulating catecholamine levels.

Prazosin may be used alone to treat mild-to-moderate hypertension, and may be particularly useful when therapy with other Step 1 agents such as diuretics or beta blockers is undesirable. The well-known adverse effects of diuretic and beta-blocking drugs, and recent growing evidence that both classes of drugs adversely affect serum lipids makes their long-term use less than ideal, and suggests that their role as Step 1 therapy needs to be reevaluated, particularly in young adults with mild or moderate hypertension.[15] Since alpha$_1$ selective blockade with prazosin is effective, associated with few adverse effects, and does not adversely affect serum lipids, it deserves serious consideration as Step 1 therapy.

Prazosin is also effective when used with a diuretic or in combination with other antihypertensive agents. The low incidence of limiting side effects during chronic therapy has made prazosin a popular alternative to nonspecific adrenergic inhibitors such as reserpine, alpha-methyldopa, clonidine, and guanethidine. Prazosin is effective in patients with moderate-to-severe hypertension, and may be used in place of hydralazine. Prazosin's effects are additive to those of diuretics, beta-adrenergic blockers, and essentially all other antihypertensive agents. Prazosin may be a highly effective agent alone or with a beta-blocker for the presurgical management of patients with severe hypertension due to pheochromocytoma.[16] Despite extensive clinical trials for periods of therapy ranging from weeks to years, there is virtually no evidence of attenuation of prazosin's antihypertensive effect during chronic therapy.[17,18]

In hypertensive patients with normal renal function, prazosin has no significant effect on glomerular filtration rate or effective renal plasma flow. In hypertensive patients with renal insufficiency, glomerular filtration rate is either unchanged or increased. Although prazosin is primarily metabolized by the liver, some data suggest that drug levels may be higher, elimination half-life prolonged, and the degree of protein-bound drug reduced in patients with chronic renal insufficiency. These alterations in drug pharmacokinetics may account for clinical reports of increased drug potency in renal insufficiency. Used alone or in combination, prazosin is an effective antihypertensive agent in dialysis patients with volume-responsive or volume-independent hypertension.

The major side effect of prazosin therapy in patients with hypertension is postural hypotension, which is usually most pronounced after the initial drug administration, and therefore has been referred to as the "first-dose phenomenon." This complication is dose-related. In a group of 74 hypertensive patients initially treated with a 2-mg dose of prazosin, 2 patients had syncope and 10 others had significant symptoms of postural hypotension such as dizziness, weakness, or palpitations.[19] However, when the same 12 patients were rechallenged with a 0.5-mg dose 3 weeks after

control subjects. During prazosin therapy, blood viscosity was reduced in proportion to the decrease in perfusion pressure, so that total blood flow was largely unchanged. Prazosin preferentially reduced blood viscosity in the precapillary resistance vessels, while hardly affecting the viscous resistance to flow in the capacitance (venous) vessels. This action might explain the greater effect of prazosin on the peripheral arterial bed, although the drug is also known to affect peripheral resistance in the venous side of the circulation. In this same study, plasma renin activity, creatinine clearance, as well as daily excretion of sodium, potassium, and aldosterone were similar before and during treatment with prazosin, whereas microcirculatory blood flow and organ perfusion were well maintained.

Prazosin is rapidly and almost completely absorbed after oral administration.[2] Peak plasma concentrations are achieved within 2 to 3 hours after a dose. Prazosin is extensively metabolized by the liver, with more than 90% of an oral dose being eliminated through the feces and the remainder through the urine.[2] This antihypertensive drug does not significantly affect renal function.[4] However, its hepatic metabolism calls for caution when the drug is administered in patients with impaired liver function.

Prazosin has had no adverse effect on lipid metabolism[5-13] and has not altered glucose[14] or uric acid metabolism.[5]

## Use of Prazosin in the General Hypertensive Population

Numerous studies report that prazosin, given as single-agent therapy in the initial treatment of hypertension, is effective in reducing blood pressure in the general population with mild, moderate, and severe hypertension. Most common reactions to prazosin are generally mild and transient and include dizziness, headache, drowsiness, lack of energy, weakness, palpitations, and nausea. Rarely, a so-called "first-dose phenomenon" involving postural hypotension, syncope, or both may occur, but can usually be avoided by careful initiation of prazosin treatment (see section on Initiation and Titration of Therapy). In at least 1 study by Fauchald,[15] the first-dose effect did not occur in patients in whom diuretics were withheld and prazosin was instituted at a small dose. Apparently, volume-depleted patients are more likely to experience the postural effects of the first dose of therapy, thus arguing for initiation of drug therapy with prazosin and the later addition of a low-dose diuretic when necessary. Prazosin does not cause the marked increases in heart rate, vascular headaches, and flushing episodes often seen with direct-acting vasodilators, nor does it decrease cardiac output and heart rate as do beta-blocking drugs or cause potassium depletion as do diuretics. Therefore, prazosin seems an especially logical choice in the asymptomatic patient starting on long-term antihypertensive therapy. The lack of adverse effects on lipid, glucose, and uric acid metabolism further enhances its appropriateness.

Because most direct-acting vasodilators such as hydralazine and minoxidil have severe side effects and usually require concomitant use of a beta-blocking agent to blunt their hyperdynamic effects, they generally are used as step 3 drugs in the stepped-care approach to therapy recommended by the Joint National Committee on Detection, Evaluation and Treatment of High Blood Pressure. In contrast to these vasodilators, prazosin is recommended as a Step 2 drug by this Committee and can be used alone as Step 1, Step 2, or Step 3 therapy, without a beta-blocking drug because it usually does not affect heart rate, plasma renin activity, or plasma catecholamine levels.[1] Nevertheless, because some patients taking prazosin may accumulate fluid (although not as much as do those on hydralazine),[1] the addition of a diuretic agent may be necessary at some point in their therapy. Salt restriction is advisable if maximal effectiveness is to be achieved.

**Clinical experience:** After nearly 10 years in clinical use, prazosin, when used alone, has been an effective agent over the entire range of hypertension. Table I summarized the results of many studies in which the drug was used as single-agent therapy.[16]

Studies dating back to 1973 and earlier suggest that the optimal effect of prazosin is reached within 4 to 6 weeks in mild hypertension and within 8 weeks in moderate to severe hypertension. Harter and Delmez[16] conducted a study in 22 patients on chronic hemodialysis. Eleven patients were treated with prazosin alone (Fig. 1). Eight of these were volume-responsive, 2 volume-independent, and 1 had high-renin hypertension. The baseline predialysis blood pressure was 184 ± 5/102 ± 2 mm Hg, and after 3 months on prazosin it decreased to 154 ± 3/77 ± 3 mm Hg. Adequate control was maintained throughout the 6-month period of observation.

Kincaid-Smith,[17] who by 1977 had treated about 500 hypertensive patients with prazosin over 5 years, reported that this agent was effective when used alone in the majority of patients, including those with severe hypertension. In 16 patients treated with prazosin alone over 4 weeks, increasing the dose from 0.5* mg 3 times a day to 5 mg 3 times a day reduced the supine systolic blood pressure from 194 to 142 mm Hg and the supine diastolic pressure from 118 to 84 mm Hg. Prazosin was well tolerated by the patients.

O'Connor et al[18] compared the efficacy of prazosin with that of propranolol in a crossover study of 12 patients with essential hypertension, each treated for 1 month with placebo, prazosin alone, and propranolol alone. Both active drugs were titrated upward until the blood pressure was normalized and then kept constant for 1 month. The mean prazosin dose was 5.8 mg/day and the mean propranolol dose was 170 mg/day. Both drugs normalized systemic blood pressure, including

* In this clinical trial, tablets rather than capsules were used. Prazosin capsules are the only dosage form presently available in the United States. Prazosin, 0.5 mg, is unavailable in the United States. Because of lower bioavailability of the capsule formulation, when a dose of 0.5 mg of prazosin is referred to in the present study, it should be considered equal in antihypertensive activity to a 1 mg capsule of prazosin.

**TABLE I Summary of Results From Studies Demonstrating the Efficacy of Prazosin as Single-agent Therapy for Hypertension (Total, 324 Patients)**

| Study | Supine BP (mm Hg) | | Net BP Reduction (mm Hg) Over Baseline* | n | Prazosin Mean Dose/Day (mg) |

BP = blood pressure.

systolic, diastolic, and mean arterial pressure, although the final diastolic and mean arterial pressure was somewhat lower with propranolol (Table II). Glomerular filtration rate, renal plasma flow, and renal blood flow all decreased significantly during propranolol treatment, whereas they were preserved during prazosin treatment (Table II).

Letcher et al[3] evaluated therapy with prazosin alone in 11 patients who received a mean dose of 10 mg/day. Seated blood pressure decreased from a baseline of 178/107 to 158/94 mm Hg after 4 weeks of therapy at the maintenance dose level. Heart rate and body weight were similar before and during prazosin therapy.

In a double-blind, placebo-controlled, randomized, crossover study by Mulvihill-Wilson et al,[19] the efficacy of prazosin as single-agent therapy was compared with that of phenoxybenzamine in 11 patients with essential hypertension. Both drugs produced similar significant reductions in standing blood pressure, but only prazosin caused a significant decrease in supine blood pressure from 157/99 to 142/91 mm Hg (Table III). Prazosin was well tolerated by most patients in this study.

Turner et al[20] treated 50 mild to severely hypertensive patients with an initial dose of 1 mg titrated upward until satisfactory control was achieved or a maximal dose of 20 mg/day was reached. Twenty-four achieved satisfactory control with prazosin alone (standing blood pressure of 168/103 mm Hg was reduced to 134/82 mm Hg) and of these 20 became normotensive. The remaining 26 required the addition of a beta-blocking agent, together with a thiazide diuretic in 14 patients. Although prazosin alone produced a mean blood pressure reduction of 21/13 mm Hg in this group of 26, the combined therapy achieved a further reduction of 21/15 mm Hg.

When 101 patients, half of whom had moderate to severe hypertension, were treated with up to 20 mg/day of prazosin for 8 weeks (Table IV),[21] almost 50% became normotensive (diastolic <90 mm Hg), and the supine diastolic pressure was reduced to <100 mm Hg in 75% of the patients. Average blood pressure was reduced from 168/102 to 153/89 mm Hg. A decrease in severity of illness was reported in 83% of the patients.

Smith et al[22] reported on 38 patients treated with

| | | Diastolic <100 | 80.6 |
| | | Improvement in severity | 83.7 |

prazosin alone. Mean arterial pressure in the supine position decreased from a control level of 134 to 121 mm Hg after 6 months of therapy with prazosin.

Fernandes et al[23] used prazosin alone (6 to 10 mg/day) in 48 ambulatory patients with essential hypertension for 4 to 6 months after a preliminary 4-to-10-week period of placebo administration. Treatment with prazosin produced a significant reduction in blood pressure in both the supine and the standing position. There was a 10% decrease (from 116 to 104 mm Hg) in the average supine diastolic blood pressure and an 11% decrease (from 117 to 101 mm Hg) in the average standing diastolic pressure. Prazosin was well tolerated.

Adriaensen and Vryens[24] determined that in blood pressure reduction 3 mg/day of prazosin was approximately equal to 750 mg/day of methyldopa in a group of 20 patients with mild to moderate fixed essential hypertension. Prazosin normalized the blood pressure (supine diastolic <90 mm Hg) in 65% (13 of 20) of the patients; methyldopa produced a similar response in only 45% (9 of 20). Although the blood-pressure–lowering effect of prazosin was already noticeable in the first week of therapy, optimal effects were reached between the fourth and sixth weeks. The investigators thought that such a progressive blood-pressure–decreasing effect was an advantage, especially in subjects demonstrating the effects of arterial aging. Prazosin alone had no effect on serum levels of electrolytes, glucose, or uric acid.

Bolli and Simpson[25] successfully treated 24 hypertensive patients with prazosin, 6 of them with prazosin alone. In the 6 patients who received prazosin as the sole antihypertensive agent,* the mean decrease in supine and standing blood pressure was 16/12 and 18/16 mm

* These investigators used initial doses greater than those currently recommended.

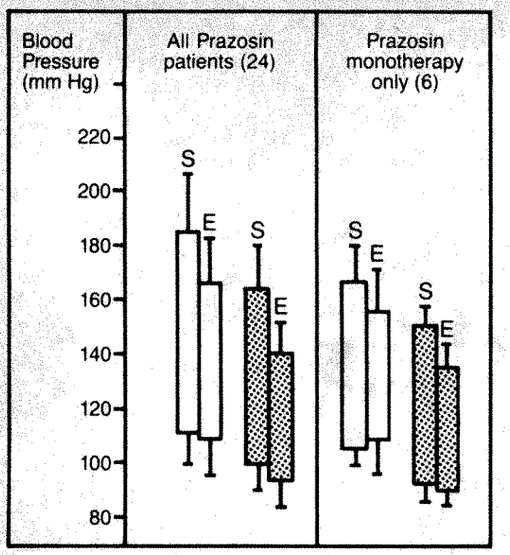

**FIGURE 2.** Mean blood pressure before (**paired white columns**) and during (**paired dark columns**) prazosin therapy. Standard deviations are indicated in **vertical lines.** E = erect; S = seated. (Adapted from Bolli and Simpson,[25] with permission.)

Hg, respectively (Fig. 2). The mean daily dose in this group was 9.9 mg.

Prazosin, therefore, has been shown over the years to be an effective antihypertensive agent when used alone as initial therapy in a large percentage of patients. In addition, it also elicits good blood pressure decrease when used concomitantly with other antihypertensive agents.

**Initiation and titration of therapy:** Current recommendations in the United States call for an initial dose of 1 mg 2 or 3 times a day. This dosage may be slowly titrated upward to a maximal total daily administration of 40 mg in divided doses. The therapeutic dosage most commonly used in this country has ranged from 6 to 15 mg daily in divided doses. Prazosin seems to have a dose-related plateau, probably reflecting full blockade of alpha-adrenergic receptors. Hence, >20 mg/day usually does not increase efficacy. However, a few patients may benefit from further increases to 40 mg daily in divided doses. Most patients can be maintained adequately on a twice-daily regimen.

In clinical experience with 22,000 patients receiving an initial dose of 1 mg of prazosin,[21] syncope was reported in 1 of 667 patients (0.15%). Although the incidence of syncope is low, patients should be cautioned to avoid situations in which injury could result if syncope should occur during initiation of therapy.

Preexisting sodium depletion from either dietary sodium restriction or diuretic therapy may contribute to the occurrence of the first-dose phenomenon with prazosin.[2] Fauchald et al[15] reported that when diuretics were withheld for 1 day before initiation of prazosin therapy, the first dose of prazosin was administered at bedtime, and the initial dose was limited to 0.5 or 1.0 mg,* no case of first-dose syncope occurred in a series of 1,151 hypertensive patients; also, symptomatic postural hypotension declined as therapy proceeded.

Too rapid dosage increases of prazosin or the introduction of another antihypertensive agent into the regimen of a patient taking large doses of prazosin also have been associated occasionally with syncopal episodes.[26] Such episodes can be minimized by slow, gradual increases in prazosin and by careful introduction of any additional antihypertensive agents, when needed.

## Prazosin as Initial Therapy in Hypertensive Subpopulations

Prazosin is particularly useful and appropriate across the broad spectrum of hypertensive individuals. In addition, the many hemodynamic and metabolic advantages of prazosin make it particularly appropriate in certain populations with complicated hypertension.

**Patients with impaired renal function:** Thiazide diuretics lose much of their antihypertensive effectiveness in the presence of renal insufficiency and therefore are usually replaced by powerful loop diuretics such as furosemide in patients with renal impairment.[27] As with beta-blocking drugs, propranolol causes a decrease in glomerular filtration rate, renal blood flow, and renal plasma flow.[18] These functions were preserved during prazosin therapy.

So far as medical treatment is concerned, except for the severity of hypertension and the need to consider the effect of different drugs on renal function, no major differences in treatment exist between patients with renovascular hypertension and those with essential hypertension.[17] Patients with an underlying renal cause and those with impaired renal function responded well to prazosin.[28-30]

**Hemodialysis:** The plasma concentrations of prazosin are not affected by hemodialysis.[31] Harter and Delmez[16] preferred to use prazosin in patients on chronic hemodialysis because methyldopa could cause somnolence and impotence (compounding conditions already present in patients on dialysis); hydralazine is associated with cephalgia and tachycardia. Prazosin was also preferred because it can easily be titrated to large doses, has minimal side effects, and is well accepted.

Adequate control of pre- and postdialysis blood pressure was maintained throughout a 12-month study[16] in all patients treated with prazosin alone (Fig. 1). Prazosin alone was most effective in 16 patients with volume-responsive hypertension whose persistent high blood pressure was due to interdialysis weight gain. Prazosin was well tolerated by most patients.

Goldberg et al[11] pointed out that uremic patients treated with hemodialysis developed accelerated atherosclerosis. Among the factors thought to be responsible are hypertension and abnormal lipid and carbohydrate metabolism. Hypertension and hyperlipidemia are very common and may be major coronary risk fac-

* See footnote in section on Clinical Experience.

tors in this subpopulation. Therefore, in treating hypertensive patients on dialysis, agents used must have no adverse effect on serum lipids. Hyperlipidemia in this group is characterized by hypertriglyceridemia and reduced high density lipoprotein (HDL) cholesterol. In this pilot survey, dialysis patients on propranolol had increased plasma triglyceride levels and reduced HDL concentrations, whereas those on prazosin had no adverse effect.

**Heart block:** Prazosin does not significantly affect the electrical conduction of the heart and can be used safely in hypertensive patients who also have conduction problems.

**Bronchospasm:** Prazosin can safely be used in patients with hypertension who also have obstructive bronchospastic disease.

**Diabetes mellitus:** Thiazide diuretics can trigger diabetes or aggravate preexisting hyperglycemia[32] because they increase blood glucose levels and can even lead to nonketotic hyperosmolar coma. The hyperglycemic properties of diuretics are also related to the hypokalemic effect of these drugs. Prazosin can be used safely in hypertensive patients with diabetes or hyperglycemia because it has minimal or no effects on glucose metabolism.[14]

**Effects on lipid metabolism:** Diuretics such as chlorthalidone and hydrochlorothiazide significantly increase plasma total cholesterol, VLDL cholesterol, and plasma triglycerides; chlorthalidone increased LDL cholesterol as well.[33] Recently, Ames and Hill[34] indicated that methyldopa significantly lowers the serum levels of protective HDL cholesterol. Propranolol and atenolol[35] and, to a lesser extent, the cardioselective beta-adrenergic blocking agents such as metoprolol decrease the HDL cholesterol and increase triglyceride concentrations.

The actual clinical benefit of decreasing elevated blood lipid levels in hypertensive patients has not been clearly established, although some studies have found a definite correlation between the mortality from coronary heart disease and decreasing the lipid levels (through reduced intake of saturated fats, no smoking, and increased exercise) in normotensive subjects.[36] Hopefully, decreasing the blood pressure by drug therapy will further reduce mortality from coronary heart disease. However, several large trials, including the recent Multiple Risk Factor Intervention Trial (MRFIT),[37] suggest that decreasing the blood pressure with a number of drugs including thiazides, chlorthalidone, methyldopa, reserpine, guanethidine, and propranolol may fail to produce any clear cut benefit in terms of mortality from coronary heart disease. We might hypothesize that the adverse metabolic effects of these drugs (including increases in very low density lipoprotein (VLDL) + LDL and decreases in HDL) negated the beneficial effect expected from decreasing the blood pressure. No similar trials have yet been conducted with prazosin, but other studies have shown it to have no adverse effect on lipid metabolism.

**Hyperuricemia:** Prazosin has no effect on uric acid metabolism[5] and therefore can be used in hypertensive patients with gout or hyperuricemia without the need to add an antigout agent, thus simplifying therapy and encouraging compliance with the regimen.

## Side Effects

The side effects of prazosin therapy, which include dizziness, lightheadedness, headache, drowsiness, weakness, and palpitation, are generally mild and transient and seldom require discontinuation of the drug. Sexual dysfunction, which may occur with some other antihypertensive agents such as methyldopa, diuretics, and reserpine, is uncommon with prazosin.[38]

As previously indicated, the most significant side effect of prazosin is the "first-dose phenomenon." Syncopal episodes may occur in rare instances, usually after the initial dose. However, withholding diuretics for 1 day before initiating prazosin therapy, limiting the initial dose to 1 mg, and taking it at bedtime are all helpful in eliminating many of the initial adverse effects. Fluid retention necessitating the addition of a diuretic sometimes develops on long-term therapy with prazosin.

**Drug interactions:** In patients who initially receive prazosin but who need more antihypertensive effect, the required dose of diuretic or beta-blocking drug or both is reduced, thus avoiding some of the adverse effects of these additional drugs.

In clinical practice prazosin has been administered without any adverse drug interactions with cardiac glycosides (digitalis and digoxin), hypoglycemics (insulin, chlorpropamide, phenformin, tolazamide, and tolbutamide), tranquilizers and sedatives (chlordiazepoxide, diazepam, and phenobarbital), antigout agents (allopurinol, colchicine, and probenecid), antiarrhythmics (procainamide and quinidine), as well as analgesics, antipyretics, and anti-inflammatory agents (propoxyphene, aspirin, indomethacin, and phenylbutazone). Hypertension may develop in patients given prazosin who are also receiving a beta-blocker such as propranolol.

**Conclusions:** In a substantial number of studies dating back to 1973 and before, prazosin given as initial single therapy was an effective and well tolerated antihypertensive agent in all degrees of hypertension (mild, moderate, and severe).

Prazosin decreases blood pressure by reducing total peripheral resistance, which is the underlying hemodynamic problem in most patients with essential hypertension. It does not affect, or minimally increases, cardiac output, heart rate, plasma renin activity, plasma catecholamines, or plasma electrolytes. It has no adverse effect on glucose, uric acid, or lipid metabolism. It does not affect renal function in otherwise normal hypertensive patients and may enhance renal function in patients with concomitant heart failure.

The mild side effect profile of prazosin and its lack of adverse metabolic actions make this drug an attractive choice as initial therapy because it may provide more benefits over the long term than do the first-line agents currently used to treat hypertension. If combined therapy with a diuretic or a beta-blocking agent is re-

iired, the choice of prazosin as initial therapy may ake it possible to reduce the dose of the concomitant ug.

The "first-dose phenomenon" is rare when initial ses of 1 mg of prazosin, preferably taken at bedtime, e used.

# Treating the Patient With Mild Hypertension And Renal Insufficiency

J. CAULIE GUNNELLS, Jr., MD

**The Hypertension Detection and Follow-up Program (HDFP) first demonstrated that treatment of patients with mild hypertension (90 to 104 mm Hg diastolic) could reduce morbidity and mortality in coronary heart disease (CHD). Previous studies had already shown the beneficial effect of blood pressure reduction on renal disease, heart failure, and cerebrovascular disease. When uncontrolled, mild hypertension in the patient with renal disease will lead to further deterioration of renal function. To prevent this and other complications (such as atherosclerosis) of hypertension, whether primary or secondary, one should place these patients on antihypertensive therapy. However, standard stepped-care therapy with diuretic drugs and beta-blocking agents is now under reevaluation in view of the potential adverse effect of these agents on serum lipid and renal function. Beta-blocking drugs, further more, tend to increase peripheral resistance, a he modynamic effect opposite to that desired in thes patients. Other drugs, acting centrally or peripherall on the nervous system, also have some undesirabl features in addition to troublesome side effects Prazosin, a vasodilator and effective antihyperten sive agent with a different mechanism of action, ha no adverse action on lipids and renal functior lowers peripheral resistance, and does not caus many of the side effects that limit use of the othe drugs. It therefore appears to be a good choice fo initial therapy in mild to moderate hypertension wit associated renal insufficiency.**

The proposition that lowering high blood pressure could reduce cardiovascular morbidity and mortality was clearly demonstrated for the first time by the Veterans Administration Study.[1] Conducted over 10 years ago, this study definitely showed that antihypertensive drug therapy could prevent complications of hypertension such as hemorrhagic stroke, renal failure, left ventricular failure, and aortic dissection. However, it failed to demonstrate any significant benefit in preventing the so-called atherosclerotic complications of hypertension, including coronary heart disease (CHD).

On the basis of that study, general guidelines regarding indications for therapy in hypertensive patients (Table I) were established. Patients with severe hypertension (diastolic blood pressure ≥120 mm Hg) required immediate evaluation and treatment. Treatment was also indicated for patients whose diastolic blood pressure fell within the range of 105 to 119 mm Hg.

From these beginnings, the concept of "stepped care" for the treatment of high blood pressure also evolved (Fig. 1). This approach, which usually calls for sodium restriction and a diuretic agent as the first step, followed by stronger measures if necessary, has been effective in bringing the blood pressure of moderate to severe hypertensive patients under control.

However, the Veterans Administration Study faile to address clearly the problem of the patient with mil hypertension (diastolic pressure in the range of 90 to 10 mm Hg). An important question has been whether o not the physician should institute antihypertensiv treatment in such patients and, if so, what drug an under what regimen.[2] A secondary issue may be th implication of what such a treatment, or lack of it, woul hold for the patient with renal insufficiency.

In late 1979 and early 1980, the Hypertension De tection and Follow-up Program (HDFP)[3] addresse some of these questions by studying approximatel 11,000 patients with diastolic blood pressure levels o 90 to 104 mm Hg. For the first time the study demon strated the effectiveness of treating mild hypertensior Reducing blood pressure by only 10 mm Hg was foun to be beneficial in decreasing the CHD mortality rat in this group.

The vast majority (70%) of all hypertensive patient in the United States have mild hypertension, well withi the range of 90 to 105 mm Hg (Fig. 2). Thus, if we accep the recommendation to treat mild hypertension, w automatically create an enormous number of patient who must undergo drug therapy.

We must ask whether the benefit relative to the ris involved in treating these patients is really worth it, a issue previously addressed by Freis[2] and brought int sharper focus along with other questions in certain se lect patients as reported in the Multiple Risk Facto Intervention Trial (MRFIT).[4] The overall benefit o previous antihypertensive drug regimens (that i

stepped-care) is clearly established. Very long experience with diuretic drugs has established these agents as the cornerstone of blood pressure therapy. However, with increasing awareness of the long-term biochemical changes produced by them important questions have been raised regarding the possible effects of diuretic therapy on the atherosclerotic potential of hypertension, namely that seen in CHD. Diuretic drugs are known to have potentially serious side effects,[5–8] including a few—such as volume contraction, hypokalemia, alterations in carbohydrate tolerance, elevation of serum lipid and uric acid levels which may be troublesome to patients with renal insufficiency. Beta-blocking drugs also have been reported to adversely affect lipid, glucose, and uric acid concentrations. Furthermore, because patients with renal impairment are susceptible to accelerated atherosclerosis and premature cardiovascular complications, the relation between antihypertensive drugs and their effect on other risk factors for CHD (such as the lipid profile) needs study. Taking into consideration the long-standing success of diuretic and beta-blocking drugs in the hypertensive population, should we reexamine the way in which we initiate therapy, particularly in patients with mild to moderate hypertension with and without renal involvement? It will not do merely to stop treating mild hypertension with drugs. Unfortunately, the disease and its consequences continue to progress in many patients, unless appropriate drug therapy is used.

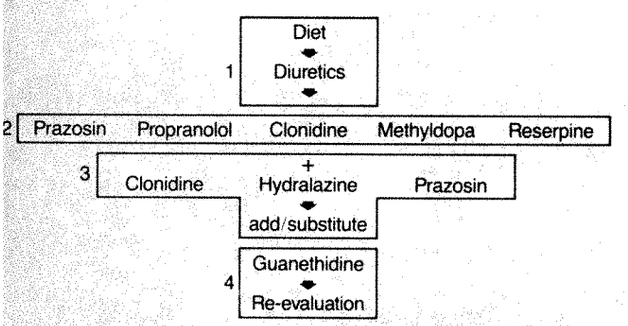

**FIGURE 1.** Stepped-care approach to therapeutic goal. (Modified from the 1980 Report of the Joint National Committee on the Detection, Evaluation and Treatment of High Blood Pressure.)

## Renal Involvement: Primary and Secondary

Renal disease can be both the cause and the result of hypertension.[9] In either case, the aims of treatment for the patient with mild hypertension and renal disease are twofold: (1) protect kidney function, and (2) prevent the complications of high blood pressure, especially atherosclerosis, to which renally impaired patients are prone. This latter aim applies even in patients undergoing dialysis.[10]

The natural progression of untreated primary (essential) hypertension is grim (Fig. 3). One of the major hemodynamic effects in essential hypertension is an early and sustained increase in peripheral vascular resistance, which eventually leads to accelerated atherosclerosis. Sooner or later, this results in target organ damage. Left uncontrolled, hypertension causes irreparable damage to the kidney, leading to end-stage renal disease. The Veterans Administration Study[1] clearly demonstrated that effective treatment of hypertension reduces the incidence, prevalence, and subsequent development of renal insufficiency.

Renal impairment is a definite possibility in patients with mild hypertension. Up to 3% of patients with mild to moderate hypertension (90 to 125 mm Hg diastolic), as reflected by minimal changes in the optic fundi (grades I and II), will show progression to renal insufficiency over a 5- to 7-year period (Table II). With persisting hypertension, about 3 to 5% will show evidence of renal damage. The important point to be made here is that if these patients with mild to moderate hypertension are treated, the progression toward renal insufficiency can be reduced to almost zero.

For patients with grade III fundi (with hemorrhages and exudates) and diastolic pressure ≥125 mm Hg, the situation is worse: 7 to 12% will progress to renal failure in 5 years (Table III). Furthermore, only 10 to 15% will be alive in 10 years. But even in this group, treatment can reduce the progression to renal failure—particularly in those who present with initially normal renal function—to <5% in 5 years.[11] It is now realized that by treating hypertension we protect kidney function and reduce the incidence of renal insufficiency. If we weigh the cost of dialysis against daily intake of medication, the choice becomes even clearer.

We see a slightly different picture with secondary hypertension caused by parenchymal disease (such as glomerulopathies, the tubulointerstitial and infiltrative diseases, and so on ). Table IV lists some causes and mechanisms of parenchymal renal disease with coexistent hypertension. The management of hypertension in these patients, regardless of the cause of the disease, is similar with both primary and secondary hypertension.[9] Ideally, one should be able to treat the underlying primary glomerulopathies and similar diseases, but unfortunately these may progress independently of blood pressure therapy. However, by instituting antihypertensive therapy, we can offer some degree of protection from vascular (especially cerebrovascular) deterioration.[12] This is particularly beneficial in diabetic patients and in patients with renovascular disease. And,

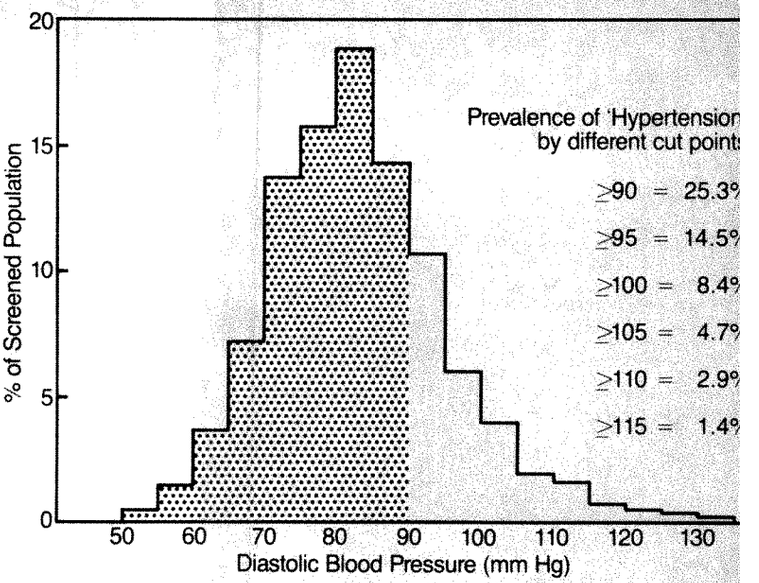

**FIGURE 2.** Frequency of distribution of diastolic blood pressure at home screening of 158,906 persons, 30 to 69 years of age. (Hypertension Detection and Follow-up Program, 1973–1974.) Note that a great majority of those with hypertension (diastolic blood pressure ≥90 mm Hg) have a diastolic blood pressure in the range of 90 to 104 mm Hg (mild hypertension). (From Hunt JC, Cooper T, Frohlich ED, Gifford RW, Kaplan NM, Laragh JH, Maxwell MH, Strong CG (eds). Hypertension Update Mechanism, Epidemiology, Evaluation, Management. From the program Dialogues in Hypertension, Hunt JC (ed). Copyright 1980 Health Learning Systems, Bloomfield, NJ.)

indeed, control of blood pressure will offer some degree of protection of renal function and involvement from primary hypertension.

Management of the patient with renal disease and associated hypertension is similar to treatment of the patient with primary hypertension and secondary renal involvement, with 1 exception. In the former group, we seek to treat the underlying disease (if a treatment is available) in order to stop the particular abnormality from progressing (Table V). Good control of blood pressure, however, is a must. In patients whose kidneys are deficient in their ability to excrete salt and water, we would first reduce salt intake and institute appro priate diuretic therapy. The great majority of thes patients with significant renal impairment will usuall require a potent loop diuretic drug such as furosemid which affects renal function only minimally.

In patients with renal disease, cholesterol ratios ar often unfavorably balanced in the direction of athero genic fractions. The plasma concentration of hig density lipoprotein (HDL) cholesterol, which correlate inversely with coronary risk (the lower the concentra tion, the greater the risk), is low in these patients.[13,1 Thus the ratio of antiatherogenic HDL cholesterol t

**TABLE II Natural History and Results of Treatment in Mild to Moderate Primary Hypertension**

**With Hypertension**

Causes
- Glomerulopathies with or without nephrosclerosis
- Interstitial renal disease
  - Pyelonephritis
  - Obstructive disease
  - Polycystic disease
- Infiltrative renal disease (metabolic)
  - Diabetic—mainly nephrosclerotic
  - Amyloidosis
- Renovascular disease
- Most diseases producing a "pure" nephrotic syndrome and normal renal function do not have hypertension as a prominent feature

Mechanisms
- Salt/volume dependent
- Renin dependent
- Combination

he atherogenic low density lipoprotein (LDL) cholesterol is frequently low, suggesting that clearance of holesterol from the peripheral tissues may be impaired. These patients may also have a defect in the clearance f triglycerides and thus an elevated plasma triglyceride evel, which has also been associated with increased risk or coronary heart disease, although to a lesser degree han LDL.[15] Therefore, because patients with renal isease are susceptible to accelerated atherosclerosis nd to premature cardiovascular complications, therapy hould be aimed at favorably altering the cholesterol atio (or at least not making it worse) and reducing erum triglycerides in addition to reducing blood ressure.

## Criteria for an Ideal Antihypertensive Drug in Patients With Renal Impairment

In the management of hypertension with the aim of verall kidney protection, there are several requirements for an ideal drug.

First, we need an agent that is effective in reducing lood pressure without adversely affecting renal function.

Second, because peripheral vascular resistance is sually increased in patients with renal insufficiency, hile cardiac output remains normal or slightly elevated, we would like to have an agent that reduces peipheral resistance, and has little effect on cardiac utput.

Third, the agent should be effective at all levels of lomerular filtration rate (GFR). In this interest, the oute or mode of excretion should be known and, if ecessary, appropriate dosage adjustments can be ade.

Fourth, the ideal agent should not have adverse rug-drug interactions. So many of today's patients are n multiple drug regimens that it would be wise not to ave the antihypertensive drug interfere with the beneficial effect of another agent, and vice versa. For example, the inadvertent addition of some nonsteroidal nti-inflammatory drugs may bring about a redistribution of renal function in patients with marginal or reduced intravascular volume.[16]

Fifth, a main eventual aim in all these patients is volume expansion control, which leads to a further reduction in blood pressure without adverse effects on renal and cardiac function. The agent should be free from the effects of inappropriate volume expansion which has previously been well demonstrated in classic vasodilators.

Finally, the drug should not adversely affect other risk factors for CHD. Increases in other risk factors are now believed to be a major reason for the lack of impact of blood pressure lowering on CHD mortality and morbidity.

How do the presently available antihypertensive drugs measure up to these criteria?

## Available Antihypertensive Agents

**Diuretic drugs (thiazides):** These agents have proved very effective in lowering high blood pressure, when used either alone or in combination with other therapy. They tend to change peripheral vascular resistance in the right direction, but may decrease cardiac output (through volume contraction) in some patients.

More than any other class of antihypertensive agents, diuretic drugs accomplish the goal of volume expansion control. However, in patients with renal impairment, diuretic drugs may also pose a potentially serious hazard. The physician should be careful not to use these drugs in excess, because undesirable volume contraction and dehydration may result. This, in turn, could lead to further impairment of renal blood flow and glomerular filtration, thus exacerbating the underlying renal insufficiency. In these patients, loop diuretic drugs such as furosemide, which have minimal effect on renal function, are usually preferred.

The main problems with diuretic agents lie in their biochemical side effects, particularly in their adverse actions on serum potassium, lipids, glucose, uric acid, renin, and magnesium. Diuretic use poses a significant risk of spontaneous arrhythmias in patients whose potassium tends to be below or slightly above 3.0 mEq/liter.[17] Without careful laboratory monitoring in the patient with renal disease, routine potassium replacement therapy poses local and systemic hazards as well. McMahon et al[18] has shown that many of the potassium

**TABLE V Management of Chronic Parenchymal Renal Disease Associated With Hypertension**

- Treat the underlying disease
- Good control of blood pressure is a must
- Reduce salt intake
- Use diuretics
  - Thiazides (Metolazone)
  - Furosemide
- Do not volume contract the patient
- Add standard antihypertensives (avoid guanethidine)

chloride substitutes are associated with erosion and symptomatic bleeding lesions in the gastrointestinal tract. Because the patient with renal disease is at equal or greater risk for the development of hyperkalemia, the use of potassium-sparing diuretic drugs (such as spironolactone, triamterene, and amiloride), alone or in combination with other diuretic drugs, should be avoided. Potassium levels should be kept as stable and normal as possible, especially in patients with known coexistent heart disease. Because so many patients are unaware of their silently progressing heart disease, they may be at risk if their potassium balance is disturbed.[19] The prudent physician, in treating the hypertensive patient with renal disease, will take a serum potassium reading before giving diuretic drugs and monitor this important electrolyte often along with continuing observance of any change in GFR.

Diuretic drugs have been shown to have a detrimental effect on blood lipids. Concentrations of the atherogenic low density and very low density lipoproteins (VLDL), as well as total cholesterol and triglycerides, may be altered and add to the risk of coronary heart disease. If therapy will be lifelong, as is often the case, the aggravation of risk factors could cancel any benefit derived from reducing the blood pressure. A 1978 report by Gluck et al[20] reported that chlorthalidone, furosemide, and mefruside increased LDL levels, with mean increases ranging from 8 to 15%. Other studies have shown that some antihypertensive drugs adversely affect blood lipids.[21–24] When choosing diuretics as an antihypertensive agent, these potential adverse effects should be taken into consideration.

**Beta-blocking drugs:** These agents have gained wide acceptance for their ability to control hypertension. However, by blocking the beta receptor in the vasculature, beta-blocking drugs tend to increase peripheral resistance, which is the opposite of the effect one wishes to achieve in the hypertensive patient.[9] Symptomatically, this becomes quite obvious in patients with Raynaud's disease, peripheral vascular occlusive disease, or even in other patients in cold climates. Patients may report cold, painful, or tender feet or hands because of impaired peripheral circulation.

The mechanism by which beta-blocking drugs reduce blood pressure seems to be related to their ability to reduce the release of renin from the kidneys and to significantly lower cardiac output. The reduced cardiac output may present a number of problems (except in patients with a hyperdynamic circulation, in whom such a reduction might be beneficial). For the patient with impaired renal function, decreased cardiac output means reduced kidney perfusion. Thus, renal blood flow, renal plasma flow, and glomerular filtration are reported as adverse effects of some beta-blocking drugs.[25,26]

Beta-blocking drugs share with diuretic agents some of the adverse lipid, glucose, and uric acid effects. Most selective and nonselective beta-blocking agents increase triglycerides or lower HDL cholesterol, or both.[27,28] The Oslo Study,[27] designed to evaluate the long-term drug treatment of uncomplicated mild hypertension in middle-aged men, found that propranolol reduced th antiatherogenic lipid fraction HDL by 13%, raise serum triglycerides by 24%, and worsened the choles terol ratio by 15.2%. A study in Montreal[28] noted tha both metoprolol and propranolol increased the choles terol ratio. These effects may partly explain the con tinuing unchanged incidence and mortality from CHD especially when beta-adrenergic blockade is combine with diuretic drugs.

In addition, beta-adrenergic blockade is contraindi cated in 25 to 30% of patients with hypertension be cause of adverse effects on bronchial asthma, franl heart failure, advanced degrees of heart block, periph eral vascular disease, sinus bradycardia, and insulin dependent diabetes mellitus.[9]

It should be pointed out that beta-blocking drugs ar useful in patients with classic angina pectoris, in thos with a hyperdynamic circulation, in certain types o supraventricular arrhythmias, and as protection afte infarction. Like all nondiuretic agents, beta-blockin drugs cause fluid retention, though not as extensivel as certain vasodilators and central-acting drugs.

**Prazosin:** Contrary to the action of beta-blockin drugs, prazosin, a selective postsynaptic alpha-adren ergic blocking agent, does not increase peripheral vas cular resistance and does not impair peripheral circu lation. In fact, it reduces total peripheral resistance Moreover, prazosin does not adversely affect rena function, and indeed may actually improve it in som patients.[29] These 2 factors make it attractive for use i patients with renal disease.

Prazosin does not have many of the unwanted he modynamic and metabolic side effects of other anti hypertensive drugs. It effectively reduces blood pressur without significantly affecting cardiac output or hear rate. As we have just pointed out, prazosin decrease peripheral vascular resistance. It does not have an ad verse effect on potassium and does not lead to hazardou hypokalemia, nor does it cause elevations in blood glu cose or uric acid, making it suitable for diabetic subject and patients with gout.

Prazosin does not adversely affect the lipid profile which is a critical attribute for patients with renal dis ease. The Oslo Study[27] also compared prazosin witl propranolol and found that prazosin had no adverse effect on blood lipids.

Prazosin may cause fluid retention in some patients but not to the extent of the classic vasodilators (hy dralazine and minoxidil) or the central-acting agent (methyldopa and clonidine). Prazosin makes it possibl to attain control of blood pressure in a significant per centage of the population, even when administered a low doses. There is a less than 1% incidence of syncop when prazosin is administered in a low initial dose ( mg, 2 or 3 times daily).[29] Whether or not a patient wil experience syncope depends both on initial dosage an on volume contraction. Syncope can be avoided in mos cases by using the drug as initial therapy, before diureti drugs are administered.

**Other antihypertensive agents:** Because of trou blesome symptomatic side effects, central- and pe

pheral-acting adrenergic drugs such as methyldopa ıd reserpine are not used as often as they were before ıe advent of beta-blocking drugs. (However, clonidine an exception.) Beta-blocking drugs seemed preferable ecause they did not cause as many or as serious central ervous system effects (dry mouth, depression, sexual ysfunction, and so on). These drugs, especially cloni- ıne, are effective blood pressure lowering agents with otency equal to that of the other agents discussed.[9] hey may be used in patients with normal as well as ıpaired renal function.

The classic vasodilators (hydralazine and minoxidil) roduce a hyperdynamic circulation, with the possibility angina and myocardial infarction in susceptible ersons. Therefore, they require the use of a beta-ad- nergic blocking agent to counter some of these effects. ittle is known about the lipid effects of these vasodi- tors. They also produce significant fluid retention hen used alone. Prazosin, however, although it is also vasodilator, avoids some of these problems simply ecause of its different mechanism of action.

Another type of vasodilator, captopril, acts through ill another mechanism. This agent inhibits the con- erting enzyme that controls the production of angio- nsin II, a potent vasoconstricting agent, thus lowering ıe amount that reaches the peripheral vascular smooth uscle cell. Although captopril does cause peripheral ıscular resistance to decrease, it has led to such renal normalities as proteinturia, decreased renal function, ıe nephrotic syndrome, and membranous glomerulo- ephritis. Therefore, in patients with renal impairment, would seem more appropriate, when possible, to use ı agent such as prazosin that does not adversely affect omerular filtration or renal blood flow.

**Conclusions:** Patients with impaired renal function e particularly susceptible to the ravages of hyper- nsion, even when it is only mild. The 2 primary aims therapy in such patients are to protect their renal ınction and prevent or delay the atherosclerotic pro- ss, which in these patients may already be accelerated. his, in turn, sets 2 main requirements for an ideal an- hypertensive agent in patients with renal insufficiency: should not unfavorably affect the lipid profile, nor rther impair an already inadequate renal function. ldditional criteria to keep in mind are the same as for her hypertensive subgroups.

Of the available drugs, diuretic and beta-blocking ugs fail to meet the basic criteria entirely. Central- ıd peripheral-acting adrenergic drugs also fall short ecause of symptomatic side effects. Due to its lack of lverse effects on lipids and on renal function, only azosin, among the antihypertensive drugs clinically ailable today, seems to fulfill these 2 main require- ents. In addition, prazosin lacks most of the metabolic ıd hemodynamic adverse effects of other antihyper- tensive agents and, therefore, should be considered a logical choice for first-line therapy in patients with mild to moderate hypertension, with or without renal im- pairment.

# Roundtable Discussion

## Moderator: J. Caulie Gunnells, Jr.

**DR. GUNNELLS:** As moderator, let me address the first question to Dr. Kaplan: One of the aims of this Symposium was to look at initial antihypertensive therapy and examine some of the controversies surrounding the widespread use of diuretics. We also wanted to consider other methods of treatment, and in particular to look at prazosin as a possible alternative as an initial therapeutic agent. Would you care to comment about physicians' patterns in choosing antihypertensive drugs, the rationale behind their choices, and where you think we stand at present in the selection of the initial agent to treat primary hypertension?

**DR. KAPLAN:** We all grew up with the idea that diuretics were effective, that they were the easiest to use, and the least expensive agents. Effectiveness is one point that needs to be reemphasized since it has not been adequately stated. There is little difference, as far as therapeutic effectiveness is concerned, when one looks at careful comparisons between a diuretic in a reasonable daily dosage and any of the other drugs, including reserpine, methyldopa, clonidine, prazosin, and various beta-blocking agents. They all seem to have about the same effect on blood pressure.

In general, therefore, the attitude has been that a single morning dose of a moderate to long-acting diuretic agent would be appropriate for beginning therapy. However, with the hazards and potential problems of diuretic therapy—which we all assume to be partly responsible for the lack of improvement in coronary disease that has been reported in most of the large therapeutic trials—the idea of using alternative drugs seems to have awakened a great deal of interest. I would predict that, in the future, increasing numbers of patients, particularly those with mild hypertension, are going to be treated with one of the alternative drugs.

As to which alternative drug it will be, obviously we are blessed with multiple choices. Many physicians have been using beta-blocking agents. However, I believe we all harbor a certain concern about their negative effects on blood lipids, aside from the fact that probably 25 to 30% of all hypertensive patients have specific contraindications to the use of beta-blockers.

Prazosin has an additional attraction in that it does not appear to adversely affect lipid levels. In addition, it offers a theoretical advantage in that it lowers the total peripheral resistance, whereas beta-blockers increase it, at least initially. Since high peripheral resistance is the hemodynamic hallmark of most essential hypertension, everyone would prefer that it be diminished rather than increased.

Furthermore, in cold climates, many people notice cold extremities and have difficulties with their peripheral circulation while on beta-blocking therapy; that does not appear to be true with the use of prazosin.

Thus, I foresee a continued increase in the use of drugs other than diuretics for initial therapy, and s cifically I see this as a very logical place for the increa use of prazosin.

The possibility of reactive volume retention—wh can happen with any of the nondiuretic drugs and is of the reasons diuretics are often chosen first—ne to be considered. Whenever blood pressure is lower the kidney tends to retain fluid. This makes it import to institute a moderate restriction in dietary sodium the first step in therapy; if drugs need to be used moderate restriction in dietary sodium becomes e more important.

**DR. CUTLER:** I agree with what Dr. Kaplan has j said. My feeling is that some education will be nee to make physicians fully aware that other drugs do have flat response curves like the diuretics, and t need to be titrated to get maximal benefits.

**DR. GUNNELLS:** That's a good point. Diuret have always been easy to use, and we all like to do thi the easiest possible way. However, we have a respon bility, based on an examination of the available da to reeducate ourselves and other physicians. This sho be a thinking process, not a conditioned reflex.

Among the problems that everyone has mentio regarding diuretics, a frequent and difficult proble that of potassium depletion and its sequelae.

**DR. OKUN:** This is a complex issue. Let me go b a step and say that, as we have heard repeatedly, uretics have in the past been the first-line drugs. I, t think this is going to change, and that we will see a cline in the use of diuretics, particularly in view of data Dr. Ames and his co-workers have obtained. Ot studies have added to this disquieting discrepancy results between improvement in cerebrovascular dise and very little, if any, improvement in coronary dise despite blood pressure reduction. I am beginning to f rather strongly that this may be due to a less than id choice of medication.

In the past, one of my choices has often been to foll sodium restriction with the use of diuretics—prima thiazide diuretics. I will have to rethink such an proach very seriously, because the risk-benefit ratio early diuretic therapy has now shifted to the po where such therapy is no longer appropriate for a la number of patients.

One of the problems posed by diuretics is that of tassium disturbance. Much has appeared in the medi literature in the past few years regarding the risks even what was once considered modest hypokalem Some work indicates that there is indeed a signific risk of spontaneous arrhythmias in persons whose tassium levels tend to drop below 3.0 mEq/liter. Havi witnessed some of these spontaneous arrhythmi which do respond to potassium replacement, we n

initiate potassium replacement very early in patients who are beginning diuretic therapy; if they are on a digitalis preparation, we institute administration of potassium immediately. The obvious reason is to avoid potentiating the toxic effects of digitalis. However, we have problems in patient acceptance of potassium supplements. In view of the data generated recently by McMahon and his group at Tulane, it seems that many of the potassium chloride substitutes that we have been using may cause problems in the gastrointestinal tract. We will have to restrict use of some of the potassium chloride preparations, and this makes potassium replacement even more difficult. But replace potassium we must, hopefully to the point of normal total body levels, a measurement that is not available to most clinicians, but can be approximated by a serum potassium determination. The use of drugs such as prazosin will probably make treatment much easier since there is no adverse effect on potassium levels at all.

**DR. COLUCCI:** Cardiologists have always been impressed with the importance of a potassium level that is as stable (that is, free of large fluctuations) and as normal as possible, especially in patients with coronary artery disease. The data from the MRFIT study are relevant in this connection. The increased mortality rate in patients with preexisting electrocardiographic abnormalities who were aggressively treated with diuretics was impressive and reinforces the bias of many cardiologists that it is important to maintain adequate serum and total body potassium levels, especially in patients with preexisting heart disease.

**DR. GUNNELLS:** To summarize, most people would consider potassium depletion with diuretics a potential problem because hypertensive patients have an unknown amount of coronary heart disease, which places them at risk even with minor alterations in potassium levels. The usual physician is more likely than not to give potassium supplements when using diuretic agents. This adds to the expense, to the possibility of compliance problems, and to a need for more frequent laboratory tests in patients with hypertension.

In the MRFIT study, thiazides, propranolol, methyldopa, hydralazine, reserpine, and guanethidine were all used. If one looks at the conclusions on mortality from coronary heart disease, none of these drugs seemed to have much of a beneficial effect. Could it be related to the hemodynamic and metabolic actions of these drugs? Or is there something else in that study that might throw some light on this issue?

**DR. AMES:** I can only speculate in this regard. We just don't know why the patients treated with diuretics and antihypertensive therapy did not do as well as we had anticipated. Although there was an equal number of deaths in the special intervention group and the usual care group, we don't know the details. Were these sudden deaths, or were they deaths of individuals with documented myocardial infarction? This would be important to know, because if they were sudden deaths, without definite evidence of coronary disease or myocardial infarction, they might have an electrical origin rather than being due to the build-up of atherosclerotic plaque. We need more information. The changes in lipids that may have occurred during therapy have not been looked at in great detail either, so that also remains speculative. I do know that at the 4-year interval, patients in the MRFIT trial who received antihypertensive therapy, specifically diuretic therapy, did not show as large a decrease in total cholesterol or triglycerides as the patients who had not received diuretic treatment. Diuretics thus appeared to counter the reduction in cholesterol that had been anticipated. The failure of cholesterol to decrease as much as expected in the hypertensive SI group could have lessened the mortality differential in comparison with the hypertensive UC group. Still, the hypertensive SI group had, in absolute terms, both lower blood pressure and lower total cholesterol than the hypertensive UC group throughout the program. The lipid hypothesis, therefore, does not seem to explain fully the failure of SI men to do better. Perhaps differences between SI and UC men in glucose tolerance or frank diabetes related to high-dose diuretic therapy could contribute to mechanisms causing the unexpected equivalence of CHD mortality in hypertensive SI and UC men. These suggestions are interesting but remain speculative. More detailed analyses of the MRFIT data are needed.

**DR. GUNNELLS:** We have talked a great deal about lipids this afternoon. This could be an important factor in connection with the problem of coronary heart disease and atherosclerosis in all hypertensives. If we're going to embark upon drug treatment, how much of a problem are the lipid effects of diuretics and beta-blockers, and how does prazosin come out in comparison?

**DR. CUTLER:** This is obviously a controversial area. You can't get 10 physicians together who will agree on that particular point. What we've talked here is taking data that are currently extant or being developed and comparing them with data from the past, namely the Framingham study, for the purpose of risk-factor calculation. The large clinical trials that we've talked about today have given us some food for thought, but they haven't truly answered the question for us. And it's not likely we will have the answers very quickly. All we can suggest at the present time is caution, in view of the correlations that have been established in the past through epidemiologic methodology. The most we can say at this point is that antihypertensive agents that increase cholesterol and perhaps change the fractions in an adverse way by increasing the low density fractions and decreasing the high density ones may have an adverse effect on coronary heart disease. The underlying and conditional word is *may*. We won't know for sure until such studies are done. But in the meantime, as Stamler and others have said, the appropriate and prudent course of treatment is to implement dietary changes and to use drugs that do not have an adverse effect on lipid metabolism. As for a comparison between prazosin and other drugs, prazosin looks better because it doesn't seem to have any adverse effects on lipids.

Diuretics seem to be more consistent in producing adverse effects that we believe may be atherogenic.

**DR. GUNNELLS:** Another important issue is that we seem to be in an exercise-oriented society. I'm constantly dodging joggers and bicycle riders on my way to the hospital. The use of drugs, specifically the beta-blockers, as first-line therapy in the physically active patient may be limiting. These agents have been advocated for the younger hypertensive patient. In these patients, the effect of the beta-blocker on the ability to exercise can often be an important side effect.

**DR. COLUCCI:** Clearly, beta-blockers have multiple effects on the blood pressure, and the overall result is a combination of these effects. As I mentioned very briefly during my presentation, the beta-receptor in the vasculature, although frequently overlooked, is an important receptor. When it's blocked, the total peripheral resistance increases. This becomes clinically obvious when one treats a patient with Raynaud's disease or peripheral vascular occlusive disease, or just living in a cold climate. So we know that beta-blockers have an effect on total peripheral resistance that is the opposite of what we would want for an antihypertensive agent. One of the mechanisms by which beta-blockers lower blood pressure is through their reduction of renin release. They also tend to have effects on the heart. Cardiac output is diminished, and this may also contribute to their antihypertensive effect. In addition, beta-blockers seem to have a central effect, perhaps by reducing central sympathetic outflow. There may be other mechanisms, but it is somewhat paradoxical that beta-blockers were the first of the selective adrenergic antagonists to be used in hypertension, inasmuch as they do not seem to improve the main underlying problem in most primary hypertension, which is increased total peripheral resistance. The ability to exercise maximally is clearly decreased by beta-blockers. In part this is because the maximal heart rate is frequently lower, and therefore the maximal cardiac work that can be done is less. Beta-blockers may result in generalized fatigue, which may be related to this decrease in cardiac output.

**DR. OKUN:** Our experience actually goes a little beyond that. Many youngsters who had been placed on beta-blockers for borderline or very mild hypertension have come to us later for other therapy because they found they couldn't exercise even to less than maximal capacity—jogging, tennis, and so on. They found themselves in difficult straits. Some animal data indicate that propranolol in particular will strikingly decrease skeletal muscle blood flow. This may be another mechanism for the easy fatigability.

**DR. GUNNELLS:** I'd like to set forth some of the features we might all agree are useful or favorable in an antihypertensive agent and see how they fit prazosin, the diuretics, and the beta-blockers. First is effectiveness. From what we've heard here, most antihypertensive drugs have equal effectiveness. In equipotent doses, prazosin is as effective as a diuretic or a beta-blocking agent in reducing blood pressure. Second, we should look at hemodynamics and side effects: Prazosin's hemodynamic profile is a rational, reasonable, and appropriate one, relative to the underlying defect in primary hypertension, namely increased peripheral vascular resistance. Prazosin is free from the biochemical side effects that most of us have raised questions about. On the other hand, concern has been expressed about the hypokalemia induced by diuretics. Patients on prazosin do not have to worry about lowered serum potassium or increased uric acid levels. Equally important, prazosin does not appear to have any adverse effects on lipid metabolism. Another favorable feature of prazosin is its low incidence of sexual dysfunction, although some has been reported.

Having said all that, I would then conclude that prazosin, as compared with diuretics and beta blockers, is an appropriate agent for consideration as initial therapy in mild or moderate hypertension.

**DR. OKUN:** I agree with you, and I have 2 comments to make. First, I feel very strongly that correction of the pathophysiology of essential hypertension, normalization of the increased peripheral resistance, is a major benefit of prazosin and one that exists without any major counterbalancing effects in other areas. I have not seen this with any of the other drugs. That, to me, is a very positive aspect of prazosin. Second, I also feel very strongly about using prazosin more as initial therapy, along with a sodium-restricted diet. I think prazosin will be highly successful in controlling blood pressure in a great many patients without worsening risks—the other edge of the sword, so to speak.

**DR. COLUCCI:** As Dr. Kaplan pointed out, given the choice of a number of drugs which have the same endpoint, namely the lowering of hypertension, the onus is now on the physician to choose the drug that will be safest in the long run. I certainly would be careful in my choice of agent. Clearly, of the agents currently available prazosin is the most specific in terms of pathophysiologic effects. Selective alpha blockade makes more sense than beta blockade or other more generalized methods of adrenergic suppression.

A question usually arises about prazosin in regard to orthostatic hypotension and syncope. The overall incidence of syncope with the first dose of prazosin is about 0.1 to 0.2%, if one looks at a large series of patients and totals up the results. The incidence in any particular study will depend on a lot of factors. One of the factors identified as important was the dose of the drug used during the first administration. It is recommended that therapy be initiated with a 1 mg dose.

Another important factor in determining whether a patient will have a syncopal or orthostatic reaction to the first dose is volume status. Patients who are volume contracted, whether because of diuresis or other reasons, are much more sensitive. This is presumably due to a lower initial venous filling pressure in these patients. The venous dilatation effects of prazosin then may result in a further decrease in preload.

In the hypertensive patient without heart failure, when diuretics are withheld, syncope is rare. In one

ificant orthostatic symptoms after the first adminis-ation of a 2-mg dose of prazosin. When these patients ere withdrawn from prazosin for three weeks, then challenged with a lower dose (1 mg), none had severe mptoms, and only 2 had mild dizziness. Therefore, icking a low dose and avoiding diuresis are probably ie 2 major things the physician can do to prevent this roblem. In practice, good recommendations are to start ith a low dose of 1 mg preferably at bed time when the atient can remain supine. If the patient is receiving iuretics, withhold the diuretics for 1 or 2 days, to allow ie intravascular volume to reequilibrate. Diuretics can ien be readministered. That raises an interesting uestion: If prazosin were to be used as first-line ther-py, before diuretics, would we see the same incidence f syncope as when the drug is used as a Step 2 therapy? speculate that we would not, and therefore this would e another good reason to consider prazosin as initial ierapy before diuretics.

**DR. GUNNELLS:** With diuretic agents we still have ie problem of potassium depletion and other effects ot associated with prazosin. Among the antihyper-ensive drugs for which data are available, the treatment rofile of prazosin—side effects and therapeutic effec-veness—is extremely favorable. Therefore, prazosin a very reasonable and rational drug as initial therapy or hypertension. I think it is fair to say there is general greement on this among the panel members, and we ll agree it is appropriate that we reexamined past ractices and began to ask ourselves questions instead f just prescribing as a reflex.

**DR. CUTLER:** We've talked a lot about step ther-py, but we should place it in perspective. It was very good way to approach hypertension. The initial thrust in step care was provided by Wilkins many years ago with the advent of diuretics, reserpine, and vasodilators. We have now reached the point where the menu of therapeutic agents is quite large, and as when we visit a favorite restaurant, we probably need to pick and choose more appropriately, depending on the patient and the problem at hand. We can no longer deal simply with starting here and advancing to there, but rather we need to think of the clinical pharmacologic features of each agent, and use it as appropriately as we can in treating a particular patient.

**DR. GUNNELLS:** To summarize, we're not debating whether patients with mild hypertension should be treated with drug therapy, but rather what is the best way to treat them when drug therapy is chosen—how to provide the greatest benefit with the lowest risk. However, in discussing a new concept of therapy that provides an alternative to the traditional diuretic approach to initial therapy, a great deal of data are required on each specific agent. We have discussed the efficacy, hemodynamic profile, side effect profile, and effect on other risk factors for coronary heart disease (such as blood lipid levels) for at least 1 nondiuretic antihypertensive agent, namely prazosin, and it appears to fit a profile of an appropriate agent for the initial treatment of hypertension.

If we are to make significant inroads into populations with hypertension, we cannot wait until they reach the point of target organ damage or of severe degrees of blood pressure, which will require more intensive and complicated therapy with greater likelihood of side effects and less than ideal control.

SUSTAINED RELEASE
Procan® SR
(PROCAINAMIDE
HYDROCHLORIDE TABLETS)
250-mg tablet / 500-mg scored tablet / 750-mg scored tablet

**INED RELEASE**

**prescribing, please see full prescribing information.**
**Summary follows.**

prolonged administration of procainamide often leads to the develop- of a positive antinuclear antibody (ANA) test with or without symp- of lupus erythematosus-like syndrome. If a positive ANA titer lops, the benefit/risk ratio related to continued procainamide therapy ld be assessed. This may necessitate consideration of alternative rrhythmic therapy.

**ITIONS AND USAGE:** Oral procainamide is indicated in the treatment nature ventricular contractions and ventricular tachycardia, atrial fibril- and paroxysmal atrial tachycardia.

**RAINDICATIONS:** It has been suggested that procainamide be contra- ed in patients with myasthenia gravis. Hypersensitivity to the drug is an e contraindication; in this connection, cross-sensitivity to procaine and drugs must be borne in mind. Procainamide should not be adminis- patients with complete atrioventricular heart block. Procainamide is ntraindicated in cases of second-degree and third-degree A-V block an electrical pacemaker is operative.

**AUTIONS: General** —During administration of the drug, evidence of rd myocardial responses should be carefully watched for in all s. In the presence of an abnormal myocardium, procainamide may at roduce untoward responses. In atrial fibrillation or flutter, the ventricu- may increase suddenly as the atrial rate is slowed. Adequate digitali- educes, but does not abolish, this danger. If myocardial damage ventricular tachysystole is particularly hazardous. Correction of atrial on, with resultant forceful contractions of the atrium, may cause a dis- ent of mural thrombi and produce an embolic episode. However, it has uggested that in a patient who is already discharging emboli, pro- ide is more likely to stop than to aggravate the process.

npts to adjust the heart rate in a patient who has developed ventricular ardia during an occlusive coronary episode should be carried out with e caution. Caution is also required in marked disturbances of atrioven- conduction such as A-V block, bundle branch block, or severe digi- oxication, where the use of procainamide may result in additional sion of conduction and ventricular asystole or fibrillation.

use patients with severe organic heart disease and ventricular tachy- may also have complete heart block, which is difficult to diagnose hese circumstances, this complication should always be kept in mind eating ventricular arrhythmias with procainamide. If the ventricular rate ficantly slowed by procainamide without attainment of regular atrioven- conduction, the drug should be stopped and the patient reevaluated systole may result under these circumstances.

tients receiving normal dosage, but who have both liver and kidney e, symptoms of overdosage (principally ventricular tachycardia and hypotension) may occur due to drug accumulation.

nces of a syndrome resembling lupus erythematosus have been d in connection with maintenance procainamide therapy. The mecha- this syndrome is uncertain. Polyarthralgia, arthritis, and pleuritic pain mmon symptoms; to a lesser extent, fever, myalgia, skin lesions, pleural , and pericarditis may occur. Rare cases of thrombocytopenia or s-positive hemolytic anemia have been reported which may be related syndrome.

**tory Tests**—Patients receiving procainamide for extended periods of in whom symptoms suggestive of a lupus-like reaction appear, should ntinuclear antibody titers measured at regular intervals. The drug be discontinued if there is a rising titer (antinuclear antibody) or clinical ms of LE appear. The LE syndrome may be reversible upon discontin- of the drug. If discontinuation of the drug does not cause remission of mptoms, steroid therapy may be effective. If the syndrome develops in nt with recurrent life-threatening arrhythmias not controllable by other ythmic agents, steroid suppressive therapy may be used concomi- ith procainamide. It is recommended that tests for lupus erythema- e carried out at regular intervals in patients receiving maintenance namide therapy.

ine blood counts are advisable during maintenance procainamide .

**RSE REACTIONS:** Agranulocytosis has occasionally followed the d use of the drug, and deaths have occurred. Therefore, routine blood are advisable during maintenance procainamide therapy. The patient should be instructed to report any soreness of the mouth, throat, or gums, unexplained fever, or any symptoms of upper respiratory tract infection. If any of these should occur, and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately.

Hypersensitivity reactions, such as angioneurotic edema and maculopapular rash have also occurred.

A syndrome resembling lupus erythematosus has been reported (see PRECAUTIONS).

Hypotension following oral administration is rare.

Large oral doses of procainamide may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

Reactions consisting of fever and chills have also been reported, including a case with fever and chills plus nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following single doses of the drug. Bitter taste, diarrhea, weakness, mental depression, giddiness, and psychosis with hallucinations have been reported. The possibility of such untoward effects should be borne in mind.

**DOSAGE AND ADMINISTRATION:** Procan SR (procainamide hydrochloride) tablets are a sustained-release product form. The duration of action of procainamide hydrochloride supplied in this sustained-release product form allows dosing at intervals of every six hours instead of the more frequent every-three-hour dosing interval required for standard preparations of oral procainamide hydrochloride. The convenient six-hour dosing schedule may encourage patient compliance.

**Ventricular tachycardia**—Treatment with standard procainamide hydrochloride is recommended until the tachycardia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows: An initial dose of 1 g of standard procainamide hydrochloride followed thereafter by a total daily dose of 50 mg/kg of body weight given at three hour intervals. The suggested oral dosage for premature ventricular contractions is 50 mg/kg of body weight daily given in divided doses at three-hour intervals.

The suggested maintenance dosage of Procan SR is 50 mg/kg of body weight daily given in divided doses at six-hour intervals.

Although the dosage for each patient must be determined on an individual basis, the following may be used as a guide for providing the total daily dosage: patients weighing less than 55 kg (120 lb), 0.5 g every six hours; patients weighing between 55 and 91 kg (120 and 200 lb), 0.75 g every six hours; and patients weighing over 91 kg (200 lb), 1 g every six hours.

**Atrial fibrillation and paroxysmal atrial tachycardia**—Treatment with standard procainamide hydrochloride is recommended until the arrhythmia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows. An initial dose of 1.25 g of standard procainamide hydrochloride may be followed in one hour by 0.75 g if there have been no electrocardiographic changes. Standard procainamide hydrochloride may then be given at a dose of 0.5 to 1 g every two hours until interruption of the arrhythmia or the tolerance limit is reached.

The suggested maintenance dosage for Procan SR is 1 g every six hours.

If procainamide therapy is continued for appreciable periods, electrocardiograms should be made occasionally to determine the need for the drug.

**HOW SUPPLIED:** Procan SR 250 mg (green, film-coated tablet, P-D 202) is available in bottles of 100 (N 0071-0202-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0202-40). Each sustained-release tablet contains 250 mg procainamide hydrochloride.

Procan SR 500 mg (yellow, scored, film-coated tablet, P-D 204) is available in bottles of 100 (N 0071-0204-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0204-40). Each sustained-release tablet contains 500 mg procainamide hydrochloride.

Procan SR 750 mg (orange, scored, film-coated tablet, P-D 205) is available in bottles of 100 (N 0071-0205-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0205-40). Each sustained-release tablet contains 750 mg procainamide hydrochloride.

**Storage—Protect from moisture. Store bottles below 86° F (30° C). Store unit-dose packages at controlled room temperature, 59°-86° F (15°-30° C).**

# In Cardiac Edema*...

Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

Dyazide® is a trademark of SK&F Co.

## When You Need to Conserve K+

**SK&F CO.**
a SmithKline company
Carolina, P.R. 00630

## Serum K+ and BUN should be checked periodically (see Warnings).

**Before prescribing, see complete prescribing information in SK&F CO. literature or *PDR*. The following is a brief summary:**

* **WARNING**

This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

**Contraindications:** Concomitant use with other potassium-sparing agents such as spironolactone or amiloride. Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

**Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired.** If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum $K^+$ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict $K^+$ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

**Precautions:** Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids, and during concurrent use with amphotericin B or corticosteroids or corticotropin [ACTH]). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Cumulative effects of the drug may develop in patients with impaired renal function. Thiazides should be used with caution in patients with impaired hepatic function. They can precipitate coma in patients with severe liver disease. Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic and hemolytic anemia have been reported with thiazides. Thiazides may cause manifestation of latent diabetes mellitus. The effects of oral anticoagulants may be decreased when used concurrently with hydrochlorothiazide; dosage adjustments may be necessary. Clinically insignificant reductions in arterial responsiveness to norepinephrine have been reported. Thiazides have also been shown to increase the paralyzing effect of nondepolarizing muscle relaxants such as tubocurarine. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. Triamterene has been found in renal stones in association with the other usual calculus components. Therefore, Dyazide should be used with caution in patients with histories of stone formation. A few occurrences of acute renal failure have been reported in patients on Dyazide when treated with indomethacin. Therefore, caution is advised in administering nonsteroidal anti-inflammatory agents with Dyazide. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication (in hypokalemia), decreasing alkali reserve with possible metabolic acidosis. Dyazide interferes with fluorescent measurement of quinidine. Hypokalemia is uncommon with Dyazide, but should it develop, corrective measures should be taken such as potassium supplementation or increased dietary intake of potassium-rich foods. Corrective measures should be instituted cautiously and serum potassium levels determined. Discontinue corrective measures and Dyazide should laboratory values reveal elevated serum potassium. Chloride deficit may occur as well as dilutional hyponatremia. Concurrent use with chlorpropamide may increase the risk of severe hyponatremia. Serum PBI levels may decrease without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. Dyazide should be withdrawn before conducting tests for parathyroid function.

Thiazides may add to or potentiate the action of other antihypertensive drugs.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

**Adverse Reactions:** Muscle cramps, weakness, dizziness, headache, dry mouth, anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions, nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances, postural hypotension (may be aggravated by alcohol, barbiturates or narcotics). Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and respiratory distress including pneumonitis and pulmonary edema, transient blurred vision, sialadenitis, and vertigo have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components. Rare incidents of acute interstitial nephritis have been reported. Impotence has been reported in a few patients on Dyazide, although a causal relationship has not been established.

**Supplied: Bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak® unit-of-use bottles of 100.**

| | | | | 120 | 185 |
| | | | | 165 | 140 |
| | | | | 250 | 55 |

## Important Information — Sequicor, Models 233D and 233E

**Indications and Contraindications**
The medical literature describes currently accepted indications for various pacing modes. The physician's clinical experience and judgment must ultimately be the guide in selecting the pacing mode best suited to the patient's needs. *The physician should be thoroughly familiar with the pacing mode chosen.*

Pacing of the ventricles (VVI) is indicated for control of heart rate in patients with A-V block or sick sinus syndrome. *Asynchronous pacing is contraindicated when inherent activity is present or is likely to be present in the chamber being paced.* There are no other known contraindications for ventricular pacing to control heart rate.

Atrial-synchronized ventricular pacing (VDD) is indicated for permanent or intermittent complete heart block with normal atrial rhythm. A-V sequential (DVI) pacing is indicated for permanent sinus bradycardia with or without heart block. Automatic dual-chamber demand pacing (DDD) is indicated when there is an A-V conduction disturbance and/or sinus mode dysfunction (sinus bradycardia with A-V block or bradytachy syndrome). These atrial pacing modes are intended for patients who would benefit from the restoration of atrial contribution to cardiac output.

*Atrial-synchronized ventricular pacing and automatic dual-chamber demand pacing modes are contraindicated for use in the presence of persistent atrial flutter or atrial fibrillation.* VVI mode is recommended for these conditions.

**Precautions**
Cordis Sequicor pacers may respond to programmers of other manufacturers. Because of the unknown nature of such response, use only the Cordis Omnicor Programmer, Model 222C (with the 222C-8 control panel card), the Cordis Programmer III, Model 225A or the Cordis Interactive Programmer, Model 256A for reprogramming.

**Warnings**
None

**Adverse Effects**
The following list includes a number of complications related to pacer therapy that have been reported in the medical literature. Noninvasive techniques for assessing and managing such complications are available to the physician. Malfunctions occur randomly and may occur at any time after implant. Complications associated with pacer therapy are listed below.

*Pacer*—battery depletion, component malfunction, electromagnetic interference, decreased sensitivity.

*Lead*—unsatisfactory electrode position, fracture, displacement, penetration/perforation of heart wall, faulty connection with pacer.

*Patient*—reaction, infection/erosion, increase in stimulation threshold.

Before implantation, refer to pacer Instructions for Use supplied with the pacer.

**Caution:** Federal (U.S.A.) law restricts this device to sale by or on the order of a physician.

# Author-Editor-Reviewer: How the Triumvirate Is Working at the AJC

An author submitting a manuscript to be considered for publication in a medical journal deserves to know how the manuscript will be evaluated by that journal. This piece describes the process as it now works at the AJC.

**Early decision by editor only or thorough evaluation by out-of-office reviewers:** Once logged and given a number, each manuscript is given to the Editor-in-Chief, who asks 4 basic questions as he reads it: (1) Is the subject of the manuscript appropriate at this time for the AJC? (2) Would the manuscript have wide or narrow appeal to the readers of the Journal? (3) Does the manuscript represent scientific quality? (4) Is the subject of the manuscript presented clearly and succinctly?

If the manuscript is considered inappropriate for the Journal, of insufficient interest to its readers, of obviously poor scientific quality, or poorly presented, it is returned immediately to the author with a statement that it is unacceptable for publication in the AJC. For manuscripts rejected solely on the basis of poor presentation, a request for reconsideration might be granted provided the manuscript is thoroughly revised. During my 9-month tenure as Editor, about 10% of submitted manuscripts have fallen into this immediate-reject category. This prompt decision allows the author to send his manuscript elsewhere or revise it without delay. Furthermore, it prevents having reviewers provide reviews simply to justify an editor's decision that already had been made. Although such an early decision by the editor may not engender friendship from the submitting author, it conserves the time and energy of all parties involved.

About 5% of manuscripts submitted are reviewed solely by the Editor; a rare one is accepted virtually without change, and his suggestions for improving the other manuscripts are returned to the authors immediately. If appropriate changes are made or if appropriate explanations are provided as to why changes were not made, the revised manuscript is accepted.

The remaining approximately 85% of manuscripts are sent out of office to be reviewed by 2 or more editorial board members or nonboard consultants. Some manuscripts, particularly potentially controversial ones, may be sent immediately to 3 rather than 2 reviewers.

**Selection of reviewers:** A major editorial decision in the manuscript-evaluation process is the selection of the most appropriate reviewers. Many submitting authors now participate in this decision (see the From-the-Editor column, July 1982, page A3), but the final selection is made by the Editor. When submitting authors request that their manuscript not be reviewed by a particular consultant or editorial board member or group of investigators, this request is honored by the Editor. If authors suggest 1 or more nonbiased, nonlocal reviewers for their manuscript, usually 1 author-suggested reviewer and 1 editor-selected reviewer are chosen. The Editor, of course, seeks the most objective reviewers, recognizing that this selection can predetermine the final decision regarding a manuscript.

**Evaluation of reviews by the Editor:** After reviews are returned to the Editor, the manuscript is reevaluated in light of the criticisms and recommendations of the reviewers. When both reviews are favorable, the Editor's decision is usually simple. When both reviews are negative, the Editor's decision also is usually easy. In these 2 situations the Editor's initial reaction to the manuscript is usually compatible with the reviewer's recommendations.

When 1 reviewer's recommendation is unequivocal rejection and that of the other is unequivocal acceptance, the manuscript is often sent out for a third review. Many times, however, the third reviewer is not necessary. One of the 2 reviewers may have made a far stronger case for his point of view than the other reviewer, or the Editor may feel comfortable with the subject of the manuscript and therefore can make the decision without the delay produced by seeking another out-of-office opinion. When 1 of 2 reviewers returns a manuscript unreviewed (he may be out of town, sick, or too busy), the Editor must then decide whether to seek another review or to make a decision based on

Continued on page A10

only 1 outside review and his own analysis. This decision generally depends on the quality of the single out-of-office review.

After the manuscript has been returned to the Editor after having been reviewed by 1 or more outside consultants or editorial board members and the decision is made to probably accept the manuscript, the Editor at this stage carefully examines the manuscript to suggest other alterations and to make sure that the authors have adhered to the style of the Journal. If certain changes are to be required in the manuscript for its acceptance, the authors are so informed at this stage. When a manuscript is tentatively accepted, the Editor often makes editorial changes on a xerographic copy of the manuscript containing his initials on the title page so that these changes can be considered for incorporation into the revision by the author. The Editor spends more time on a manuscript at this point than at any other stage, excluding manuscripts accepted without outside review.

**Return of the manuscript and reviews to the author:** When a manuscript is tentatively accepted pending either major or minor revision, the manuscript must be revised appropriately or the suggestions of the reviewers and the Editor must be rebutted appropriately. Authors must be careful not to be offended by criticisms of their manuscripts. Such criticism is provided by both outside reviewers and by the Editor in an attitude of genuine helpfulness. The author should evaluate critical comments carefully before discounting them as inappropriate. The revised manuscript must be retyped and resubmitted. The author also is asked to return the original version of the manuscript containing the Editor's handwritten suggestions.

**Evaluation of the revised manuscript:** The Editor evaluates the revised manuscript in light of the comments of the reviewers and the changes or rebuttals of the authors. If the changes made by the authors are considered appropriate, the manuscript at this stage is accepted without delay. Occasionally, however, the Editor considers the changes by the author inadequate or inappropriate and returns the manuscript for further changes. At times, the revised manuscript is returned to an earlier reviewer for reexamination. When this reexamination by an earlier reviewer is done, the authors usually are so advised when their manuscript was initially returned to them.

**Manuscript to the publisher:** After a final review by the Editor, the manuscript is sent to the publisher for copy editing and printing. Both the Editor and the Publisher have made strenuous efforts to diminish the lag time from acceptance to publication in the AJC. This time period is now *4 months*, and it is my intent to keep this short interval in the future. This means that manuscripts accepted in March 1983 will be scheduled for publication in July 1983.

William C. Roberts, MD
Editor-in-Chief

# yes... because it's Sanka®

BRAND
DECAFFEINATED COFFEE

Antihypertensive therapy often involves diet modification–restricting favorite foods and beverages. But there's one enjoyable beverage hypertensive patients can continue to enjoy: coffee.

Sanka® is 100% real coffee, but it's 97% caffeine-free. That's why it will not exacerbate underlying hypertension in patients who are bothered by too much caffeine.

And because Sanka® tastes good, it aids patient compliance. What's more, it's available in instant, freeze-dried and ground forms. It can even be found at restaurants in convenient single-service packages.

Nonstimulating Sanka® is ideally suited to many special diets. And physicians recommend it more than all other brands of decaffeinated coffee combined.

for many post-MI patients...

# Cardio-protective.

Cardioprotective is a word you won't find in standard medical dictionaries.

But you will find it appearing in the medical literature. And you will be hearing it in medical discussions. Until dictionaries recognize the term, MSD invites you to use this as a working definition of *cardioprotective:*

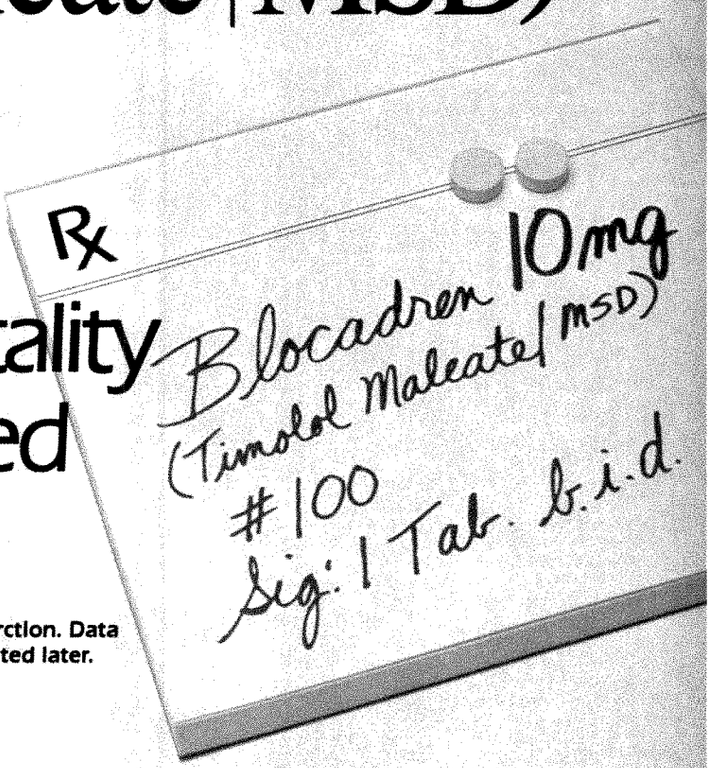
**"reduction of the risk of reinfarction and cardiac mortality for many stabilized post-MI patients."**

We at MSD feel it is appropriate to bring you this definition of cardioprotective since it was MSD that brought you the impressive clinical data[1] that documented the cardioprotective benefits of BLOCADREN® (Timolol Maleate, MSD) for many stabilized patients who have survived the acute phase of a myocardial infarction.

[1]The Norwegian Multicenter Study Group: Timolol-induced reduction in mortality and reinfarction in patients surviving acute myocardial infarction, N. Engl. J. Med. 304(14):801-807, April 2, 1981.

BLOCADREN is contraindicated in patients with bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see below); cardiogenic shock; and hypersensitivity to this product.

Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated.



In patients without a history of cardiac failure, continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure.

**Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal**—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy, exacerbation of angina and, in some cases, myocardial infarction have occurred after **abrupt** discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart

Copyright © 1982 by Merck & Co., Inc.

# Blocadren®
# (Timolol Maleate | MSD)

## reduces the risk of reinfarction and cardiac mortality for many stabilized post-MI patients

**Treatment should be initiated within 1 to 4 weeks after infarction. Data are not available as to whether benefit would ensue if initiated later.**

disease, the dosage should be gradually reduced over a period of one to two weeks, and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

MSD
MERCK SHARP & DOHME

For a Brief Summary of Prescribing Information, please see next page of this advertisement.

# BLOCADREN®
## (TIMOLOL MALEATE | MSD)

**CONTRAINDICATIONS:**

Bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see WARNINGS); cardiogenic shock; hypersensitivity to this product.

**WARNINGS:**

*Cardiac Failure*: Sympathetic stimulation may be essential for support of the circulation in individuals with diminished myocardial contractility, and its inhibition by beta-adrenergic receptor blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated, usually with digitalis and diuretics. Both digitalis and timolol maleate slow AV conduction. If cardiac failure persists, therapy with BLOCADREN should be withdrawn.

*In Patients without a History of Cardiac Failure*: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of cardiac failure, patients receiving BLOCADREN should be digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues despite adequate digitalization and diuretic therapy, BLOCADREN should be withdrawn.

*Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal*—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

*Major Surgery*: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. Beta-adrenergic receptor blockade impairs the ability of the heart to respond to beta-adrenergically mediated reflex stimuli. This may augment the risk of general anesthesia in surgical procedures. Some patients receiving beta-adrenergic receptor blocking agents have been subject to protracted severe hypotension during anesthesia. Difficulty in restarting and maintaining the heartbeat has also been reported. For these reasons, in patients undergoing elective surgery, some authorities recommend gradual withdrawal of beta-adrenergic receptor blocking agents.

If necessary during surgery, the effects of beta-adrenergic blocking agents may be reversed by sufficient doses of such agonists as isoproterenol, dopamine, dobutamine, or levarterenol.

*Diabetes Mellitus*: BLOCADREN should be administered with caution in patients subject to spontaneous hypoglycemia or to diabetic patients (especially those with labile diabetes) who are receiving insulin or oral hypoglycemic agents. Beta-adrenergic receptor blocking agents may mask the signs and symptoms of acute hypoglycemia.

*Thyrotoxicosis*: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

**PRECAUTIONS:**

*General: Impaired Hepatic or Renal Function*: Since BLOCADREN is partially metabolized in the liver and excreted mainly by the kidneys, dosage reductions may be necessary when hepatic and/or renal insufficiency is present.

*Dosing in the Presence of Marked Renal Failure*: Marked hypotensive responses have been seen in patients with marked renal impairment undergoing dialysis after 20-mg doses. Dosing in such patients should therefore be especially cautious.

*Drug Interactions*: Close observation of the patient is recommended when BLOCADREN is administered to patients receiving catecholamine-depleting drugs such as reserpine, because of possible additive effects and the production of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

*Carcinogenesis, Mutagenesis, Impairment of Fertility*: In a two-year study of timolol maleate in rats, there was a statistically significant ($p \leq 0.05$) increase in the incidence of adrenal pheochromocytomas in male rats administered 300 times the maximum recommended human dose (1 mg/kg/day). Similar differences were not observed in rats administered doses equivalent to 25 or 100 times the maximum recommended human dose. In a lifetime study in mice, there were statistically significant ($p \leq 0.05$) increases in the incidence of benign and malignant pulmonary tumors and benign uterine polyps in female mice at 500 mg/kg/day, but not at 5 or 50 mg/kg/day. There was also a significant increase in mammary adenocarcinomas at the 500-mg/kg/day dose. This was associated with elevations in serum prolactin which occurred in female mice administered timolol at 500 mg/kg, but not at doses of 5 or 50 mg/kg/day. An increased incidence of mammary adenocarcinomas in rodents has been associated with administration of several other therapeutic agents which elevate serum prolactin, but no correlation between serum prolactin levels and mammary tumors has been established in man. Furthermore, in adult human female subjects who received oral dosages of up to 60 mg of timolol maleate, the maximum recommended human oral dosage, there were no clinically meaningful changes in serum prolactin.

There was a statistically significant increase ($p \leq 0.05$) in the overall incidence of neoplasms in female mice at the 500-mg/kg/day dosage level.

Timolol maleate was devoid of mutagenic potential when evaluated *in vivo* (mouse) in the micronucleus test and cytogenetic assay (doses up to 800 mg/kg) and *in vitro* in a neoplastic cell transformation assay (up to 100 μg/ml). In Ames tests the highest concentrations of timolol employed, 5000 or 10,000 μg/plate, were associated with statistically significant elevations ($p \leq 0.05$) of revertants observed with tester strain TA100 (in seven replicate assays) but not in the remaining three strains. In the assays with tester strain TA100, no consistent dose response relationship was observed nor did the ratio of test to control revertants reach 2. A ratio of 2 is usually considered the criterion for a positive Ames test.

Studies in rats showed no adverse effect on male or female fertility at doses up to 150 times the maximum recommended human dose.

*Pregnancy—Category C*: Should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

*Nursing Mothers*: Because of the potential for serious adverse reactions from timolol in nursing infants, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

*Pediatric Use*: Safety and effectiveness in children have not been established.

**ADVERSE REACTIONS:**

BLOCADREN is usually well tolerated in properly selected patients. Most adverse effects have been mild and transient.

In a multicenter (12-week) clinical trial comparing timolol maleate and placebo, the following adverse reactions were reported spontaneously and considered to be causally related to timolol maleate:

| | Timolol Maleate (n=176) % | Placebo (n=168) % |
|---|---|---|
| BODY AS A WHOLE | | |
| fatigue/tiredness | 3.4 | 0.6 |
| headache | 1.7 | 1.8 |
| chest pain | 0.6 | 0 |
| asthenia | 0.6 | 0 |
| CARDIOVASCULAR | | |
| bradycardia | 9.1 | 0 |
| arrhythmia | 1.1 | 0.6 |
| syncope | 0.6 | 0 |
| edema | 0.6 | 1.2 |
| DIGESTIVE | | |
| dyspepsia | 0.6 | 0.6 |
| nausea | 0.6 | 0 |
| INTEGUMENTARY | | |
| pruritus | 1.1 | 0 |
| NERVOUS SYSTEM | | |
| dizziness | 2.3 | 1.2 |
| vertigo | 0.6 | 0 |
| paresthesia | 0.6 | 0 |
| PSYCHIATRIC | | |
| decreased libido | 0.6 | 0 |
| RESPIRATORY | | |
| dyspnea | 1.7 | 0.6 |
| bronchial spasm | 0.6 | 0 |
| rales | 0.6 | 0 |
| SPECIAL SENSES | | |
| eye irritation | 1.1 | 0.6 |
| tinnitus | 0.6 | 0 |

These data are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, e.g., a group excluding patients with bronchospastic disease, congestive heart failure, or other contraindications to beta-blocker therapy. These adverse reactions can also occur in patients with coronary artery disease.

In a different population, the coronary artery disease population, studied in the Norwegian multicenter trial (see CLINICAL PHARMACOLOGY), the frequency of the principal adverse reactions and the frequency with which these resulted in discontinuation of therapy in the timolol and placebo groups were:

| | Adverse Reaction† | | Withdrawal‡ | |
|---|---|---|---|---|
| | Timolol (n=945) % | Placebo (n=939) % | Timolol (n=945) % | Placebo (n=939) % |
| Asthenia or Fatigue | 5 | 1 | <1 | <1 |
| Heart Rate <40 beats/minute | 5 | <1 | 4 | <1 |
| Cardiac Failure—Nonfatal | 8 | 7 | 3 | 2 |
| Hypotension | 3 | 2 | 3 | 1 |
| Pulmonary Edema—Nonfatal | 2 | <1 | <1 | <1 |
| Claudication | 3 | 3 | 1 | <1 |
| AV Block 2nd or 3rd degree | <1 | <1 | <1 | <1 |
| Sinoatrial Block | <1 | <1 | <1 | <1 |
| Cold Hands and Feet | 8 | <1 | <1 | 0 |
| Nausea or Digestive Disorders | 8 | 6 | 1 | <1 |
| Dizziness | 6 | 4 | 1 | 0 |
| Bronchial Obstruction | 2 | <1 | 1 | <1 |

†When an adverse reaction recurred in a patient, it is listed only once.

‡Only principal reason for withdrawal in each patient is listed.

These adverse reactions can also occur in patients treated for hypertension.

The following additional adverse effects have been reported in clinical experience with the drug: *Body as a Whole*: extremity pain, decreased exercise tolerance, weight loss; *Cardiovascular*: cardiac failure, cerebral vascular accident, worsening of angina pectoris, worsening of arterial insufficiency, Raynaud's phenomenon, palpitations, vasodilatation; *Digestive*: gastrointestinal pain, hepatomegaly, vomiting, diarrhea, dyspepsia; *Endocrine*: hyperglycemia, hypoglycemia; *Integumentary*: rash, skin irritation, increased pigmentation, sweating; *Musculoskeletal*: arthralgia; *Nervous System*: local weakness; *Psychiatric*: depression, nightmares, somnolence, insomnia, nervousness, diminished concentration; *Respiratory*: cough; *Special Senses*: visual disturbances, dry eyes; *Urogenital*: impotence, urination difficulties.

*Potential Adverse Effects*: In addition, a variety of adverse effects not observed in clinical trials with BLOCADREN, but reported with other beta-adrenergic blocking agents, should be considered potential adverse effects of BLOCADREN: *Nervous System*: reversible mental depression progressing to catatonia; hallucinations, an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics; *Cardiovascular*: intensification of AV block (see CONTRAINDICATIONS); *Gastrointestinal*: mesenteric arterial thrombosis, ischemic colitis; *Hematologic*: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura; *Allergic*: erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress; *Miscellaneous*: reversible alopecia, Peyronie's disease. Multisystem syndrome reported with practolol.

*Clinical Laboratory Test Findings*: Slight increases in blood urea nitrogen, serum potassium, and serum uric acid, and slight decreases in hemoglobin and hematocrit occurred, but were not progressive or associated with clinical manifestations.

## CONTENTS IN BRIEF

MARCH 1, 1983 • VOLUME 51 • NUMBER 5

A note from the Editor-in-Chief, William C. Roberts, MD, appears on pages A9 and A10 of this issue.

Coming March 15th: our second March issue.

### CORONARY HEART DISEASE

661 **Influence of Partial Sympathetic Denervation on the Results of Myocardial Revascularization in Variant Angina.** Amadeo Betriu, Jose Luis Pomar, Martial G. Bourassa, and Claude M. Grondin

668 **Digital Angiography in Assessment of Ventricular Function and Wall Motion During Pacing in Patients With Coronary Artery Disease.** Jonathan Tobis, Orhan Nalcioglu, Warren D. Johnston, Anthony Seibert, Lloyd T. Iseri, Werner Roeck, and Walter L. Henry

676 **Angiographic Changes Produced by Percutaneous Transluminal Coronary Angioplasty.** David R. Holmes, Jr., Ronald E. Vlietstra, Michael B. Mock, Guy S. Reeder, Hugh C. Smith, Alfred A. Bove, John F. Bresnahan, Jeffrey M. Piehler, Hartzell V. Schaff, and Thomas A. Orszulak

684 **Ergonovine Provocation to Assess Efficacy of Long-Term Therapy With Calcium Antagonists in Prinzmetal's Variant Angina.** Michael D. Winniford, Stacey M. Johnson, David R. Mauritson, and L. David Hillis

689 **Frequency in Nonangioplasty Patients of Morphologic Findings Reported in Coronary Arteries Treated with Transluminal Angioplasty.** Jeffrey M. Isner and Roberta V. Fortin

694 **Intravenous Nitroglycerin for the Treatment of Angina at Rest Unresponsive to Standard Nitrate Therapy.** Kerry Kaplan, Richard Davison, Michele Parker, Jean Przybylek, J. Russell Teagarden, and Michael Lesch

699 **Effects of Verapamil on Coronary Hemodynamic Function and Vasomobility Relative to Its Mechanism of Antianginal Action.** Christopher Y. C. Chew, B. Gregory Brown, Bramah N. Singh, Maylene M. Wong, Cindy Pierce, and Robert Petersen

706 **Nifedipine in Chronic Stable Angina: A Double-Blind Placebo-Controlled Crossover Trial.** Lon G. Sherman and Chang-Seng Liang

712 **Effect of Intravenous and Intracoronary Nifedipine on Coronary Blood Flow and Myocardial Oxygen Consumption.** Peter Schanzenbächer, Gerhart Liebau, Peter Deeg, and Kurt Kochsiek

718 **Electrocardiographic Criteria for the Diagnosis of Combined Inferior Myocardial Infarction and Left Anterior Hemiblock.** Robert A. Warner, Norma E. Hill, Sakti Mookherjee, and Harold Smulyan

723 **Improved Electrocardiographic Criteria for the Diagnosis of Left Anterior Hemiblock.** Robert A. Warner, Norma E. Hill, Sakti Mookherjee, and Harold Smulyan

727 **Effects of Provocation on Transcardiac Thromboxane in Patients With Coronary Artery Disease.** Paul D. Hirsh, Brian G. Firth, William B. Campbell, Gregory J. Dehmer, James T. Willerson, and L. David Hillis

734 **Precordial S-T Segment Depression in Inferior Myocardial Infarction. Evaluation by Quantitative Thallium-201 Scintigraphy and Technetium-99m Ventriculography.** Lawrence Ong, Benilda Valdejlon, James Coromilas, Robert Brody, Peter Reiser, and John Morrison

741 **Radionuclide-Determined Changes in Pulmonary Blood Volume and Thallium Lung Uptake in Patients With Coronary Artery Disease.** Richard A. Wilson, Robert D. Okada, Charles A. Boucher, H. William Strauss, and Gerald M. Pohost

749 **Sinus Node Coronary Arteries Studied With Angiography.** Michael K. Kyriakidis, Costas B. Kourouklis, John T. Papaioannou, Stamatis G. Christakos, George P. Spanos, and Dimitris G. Avgoustakis

751 **Beneficial Effects of Ibuprofen in Pacing-Induced Myocardial Ischemia.** Paul Walinsky, J. Bryan Smith, Allan M. Lefer, and Leslie Wiener

755 **Improved Exercise Ventilatory Responses After Training in Coronary Heart Disease During Long-Term Beta-Adrenergic Blockade.** Neil F. Gordon, Pieter E. Krüger, and Jones F. Cilliers

### ARRHYTHMIAS AND CONDUCTION DISTURBANCES

759 **Disopyramide: Evaluation of Electrophysiologic Effects and Clinical Efficacy in Patients With Sustained Ventricular Tachycardia or Ventricular Fibrillation.** Bruce B. Lerman, Harvey L. Waxman, Alfred E. Buxton, and Mark E. Josephson

765 **Effects of Oral Digoxin on Ventricular Ectopy and Its Relation to Left Ventricular Function.** Alan H. Gradman, Moira Cunningham, Mary A. Harbison, Harvey J. Berger, and Barry L. Zaret

770 **Cardiac Electrophysiologic Effects of Flecainide Acetate for Paroxysmal Reentrant Junctional Tachycardias.** Kevin J. Hellestrand, Anthony W. Nathan, Rodney S. Bexton, Roworth A. J. Spurrell, and A. John Camm

777 **Cardiac Effects of Treatment With Quinidine and Digoxin, Alone and in Combination.** Karin Schenck-Gustafsson, Tomas Jogestrand, Lars-Åke Brodin, Rolf Nordlander, and Rune Dahlqvist

### SYSTEMIC HYPERTENSION

783 **Immediate Hemodynamic Effect of a New Calcium-Channel Blocking Agent (Nitrendipine) in Essential Hypertension.** Hector O. Ventura, Franz H. Messerli, Willie Oigman, Francis G. Dunn, Efrain Reisin, and Edward D. Frohlich

787 **Predictability of Blood Pressure Response to Isometric Stress.** Robert H. Chaney and Stephan Arndt

### CONGESTIVE HEART FAILURE

791 **Clonidine in Congestive Heart Failure: A Vasodilator With Negative Inotropic Effects.** James B. Hermiller, Raymond D. Magorien, Mark E. Leithe, Donald V. Unverferth, and Carl V. Leier

### CARDIOVASCULAR PHARMACOLOGY

796 **In Vivo Quantitation of Platelet Deposition on Human Peripheral Arterial Bypass Grafts Using Indium-111–Labeled Platelets. Effect of Dipyridamole and Aspirin.** Charles W. Pumphrey, James H. Chesebro, Mrinal K. Dewanjee, Heinz W. Wahner, Larry H. Hollier, Peter C. Pairolero, and Valentin Fuster

Continued on page A16

# CONTENTS IN BRIEF

802 **Cardiovascular Effects of a Newly Synthesized Cardiotonic Agent (TA-064) on Normal and Diseased Hearts.** Masaya Kino, Yuzo Hirota, Shoji Yamamoto, Kenichi Sawada, Masatomo Moriguchi, Masahiro Kotaka, Shinichiro Kubo, and Keishiro Kawamura

**CARDIOMYOPATHY**

811 **Vulnerability of Patients With Obstructive Hypertrophic Cardiomyopathy to Ventricular Arrhythmia Induction in the Operating Room. Analysis of 17 Patients.** Kelley P. Anderson, Edward B. Stinson, Geraldine C. Derby, Philip E. Oyer, and Jay W. Mason

817 **Myocardial Texture Characterization by Two-Dimensional Echocardiography.** Anil K. Bhandari and Navin C. Nanda

826 **Sensitivity of Technetium-99m–Pyrophosphate Scintigraphy in Diagnosing Cardiac Amyloidosis.** Rodney H. Falk, Victor W. Lee, Alan Rubinow, William B. Hood, Jr., and Alan S. Cohen

831 **Survival in Men With Severe Chronic Left Ventricular Failure Due to Either Coronary Heart Disease or Idiopathic Dilated Cardiomyopathy.** Joseph A. Franciosa, Mary Wilen, Susan Ziesche, and Jay N. Cohn

**METHODS**

837 **Evaluation of Left Ventricular Performance Using Digital Subtraction Angiography.** Marvin W. Kronenberg, Ronald R. Price, Clyde W. Smith, Rose Marie Robertson, James M. Perry, David R. Pickens, Michael J. Domanski, C. Leon Partain, and Gottlieb C. Friesinger

843 **Evaluation of Intracardiac Thrombus With Computed Tomography.** Haruo Tomoda, Mitsumoto Hoshiai, Hideo Furuya, Sachio Kuribayashi, Makoto Ootaki, Seiya Matsuyama, Shirosaku Koide, Shiaki Kawada, and Akira Shotsu

853 **Absolute Left Ventricular Volume From Gated Blood Pool Imaging With Use of Esophageal Transmission Measurement.** Alan H. Maurer, Jeffry A. Siegel, Barry S. Denenberg, Blase A. Carabello, Arnold K. Gash, James F. Spann, and Leon S. Malmud

859 **Effect of Exercise Protocol on the Left Ventricular Response to Exercise.** Carl Foster, Duncan S. Dymond, James D. Anholm, Michael L. Pollock, and Donald H. Schmidt, *With the technical assistance of* John G. Carpenter

**EXPERIMENTAL STUDIES**

865 **Influence of Aortic Stenosis on the Hemodynamic Importance of Coronary Artery Narrowing in Dogs Without Left Ventricular Hypertrophy.** Robert L. Feldman, Wilmer W. Nichols, James R. Edgerton, C. Richard Conti, and Carl J. Pepine

872 **Topographic Changes in the Left Ventricle After Experimentally Induced Myocardial Infarction in the Rat.** Charles S. Roberts, Derek Maclean, Eugene Braunwald, Peter R. Maroko, and Robert A. Kloner

877 **Scar Thinning Due to Ibuprofen Administration After Experimental Myocardial Infarction.** Edward J. Brown, Jr., Robert A. Kloner, Frederick J. Schoen, Haim Hammerman, Sharon Hale, and Eugene Braunwald

884 **Effects of Flurbiprofen in Altering the Size of Myocardial Infarcts in Dogs: Reduction or Delay?** David E. Chambers, Derek M. Yellon, David J. Hearse, and James M. Downey

891 **Effects of Reduced Coronary Flow on Thallium-201 Accumulation and Release in an In Vitro Rat Heart Preparation.** Samuel Z. Goldhaber, John B. Newell, Joanne S. Ingwall, Gerald M. Pohost, Nathaniel M. Alpert, and Eric T. Fossel

**BRIEF REPORTS**

897 **Supraventricular Nonreentrant Tachycardia Due to Simultaneous Conduction Through Dual Atrioventricular Nodal Pathways.** Frederick J. Sutton and Yu-Chen Lee

900 **Survival After Sudden Obstruction of the Left Main Coronary Artery.** Moshe Y. Flugelman, Meir Shalit, Arie Shefer, Yonathan Hasin, and Mervyn S. Gotsman

901 **Hyperkalemia and Cardiac Arrest from Fluoride Exposure During Hemodialysis.** Michael McIvor, Romulo F. Baltazar, Juan Beltran, Morton M. Mower, Robert Wenk, Jack Lustgarten, and Joseph Salomon

902 **Coronary Arterial Rupture During Coronary Angioplasty.** Jeffrey E. Saffitz, Thomas E. Rose, John B. Oaks, and William C. Roberts

904 **Q-T Prolongation and Torsades de Pointes Ventricular Tachycardia Produced by the Tetracyclic Antidepressant Agent Maprotiline.** Howard C. Herrmann, Lee M. Kaplan, and Barbara E. Bierer

906 **Angiographic Evidence of Hemorrhagic Myocardial Infarction After Intracoronary Thrombolysis With Streptokinase.** William C. Little and Edwin W. Rogers

908 **Real-Time 2-Dimensional Echocardiographic Visualization of Thrombus on a Björk-Shiley Mitral Valve Prosthesis. Emergency Cesarean Section and Mitral Valve Replacement in Late Pregnancy.** Basil S. Lewis, Nearchos E. Agathangelou, Luis A. Dos Santos, and Manuel J. Antunes

909 **Cardiac Rhabdomyosarcoma Presenting as Hypereosinophilic Syndrome.** Martin J. Sullivan, Gregory P. Wanger, Steven A. Schonfeld, and Thomas M. Bashore

**POINT OF VIEW**

911 **How Should We Describe Hearts in Which the Aorta Is Connected to the Right Ventricle and the Pulmonary Trunk to the Left Ventricle? A Matter for Reason and Logic.** Anton E. Becker and Robert H. Anderson

**EDITORIALS**

913 **Q-Wave Infarction Versus S-T Infarction. Nonspecificity of Electrocardiographic Criteria for Differentiating Transmural and Nontransmural Lesions.** David H. Spodick

916 **Randomize the First Patient: Scientific, Ethical, and Behavioral Bases.** David H. Spodick

# Cardiac Bioprostheses

## Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982

**The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.**

**To order your copy of this important new book use the order form below.**

**edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD**
**ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00**

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

## Who are the editors?

**Lawrence H. Cohn, MD,** is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982*.

**Vincenzo Gallucci, MD,** is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

## Table of Contents

**Section 1 CLINICAL ANALYSIS 1.** The Evolution of the Biological Valve **2.** Heart Valve Replacement with the Hancock Bioprosthesis: A 5-11 Year Follow-up **3.** A 14-Year Experience with Valvular Bioprostheses: Valve Survival and Patient Survival **4.** A Thousand Porcine Bioprostheses Revisited. Do They Conform with the Expected Pattern? **5.** Clinical Durability of the Pericardial Xenograft Valve: 11 Years' Experience **6.** Long-term Results of 159 Porcine Valve Implantations **7.** Mid- and Long-term Evaluation of Porcine Bioprosthetic Valves: A 6-Year Experience

**Section 2 HEMODYNAMICS 8.** Hemodynamic Evaluation of the Hancock Bioprosthesis in the Mitral Position: A 1-7 Year Follow-up **9.** Hemodynamic Evaluation of the Carpentier-Edwards Standard and Improved Anulus Bioprostheses **10.** Hemodynamic Evaluation in Valvular Patients Carrying Low Profile Bioprostheses **11.** Noninvasive Scintigraphic Assessment of Left and Right Ventricular Function in Patients with Bioprosthetic Mitral Valves at Long-term Risk **12.** Orifice View Roentgenography for Evaluation of the Orifice Area of Bioprosthetic Valves

**Section 3 THROMBOEMBOLISM 13.** Alterations in Valvular Surgery: Biological Valves **14.** Early and Late Results of Porcine Bioprostheses Versus Mechanical Prostheses in Aortic and Mitral Positions **15.** Mitral Bioprostheses in 202 Patients with Chronic Atrial Fibrillation, Giant Left Atrium, and Atrial Thrombi: Long-term Results with No Anticoagulation **16.** Thromboembolism and Anticoagulation after Isolated Mitral Valve Replacement with Porcine Heterografts **17.** Preoperative Determinants of Return to Sinus Rhythm after Valve Replacement **18.** Porcine Bioprostheses Versus Mechanical Valvular Substitutes: A Retrospective Comparative Analysis

**Section 4 PEDIATRIC VALVE REPLACEMENT 19.** Valved Conduits: A Panacea for Complex Congenital Heart Defects? **20.** Factors Influencing Late Results of Extracardiac Conduit Repair for Congenital Cardiac Defects **21.** Calcification of Porcine Bioprostheses in Children **22.** Valve Replacement in Children: Biological Versus Mechanical Valves **23.** Bioprosthetic Valve Replacement in Children **24.** Aortic Root Replacement **25.** Conduits Containing Antibiotic Preserved Homografts in the Treatment Of Complex Congenital Heart Defects **26.** Dura Mater Bioprosthesis in Young Patients

**Section 5 EXPERIMENTAL PATHOLOGY 27.** Experimental Evaluation of Bioprosthetic Valves Implanted in Sheep **28.** Role of Mechanical Stress in Calcification of Bioprostheses **29.** Inhibition of Mineralization of Glutaraldehyde-fixed Hancock Bioprosthetic Heart Valves **30.** Prevention of Tissue Valve Calcification by Chemical Techniques

**Section 6 EXPLANT PATHOLOGY 31.** Complications of Replacement of either the Mitral or Aortic Valve or Both by either Mechanical or Bioprosthetic Valves **32.** Pathogenesis and Stages of Bioprosthetic Infection **33.** Structure and Classification of Cuspal Tears and Perforations in Porcine Bioprosthetic Cardiac Valves Implanted in Patients **34.** Pathological Substrates of Porcine Valve Dysfunction **35.** Mode of Failure in 226 Explanted Biological and Bioprosthetic Valves

**Section 7 BIOPROSTHETIC BIOENGINEERING 36.** The Unileaflet Heart Valve Bioprosthesis **37.** Hancock II - An Improved Bioprosthesis **38.** Design and Stress Analysis of Bioprosthetic Valves In Vivo **39.** In Vitro Comparison of the Newer Heart Valve Bioprostheses in the Mitral and Aortic Positions **40.** In Vitro and In Vivo Assessment of the Flow Characteristics of the Xenomedica Porcine Xenograft **41.** The Structure/Function Relationship of Fresh and Glutaralhyde-Fixed Aortic Valve Leaflets

**Section 8 LONG-TERM FOLLOW-UP 42.** Bioprostheses in the Tricuspid Position Versus Valvuloplasty and Mechanical Valves **43.** The Role of Porcine Heterografts in a 14-Year Experience with Tricuspid Valve Replacement **44.** Patient Prosthesis Mismatch in the Tricuspid Position: The Rationale for an Oval Pericardial Tricuspid Valve **45.** The Porcine Bioprosthesis: Failure Rates in the Elderly **46.** Causes of Valve Failure and Indications for Reoperation After Bioprosthetic Cardiac Valve Replacement **47.** Clinical Analysis of the Hancock Porcine Bioprosthesis **48.** Valve Replacement in the Small Anulus Aorta: Performance of the Hancock Modified-Orifice Bioprosthesis **49.** Decreasing Incidence of Porcine Bioprosthetic Degeneration

**Section 9 SUMMING UP 50.** A Cardiologist's Point of View and a Cardiac Surgeon's Point of View

# MYOCARDIAL REVASCULARIZATION

## MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

**The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.**

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

EDITED BY

**DEAN T. MASON, M.D.**
Professor of Medicine and Physiology
Chief, Cardiovascular Medicine
University of California at Davis
School of Medicine and University Medical Center
Davis and Sacramento, California
Editor-in-Chief, AMERICAN HEART JOURNAL

**JOHN J. COLLINS, JR., M.D.**
Professor of Surgery
Chief, Division of Thoracic and Cardiac Surgery
Harvard Medical School
Brigham and Women's Hospital
Boston, Massachusetts

## Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

## Sample Table of Contents:

**Section 1 - Stable Angina Pectoris and Asymptomatic Coronary Disease**

**Section 2 - Variant Angina Pectoris**

**Section 3 - Unstable Angina Pectoris**

**Section 4 - Acute Myocardial Infarction**

**Section 5 - Myocardial Preservation**

**Section 6 - Pharmacologic and Related Approaches to Coronary Dilatation**

**Section 7 - Percutaneous Transluminal Coronary Angioplasty**

**Section 8 - Intracoronary Thrombolysis in Evolving Myocardial Infarction**

**Section 9 - Long-Term Achievements of Myocardial Revascularization by Medical and Surgical Therapy**

**Yorke Medical Books** AJCC3
Box C-757, Brooklyn, NY 11205

Wyeth

# Another dimension in the management of hypertension

No electrolyte or metabolic risk factors
No long-term cardiovascular risk factors
No immunologic disturbances
No liver damage
No contraindications except hypersensitivity

## Side effects are usually mild and transient

Patients may experience drowsiness and dry mouth early during WYTENSIN® (guanabenz acetate) therapy, but these subjective complaints are mostly mild and transient, especially when the initial dosage is *4 mg b.i.d.*, with the second dose at bedtime.

4mg b.i.d.

## New WyTensin® (guanabenz acetate)

**Brief Summary**

**Actions:**
**Wytensin®** (guanabenz acetate) is an orally active central alpha-2 adrenergic agonist. Its antihypertensive action appears to be mediated via stimulation of central alpha adrenergic receptors, resulting in a decrease of sympathetic outflow from the brain at the bulbar level to the peripheral circulatory system. The acute antihypertensive effect of **Wytensin** occurs without major changes in peripheral resistance, but its chronic effect appears to be a decrease in peripheral resistance.

**Indications and Usage:**
Treatment of hypertension, alone or in combination with a thiazide diuretic.

**Contraindication:**
Known sensitivity to the drug.

**Precautions:**
1. Sedation: Causes sedation or drowsiness in a large fraction of patients. When used with centrally active depressants, e.g., phenothiazines, barbiturates and benzodiazepines, consider potential for additive sedative effects.

2. Patients with vascular insufficiency: Like other antihypertensives use with caution in severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease, or severe hepatic or renal failure.

3. Rebound: Sudden cessation of therapy with central alpha agonists like **Wytensin** may rarely result in "overshoot" hypertension and more commonly produces increase in serum catecholamines and subjective symptomatology.

INFORMATION FOR PATIENTS:
Advise patients on **Wytensin** to exercise caution when operating dangerous machinery or motor vehicles until it is determined they do not become drowsy or dizzy. Warn patients that tolerance for alcohol and other CNS depressants may be diminished. Advise patients not to discontinue therapy abruptly.

LAB TESTS:
In clinical trials, no clinically significant lab test abnormalities were identified during acute or chronic therapy. Tests included CBC, urinalysis, electrolytes, SGOT, bilirubin, alkaline phosphatase, uric acid, BUN, creatinine, glucose, calcium, phosphorus, total protein, and Coombs' test. During long-term use there was small decrease in serum cholesterol and total triglycerides without change in high-density lipoprotein fraction. In rare instances occasional nonprogressive increase in liver enzymes was observed, but no clinical evidence of hepatic disease.

DRUG INTERACTIONS:
**Wytensin®** was not demonstrated to cause drug interactions when given with other drugs, e.g., digitalis, diuretics, analgesics, anxiolytics, and antiinflammatory or antiinfective agents, in clinical trials. However, potential for increased sedation when given concomitantly with CNS depressants should be noted.

DRUG/LAB TEST INTERACTIONS:
No lab test abnormalities were identified with **Wytensin** use.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY:
No evidence of carcinogenic potential emerged in rats during a two-year oral study with **Wytensin** at up to 9.5 mg/kg/day, i.e., about 10 times maximum recommended human dose. In the Salmonella microsome mutagenicity (Ames) test system, **Wytensin** at 200-500 mcg per plate or at 30-50 mcg/ml in suspension gave dose-related increases in number of mutants in one (TA 1537) of five *Salmonella typhimurium* strains with or without inclusion of rat liver microsomes. No mutagenic activity was seen at doses up to those which inhibit growth in the eukaryotic microorganism, *Schizosaccharomyces pombe*, or in Chinese hamster ovary cells at doses up to those lethal to the cells in culture. In another eukaryotic system, *Saccharomyces cerevisiae*, **Wytensin** produced no activity in an assay measuring induction of repairable DNA damage. Reproductive studies showed a decreased pregnancy rate in rats given high oral doses (9.6 mg/kg), suggesting impairment of fertility. Fertility of treated males (9.6 mg/kg) may also have been affected, as suggested by decreased pregnancy rate of mates, even though females received drug only during last third of pregnancy.

PREGNANCY:
Pregnancy Category C:
WYTENSIN® MAY HAVE ADVERSE EFFECTS ON FETUS WHEN ADMINISTERED TO PREGNANT WOMEN. A teratology study in mice indicated possible increase in skeletal abnormalities when **Wytensin** is given orally at doses 3 to 6 times maximum recommended human dose of 1.0 mg/kg. These abnormalities, principally costal and vertebral, were not noted in similar studies in rats and rabbits. However, increased fetal loss has been observed after oral **Wytensin** given to pregnant rats (14 mg/kg) and rabbits (20 mg/kg). Reproductive studies in rats have shown slightly decreased live-birth-indices, decreased fetal survival rate, and decreased pup body weight at oral doses of 6.4 and 9.6 mg/kg. There are no adequate, well-controlled studies in pregnant women. **Wytensin®** should be used during pregnancy only if potential benefit justifies potential risk to fetus.

NURSING MOTHERS:
Because no information is available on **Wytensin** excretion in human milk, it should not be given to nursing mothers.

PEDIATRIC USE:
Safety and effectiveness in children less than 12 years of age have not been demonstrated; use in this age group cannot be recommended.

**Adverse Reactions:**
Incidence of adverse effects was ascertained from controlled clinical studies in U.S. and is based on data from 859 patients on **Wytensin** for up to 3 years. There is some evidence that side effects are dose-related.

Following table shows incidence of adverse effects in at least 5% of patients in study comparing **Wytensin** to placebo, at starting dose of 8 mg b.i.d.

| Adverse Effect | Placebo (%) n = 102 | Wytensin (%) n = 109 |
|---|---|---|
| Dry mouth | 7 | 28 |
| Drowsiness or sedation | 12 | 39 |
| Dizziness | 7 | 17 |
| Weakness | 7 | 10 |
| Headache | 6 | 5 |

In other controlled clinical trials at starting dose of 16 mg/day in 476 patients, incidence of dry mouth was slightly higher (38%) and dizziness was slightly lower (12%), but incidence of most frequent adverse effects was similar to placebo-controlled trial. Although these side effects were not serious, they led to discontinuation of treatment about 15% of the time. In more recent studies using an initial dose of 8 mg/day in 274 patients, incidence of drowsiness or sedation was lower, about 20%.

Other adverse effects reported during clinical trials but not clearly distinguishable from placebo effects and occurring with frequency of 3% or less: Cardiovascular—chest pain, edema, arrhythmias, palpitations. Gastrointestinal—nausea, epigastric pain, diarrhea, vomiting, constipation, abdominal discomfort. Central nervous system—anxiety, ataxia, depression, sleep disturbances. ENT disorders—nasal congestion. Eye disorders—blurring of vision. Musculoskeletal—aches in extremities, muscle aches. Respiratory—dyspnea. Dermatologic—rash, pruritus. Urogenital—urinary frequency, disturbances of sexual function. Other—gynecomastia, taste disorders.

**Drug Abuse and Dependence:**
No dependence or abuse has been reported.

**Overdosage:**
Accidental ingestion caused hypotension, somnolence, lethargy, irritability, miosis, and bradycardia in two children aged one and three years. Gastric lavage and pressor substances, fluids, and oral activated charcoal resulted in complete and uneventful recovery within 12 hours in both. Since experience with accidental overdosage is limited, suggested treatment is mainly supportive while drug is being eliminated and until patient is no longer symptomatic. Vital signs and fluid balance should be carefully monitored. Adequate airway should be maintained and, if indicated, assisted respiration instituted. No data are available on **Wytensin** dialyzability.

**Dosage and Administration:**
Individualize dosage. A starting dose of 4 mg b.i.d. is recommended, whether used alone or with a thiazide diuretic. Dosage may be increased in increments of 4 to 8 mg/day every one to two weeks, depending on response. Maximum dose studied has been 32 mg b.i.d., but doses this high are rarely needed.

**How Supplied:**
**Wytensin®** (guanabenz acetate) Tablets, 4 mg and 8 mg, bottles of 100.

### CORONARY HEART DISEASE

**661 Influence of Partial Sympathetic Denervation on the Results of Myocardial Revascularization in Variant Angina**

AMADEO BETRIU, JOSE LUIS POMAR, MARTIAL G. BOURASSA, and CLAUDE M. GRONDIN

Thirty-one patients with variant angina and severe coronary artery disease underwent myocardial revascularization; in 14 patients partial sympathetic denervation was performed in addition to coronary artery grafting. The average follow-up was just under 2 years. Actuarial curves showed the probability of recurrence of variant angina to be significantly lower in the 14 who had partial sympathetic denervation ($p < 0.05$ and $p < 0.001$ at 6 and 10 months, respectively).

**668 Digital Angiography in Assessment of Ventricular Function and Wall Motion During Pacing in Patients With Coronary Artery Disease**

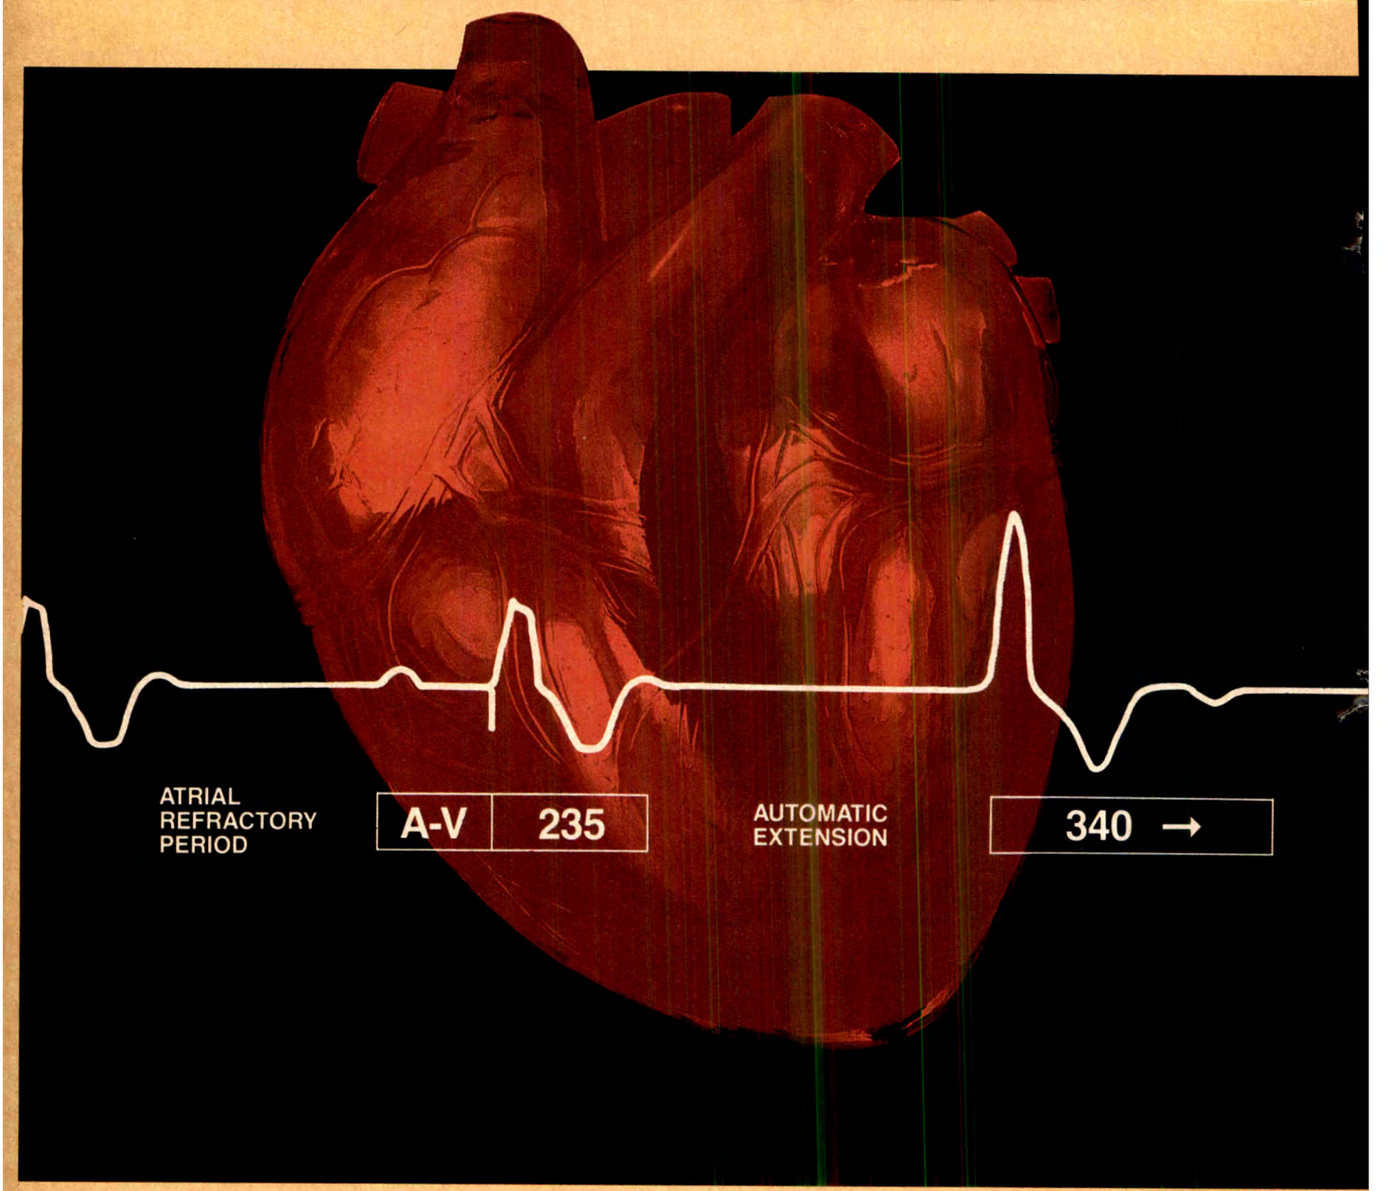
JONATHAN TOBIS, ORHAN NALCIOGLU, WARREN D. JOHNSTON, ANTHONY SEIBERT, LLOYD T. ISERI, WERNER ROECK, and WALTER L. HENRY

Using digital subtraction angiography, left ventriculograms were obtained with 10 ml of iodinated contrast material in 21 patients both at rest and during atrial pacing. In 15 patients with significant coronary artery lesions, the ejection fraction decreased during atrial pacing from a mean of 62.1 + 14.4% to 50.7 + 15.2% ($p > 0.001$). In 6 patients with chest pain but normal coronary arteries, the ejection fraction increased from a mean of 66.4 + 8.6% at rest to 71.6 + 5.7% during atrial pacing ($p < 0.01$). The digital ventriculograms demonstrated new or increased wall motion abnormalities during atrial pacing in 12 of 15 patients with coronary artery disease. Because digital subtraction angiography allows multiple left ventriculograms to be obtained during routine cardiac catheterization, intervention studies such as atrial pacing can be used to obtain a functional assessment of the severity of coronary artery lesions.

**676 Angiographic Changes Produced by Percutaneous Transluminal Coronary Angioplasty**

DAVID R. HOLMES, Jr., RONALD E. VLIETSTRA, MICHAEL B. MOCK, GUY S. REEDER, HUGH C. SMITH, ALFRED A. BOVE, JOHN F. BRESNAHAN, JEFFREY M. PIEHLER, HARTZELL V. SCHAFF, and THOMAS A. ORSZULAK

Percutaneous transluminal coronary angioplasty (PTCA) is being used with increasing frequency in the treatment of patients with symptomatic coronary artery disease. After dilatation, a range of angiographic findings may be seen which reflect, in part, the anatomic and pathologic changes produced by PTCA. The long-term effects of PTCA may depend on these anatomic and pathologic changes. Recognition and classification of these findings will become increasingly important in the evaluation of the long-term effect of coronary angioplasty and in developing new approaches for avoiding adverse effects. To facilitate communication and evaluation of the results of PTCA, a classification of the angiographic findings and potential mechanisms is presented.



**684 Ergonovine Provocation to Assess Efficacy of Long-Term Therapy With Calcium Antagonists in Prinzmetal's Variant Angina**

MICHAEL D. WINNIFORD, STACEY M. JOHNSON, DAVID R. MAURITSON, and L. DAVID HILLIS

This study was performed to compare ergonovine responsiveness with clinical and electrocardiographic evidence of disease activity in patients with Prinzmetal's angina during chronic therapy with placebo, verapamil, and nifedipine. Twenty-seven patients with variant angina received placebo and verapamil for 2 months each, after which 23 also received nifedipine for 2 months. All patients kept a diary of chest pains, all had weekly 24-

## Versatrax™ II Model 7000A Universal A-V Pacemaker

**Intended Use**

The Model 7000A universal A-V pulse generator has a wide range of application in patients requiring permanent cardiac pacing where restoration of A-V synchrony and/or sinus modulated rate variability is indicated to improve cardiac output or to protect against arrhythmias related to the sequence of cardiac impulse propagation.

With the Model 7000A programmed in the A-V universal (DDD) mode, indications may include:

- Some of the sick sinus syndrome conditions such as intermittent sinus bradycardia, sinus arrest or SA block.
- Intermittent or complete atrioventricular block with normal sinus activity.
- Symptomatic bradycardia.
- Certain drug-resistant and reentrant tachycardias. (Short A-V interval settings may be useful in controlling some reentrant tachycardias.)
- Atrial and ventricular ectopic arrhythmias.

In the A-V sequential (DVI) mode, the Model 7000A may have application in the following:

- Sick Sinus Syndrome (sinus bradycardia, sinus arrest, SA block, and the brady-tachy syndrome).
- Symptomatic bradycardia.
- Certain drug-resistant and reentrant tachycardias. (Short A-V delay settings may be useful in controlling some reentrant tachycardias.)
- Atrial and ventricular ectopic arrhythmias.

At any time, the Model 7000A can be programmed to the VVI mode in which case the device functions as a ventricular inhibited pulse generator. This mode is intended primarily as a backup mode in situations where it is necessary to disable the atrial circuitry (e.g., atrial lead malfunction).

**NOTE:** The Medtronic® Model 7000A universal A-V pulse generator is under clinical investigation in the U.S. The procedures for using this pulse generator, as well as its safety and efficacy, will be evaluated during this investigational study according to the Clinical Investigation Protocol. Therefore, the "Intended Uses" section is based on Medtronic's experience with other physiologic pulse generators. No claims for safety and efficacy can be made for the Model 7000A pulse generator during its clinical investigation. Patients should be advised that the Model 7000A pulse generator is under clinical investigation.

**Contraindications**

*General:* There are no known contraindications to the use of pacing as a therapeutic modality for control of heart rate. The patient's age and medical condition, however, may dictate the particular pacing system, mode of operation, and implantation procedure used by the physician.

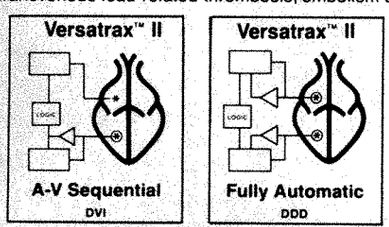
*DDD Mode:* The DDD mode is contraindicated in the presence of atrial fibrillation, atrial flutter and rapid atrial rhythms or slow retrograde conduction.

*DVI Mode:* In the DVI mode, atrial pacing is ineffective in the presence of chronic atrial fibrillation or flutter.

**Warnings**

*Diathermy:* Diathermy should not be used on patients with pacemakers because of possible heating effects in the pulse generator and at the implant site.

*Electrosurgical Units:* Electrosurgical units should never be used in the vicinity of unipolar pulse generators because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead.



*Defibrillation:* Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. Positioning a magnet or the programming head over the pulse generator makes it subject to programming. A nominal vertical magnetic field strength of 90 Gauss (in a field measured 1½ inches from the magnet's surface) from a magnet at 1¼ inches from the reed switch is required to initiate asynchronous pacing. Do not use electrocautery, diathermy, or any other source of electromagnetic interference in the vicinity of the patient once a magnet or programming head has been positioned over the pulse generator. If an electrocautery unit is used, the physician may prefer to program the pacemaker to asynchronous pacing prior to the procedure.

**Precautions**

The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

**Side Effects**

Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

ELECTROPHYSIOLOGY LABORATORY
CREIGHTON UNIVERSITY CARDIAC CENTER
601 NORTH 30th STREET, OMAHA, NEBRASKA 68131

# CHAIRPERSON

## DEPARTMENT OF THORACIC-CARDIOVASCULAR SURGERY

Nassau Hospital, a 533-bed teaching hospital of SUNY at Stony Brook is seeking outstanding candidates to chair its cardio-thoracic department. Applicants should have demonstrated clinical, teaching and administrative skills as well as proven research productivity. Senior academic rank preferred (Professor or Associate Professor of Surgery). The department conducts a fully approved open heart program and a large volume of thoracic and vascular surgery is performed. There are hospital-supported fellowship positions and an opportunity for research activities. Send CV to John F. Aloia, M.D., Professor of Medicine, Chairman, Search Committee.

## NASSAU HOSPITAL

259 FIRST STREET
MINEOLA, LONG ISLAND, NEW YORK 11501
*An Equal Opportunity Employer M/F*

**CARDIOLOGIST**—SOUTHERN CALIFORNIA. MUST BE BOARD CERTIFIED TO JOIN TWO OTHER BOARD CERTIFIED CARDIOLOGISTS. INVASIVE/NON-INVASIVE. SEND CV TO BOX 260, THE AMERICAN JOURNAL OF CARDIOLOGY, 875 THIRD AVE., NEW YORK, NY 10022.

hour Holter monitoring, and all had ergonovine testing during therapy with each agent. Of the 74 tests, 59 were negative; 6 of the negative tests occurred when the patient was having >10 chest pains/week and >25 episodes/week of S-T segment deviation. Of the 15 positive tests, 5 occurred when the patient was having no angina or S-T deviation. Thus, in the patient with variant angina, disease activity cannot be monitored reliably by ergonovine provocation, since some patients have negative ergonovine tests at a time of marked disease activity, whereas others have positive tests at a time of little (or no) disease activity.

**689 Frequency in Nonangioplasty Patients of Morphologic Findings Reported in Coronary Arteries Treated With Transluminal Angioplasty**

JEFFREY M. ISNER and ROBERTA V. FORTIN

In 33 (49%) of 70 patients in whom percutaneous transluminal angioplasty (PTA) had *not* been performed during life, necropsy examination disclosed 1 or more findings identical to those observed in necropsy studies of PTA-treated arteries. These findings included "plaque fractures" in 31 (or 44%), "dissection clefts" in 26 (33%), and medial thinning in 40 (57%). Observations in these 70 patients indicate that findings previously described in PTA-treated patients cannot necessarily be assumed to represent the result of PTA.

**694 Intravenous Nitroglycerin for the Treatment of Angina at Rest Unresponsive to Standard Nitrate Therapy**

KERRY KAPLAN, RICHARD DAVISON, MICHELE PARKER, JEAN PRZYBYLEK, J. RUSSELL TEAGARDEN, and MICHAEL LESCH

Thirty-five patients who had angina at rest unresponsive to standard therapy comprised of oral and topical nitrates and beta-blocking drugs were treated with a continuous infusion of intravenous nitroglycerin. The average infusion rate was 140 ± 15 μg/min. With intravenous nitroglycerin therapy the number of episodes of angina at rest decreased from 3.5 ± 0.4 to 0.3 ± 0.1, sublingual nitroglycerin use decreased from 1.9 ± 0.3 to 0.4 ± 0.1 mg/day, and morphine sulfate administration decreased from 5.5 ± 1.3 to 0.4 ± 0.2 mg/day (all $p < 0.001$). When each patient's response on the endpoint day was analyzed, 25 were defined as complete (no rest angina), 8 as partial (>50% decrease in number of episodes per day from control) and 2 as nonresponders. No significant drug-induced side effects occurred. Intravenous nitroglycerin appears to be effective therapy for angina at rest refractory to standard oral and topical medications.

**699 Effects of Verapamil on Coronary Hemodynamic Function and Vasomobility Relative to Its Mechanism of Antianginal Action**

CHRISTOPHER Y. C. CHEW, B. GREGORY BROWN, BRAMAH N. SINGH, MAYLENE M. WONG, CINDY PIERCE, and ROBERT PETERSEN

Intravenously administered verapamil (0.145 mg/kg followed by 0.005 mg/kg/min infusion) during cardiac catheterization in patients with coronary artery disease reduced mean arterial pressure (−14%, $p < 0.001$,) systemic vascular resistance (−27%, $p < 0.01$) with a small, insignificant (+13%) increase in coronary sinus flow and no change in myocardial oxygen consumption. A computer-assisted angiographic technique showed that the drug dilated normal as well as stenotic segments of epicardial coronary vessels, producing a mean reduction of 14% ($p < 0.01$) of estimated stenosis flow resistance; nitroglycerin produced a 28% reduction ($p < 0.01$) under comparable conditions. The data suggest that intravenously, verapamil dilates normal as well as narrowed atherosclerotic segments of coronary arteries without a change in oxygen demand. The reduction in stenosis flow resistance may contribute to its antianginal actions.

**706 Nifedipine in Chronic Stable Angina: A Double-Blind Placebo-Controlled Crossover Trial**

LON G. SHERMAN and CHANG-SENG LIANG

Thirty patients with chronic stable argina pectoris were randomized in a double-blind prospective placebo-controlled crossover trial to assess the efficacy of nifedipine in controlling symptoms and objective signs of myocardial ischemia using a symptom-limited treadmill exercise test. Adverse effects that occurred during both nifedipine and placebo treatment were minor and generally well tolerated. Twenty-three patients were analyzed from the crossover phase of the study. Nifedipine significantly reduced the frequency of angina and nitroglycerin consumption, and increased exercise time. These changes were significantly greater than those in the placebo group. Hemodynamic evaluation during exercise revealed a significant reduction in systolic and diastolic blood pressures in the nifedipine group at the onset of angina and at maximal exercise without significant differences in heart rate responses in the nifedipine and placebo groups. The pressure-rate product during submaximal exercise was significantly smaller in the nifedipine group than in the placebo group, but did not differ significantly in the 2 groups at the onset of angina or on maximal exercise. Furthermore, S-T segment depressions that occurred during exercise at the same pressure-rate products were smaller in the nifedipine period than in the placebo period. Thus, it appears that the antianginal effects of nifedipine are caused by a reduced myocardial oxygen demand for a specific work load and possibly by an increased blood supply to ischemic myocardium.

2.5, 6.5, 9.0 mg CAPSULES

# NITROSTAT® SR
# (nitroglycerin capsules)

■ complementary therapeutic effect: nitrates and beta-adrenergic blocking agents reduce myocardial oxygen demand by different mechanisms

**Mechanism I:** Nitrates reduce myocardial oxygen requirement by acting on systemic circulation. Their vasodilator action decreases venous return and systemic arterial resistance, thus improving the balance between the need and supply of oxygen. Reduction in the myocardial oxygen requirement appears to be the major action of nitrates in relieving typical angina. However, selective dilatation of large coronary vessels by nitrates may be the primary mechanism by which they benefit patients with angina due to coronary spasm.[1]

**Mechanism II:** In contrast, beta-blockers block the beta receptor sites in the heart itself. They work by reducing the heart rate and the force of contraction, thereby lowering oxygen demand. In addition to cardiac output and heart rate, blood pressure is also decreased.

Beta-blockers may reduce the oxygen requirement of the heart at any given level of effort by blocking catecholamine-induced increases in heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction.

■ diminished side effects: some of the negative aspects of the effects of each drug are reduced. For example, concomitant nitrates oppose the increased ventricular size, filling pressure, and end-diastolic pressure caused by beta-adrenergic antagonists.[1]

**The effects of NITROSTAT® SR and a beta-blocker are complementary. The result can be improved therapy for angina prophylaxis.**

■ all day and all night prophylactic action with just two or three daily doses*

How Supplied: 2.5-mg and 6.5-mg strengths, in bottles of 60 and 100 capsules. Also, 9.0-mg strength, in bottles of 60 capsules.

Please see next page for brief summary of prescribing information.

**NITROSTAT® SR...Backed by the experience and reputation of PARKE-DAVIS**

*Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indication as follows. "Possibly" effective: For the management, prophylaxis or treatment of anginal attacks. Final classification of the less-than-effective indication requires further investigation.

REFERENCE: 1. Needleman P, Johnson EM Jr: Vasodilators and the treatment of angina, in Gilman AG, Goodman LS and Gilman A (eds): Goodman and Gilman's The Pharmacological Basis of Therapeutics, ed 6. New York, Macmillan Publishing Co, Inc, 1980, pp 819-833

**NITROSTAT® SR CAPSULES**
(nitroglycerin capsules)
SUSTAINED RELEASE

Before prescribing, please see full prescribing information.
A Brief Summary follows:

**INDICATION:** Based on a review of this drug by the National Academy of Sciences–National Research Council and/or other information, FDA has classified the indication as follows.

"Possibly" effective: For the management, prophylaxis or treatment of anginal attacks.

Final classification of the less-than-effective indication requires further investigation.

**CONTRAINDICATIONS:**
Acute or recent myocardial infarction, severe anemia, closed-angle glaucoma, postural hypotension, increased intracranial pressure and idiosyncrasy to the drug.

**WARNINGS:**
Capsules must be swallowed.
FOR ORAL, NOT SUBLINGUAL USE.
Nitrostat SR Capsules are not intended for immediate relief of anginal attacks.

**PRECAUTIONS:**
Intraocular pressure may be increased; therefore, caution is required in administering to patients with glaucoma. Tolerance to this drug and cross-tolerance to other organic nitrites and nitrates may occur. If blurring of vision, dryness of mouth or lack of benefit occurs, the drug should be discontinued.

**ADVERSE REACTIONS:**
Severe and persistent headaches, cutaneous flushing, dizziness and weakness. Occasionally, drug rash or exfoliative dermatitis, and nausea and vomiting may occur; these responses may disappear with a decrease in dosage. Adverse effects are enhanced by ingestion of alcohol, which appears to increase absorption from the gastrointestinal tract.

**DOSAGE AND ADMINISTRATION:**
Administer the smallest effective dose 2 or 3 times daily, at 8- to 12-hour intervals, unless clinical response suggests a different regimen. Discontinue if not effective. 0883G010

# Marquette's New Series 7000 Patient Monitoring System

When Marquette Electronics decided to enter the patient monitoring business last year, we were determined to bring some new technology to the field. You see, in a fiercely competitive business, we only know one way to get ahead and that is to improve the state of the art by applying high technology.

That's why we're introducing the Series 7000, a new bedside monitor/computer that looks at four ECG leads **simultaneously** for greatly improved arrhythmia calls and positive identification of electrode failure.

And we extended the frequency response in blood pressure monitoring to 50 Hz with automatic pressure line compensation for cath lab quality at the bedside.

That's just two innovations we're introducing with the new Series 7000. Your Marquette sales engineer can tell you much more.

Make sure you see this innovative equipment at The American College of Cardiology meeting in New Orleans this month.

**712 Effect of Intravenous and Intracoronary Nifedipine on Coronary Blood Flow and Myocardial Oxygen Consumption**

PETER SCHANZENBÄCHER, GERHART LIEBAU, PETER DEEG, and KURT KOCHSIEK

The effect of intravenous and intracoronary nifedipine on coronary sinus blood flow, coronary vascular resistance, and myocardial oxygen consumption was studied in 20 patients with coronary artery disease. Intravenous infusion of 1.0 mg of nifedipine resulted in a decrease in mean aortic pressure, an increase in heart rate and coronary blood flow, and no significant change in myocardial oxygen consumption. In contrast, intracoronary injection of 0.1 mg of nifedipine led to a moderate reduction in mean aortic pressure, no change in heart rate, an increase in coronary blood flow, and a significant reduction in myocardial oxygen consumption. During rapid atrial pacing before and approximately 6 minutes after the intracoronary nifedipine injection, coronary blood flow and myocardial oxygen consumption reached identical levels. Thus, only intracoronary injection of nifedipine increases coronary flow in the presence of reduced myocardial oxygen consumption. After intravenous administration, reflex tachycardia counteracts the direct myocardial effect of nifedipine and the potential oxygen-saving effect of afterload reduction. There is no evidence of a prolonged oxygen-sparing effect after cessation of the immediate effects.

**718 Electrocardiographic Criteria for the Diagnosis of Combined Inferior Myocardial Infarction and Left Anterior Hemiblock**

ROBERT A. WARNER, NORMA E. HILL, SAKTI MOOKHERJEE, and HAROLD SMULYAN

New electrocardiographic criteria based on vectorcardiographic principles for diagnosing the combination of inferior infarction and left anterior hemiblock are proposed. The proposed criteria can be applied to tracings obtained with 3-channel electrocardiographic machines and are as follows: (1) leads aVR and aVL both end in R waves, with the peak of the terminal R wave in lead aVR occurring later than the peak of a terminal R wave in lead aVL, and (2) a Q wave of any magnitude is present in lead II. The performance of the proposed criteria is statistically superior to that of each of 10 sets of traditional electrocardiographic criteria for the diagnosis.

**723 Improved Electrocardiographic Criteria for the Diagnosis of Left Anterior Hemiblock**

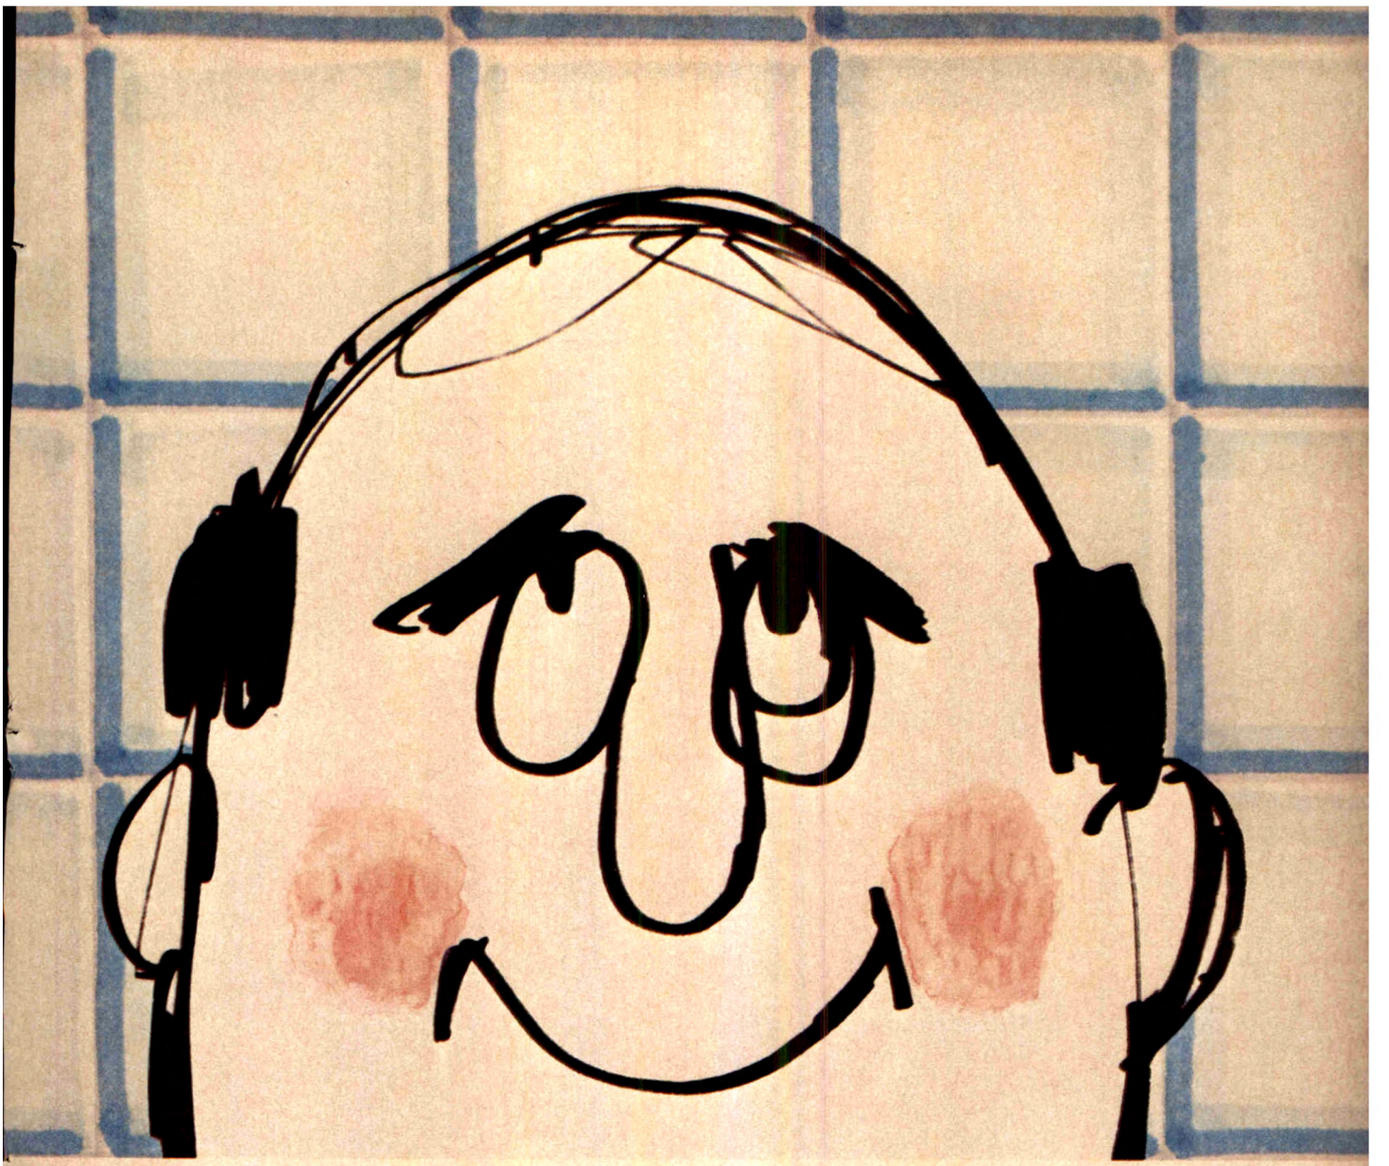
ROBERT A. WARNER, NORMA E. HILL, SAKTI MOOKHERJEE, and HAROLD SMULYAN

New electrocardiographic criteria for diagnosing left anterior hemiblock are proposed. The proposed criteria are based on a method of analysis that permits diagnostically important features of the vectorcardiographic frontal plane QRS loop to be inferred from the electrocardiogram. The proposed criteria can be applied to tracings obtained with 3-channel electrocardiographic machines and are as follows: (1) the QRS complexes in leads aVR and aVL each end in R waves (terminal R waves), and (2) the peak of the terminal R wave in lead aVR occurs later than the peak of the terminal R wave in lead aVL. The performance of the proposed criteria is statistically superior to each of 2 sets of traditional QRS axis criteria for the diagnosis.

**727 Effects of Provocation on Transcardiac Thromboxane in Patients With Coronary Artery Disease**

PAUL D. HIRSH, BRIAN G. FIRTH, WILLIAM B. CAMPBELL, GREGORY J. DEHMER, JAMES T. WILLERSON, and L. DAVID HILLIS

Simultaneous ascending aortic and coronary sinus blood samples were obtained for quantitation of thromboxane $B_2$ in 52 patients provoked with rapid cardiac pacing, cold pressor stress, or sustained isometric exertion. Five had a >3-fold increase in coronary sinus thromboxane $B_2$: 1 had unstable angina and chest pain during the previous 48 hours and 4 had a myocardial infarction within the previous 6 weeks. Similarly, 7 had a >3-fold increase in the coronary sinus/aortic thromboxane $B_2$ ratio: 1 had unstable angina and recent chest pain, 5 had a recent myocardial infarction, and 1 had both. The remaining patients with similar diagnoses did not have a marked increase in thromboxane $B_2$. None of the 35 patients with stable ischemic heart disease or nonischemic chest pain syndromes had a substantial increase in thromboxane $B_2$ ($p < 0.001$). Thus, generous amounts of thromboxane $B_2$ are released into the coronary circulation after provocation in some patients with unstable angina or recent myocardial infarction but not in those with stable ischemic heart disease or nonischemic chest pain syndromes.



**734 Precordial S-T Segment Depression in Inferior Myocardial Infarction. Evaluation by Quantitative Thallium-201 Scintigraphy and Technetium-99m Ventriculography**

LAWRENCE ONG, BENILDA VALDELLON, JAMES COROMILAS, ROBERT BRODY, PETER REISER, and JOHN MORRISON

Seventy patients with acute inferior myocardial infarction were studied with early thallium-201 scintigraphy and technetium-99m ventriculography. Patients with precordial S-T segment depression did not have significantly more anteroseptal hypokinesia, anterior thallium-201 perfusion defects, or thallium-201 redistribution abnormalities. They did have a lower mean ejection fraction, greater inferoposterior hypokinesia, and larger inferoposterior perfusion defects, indicating the presence of larger infarcts. Compared with other variables reflecting

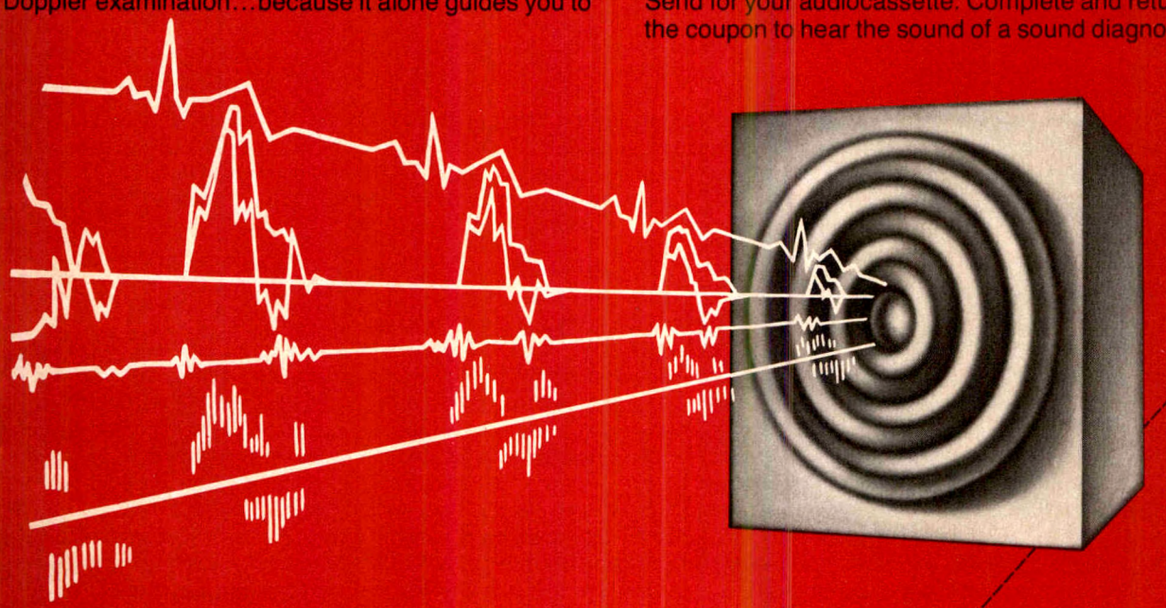
The next breakthrough in cardiac imaging..

# Full-Spectrum Doppler®:
## Because 2-D imaging alone is like watching a silent movie



**Just as a silent movie can't tell it all, a silent 2-D image can't convey everything that's happening inside the heart**

Now, the newest dimension in echocardiography only from Irex…2-D imaging, M-mode, plus FULL-SPECTRUM DOPPLER® for the noninvasive assessment of both hemodynamics and anatomy… a technique you can learn easily and quickly, with full training support from Irex.

In the unique Irex System, the Doppler audio signal is the key to getting the proper information from the Doppler examination…because it alone guides you to the optimum angle to flow for the most accurate measurement.

Once oriented correctly, pulsed Doppler provides the resolution needed for precise localization and selective sampling. CW Doppler is essential to detect the high flow velocities of most cardiac lesions and to assess the degree of obstruction. Only the Irex Phased Array Imaging System gives you *both* modes for the *complete* simultaneous 2-D/Doppler examination… plus a full-spectrum audio signal to *verify* results.

Hear FULL-SPECTRUM DOPPLER for yourself. Send for your audiocassette. Complete and return the coupon to hear the sound of a sound diagnosis.

**Come see us at the upcoming ACC meeting in New Orleans, March 21–24 at 461 Rivergate Convention Center— IREX Booth #1461.**

AJC 3/83

left ventricular dysfunction and infarct size in a multivariate analysis, the presence of precordial S-T segment depression did not have independent prognostic value. Significant independent prognostic variables were Killip class, initial left ventricular ejection fraction <40%, and pulmonary vascular congestion on admission chest radiography.

**741 Radionuclide-Determined Changes in Pulmonary Blood Volume and Thallium Lung Uptake in Patients With Coronary Artery Disease**

RICHARD A. WILSON, ROBERT D. OKADA, CHARLES A. BOUCHER, H. WILLIAM STRAUSS, and GERALD M. POHOST

Exercise-induced increases in radionuclide-determined pulmonary blood volume (PBV) and thallium lung uptake have been described in patients with coronary artery disease (CAD) and have been shown to correlate with transient exercise-induced left ventricular dysfunction. To compare these 2 techniques in the same patients, 74 patients (59 with and 15 without significant CAD) underwent supine bicycle exercise twice on the same day—first for thallium myocardial and lung imaging and then for technetium-99m gated blood pool imaging for the PBV ratio determination. Thallium activity of lung and myocardium was determined to calculate the thallium lung/heart ratio. Relative changes in PBV from rest to exercise were expressed as a ratio of pulmonary counts (exercise/rest). The results indicate the following conclusions: (1) the prevalence of an abnormal thallium lung/heart ratio is smaller than that of the PBV ratio in patients with CAD; (2) both tests are normal in normal control subjects; (3) propranolol does not cause abnormal results in normal control subjects; however, propranolol may influence lung thallium uptake in patients with CAD; and (4) when both tests are abnormal, there is a high likelihood of multivessel disease.

**749 Sinus Node Coronary Arteries Studied With Angiography**

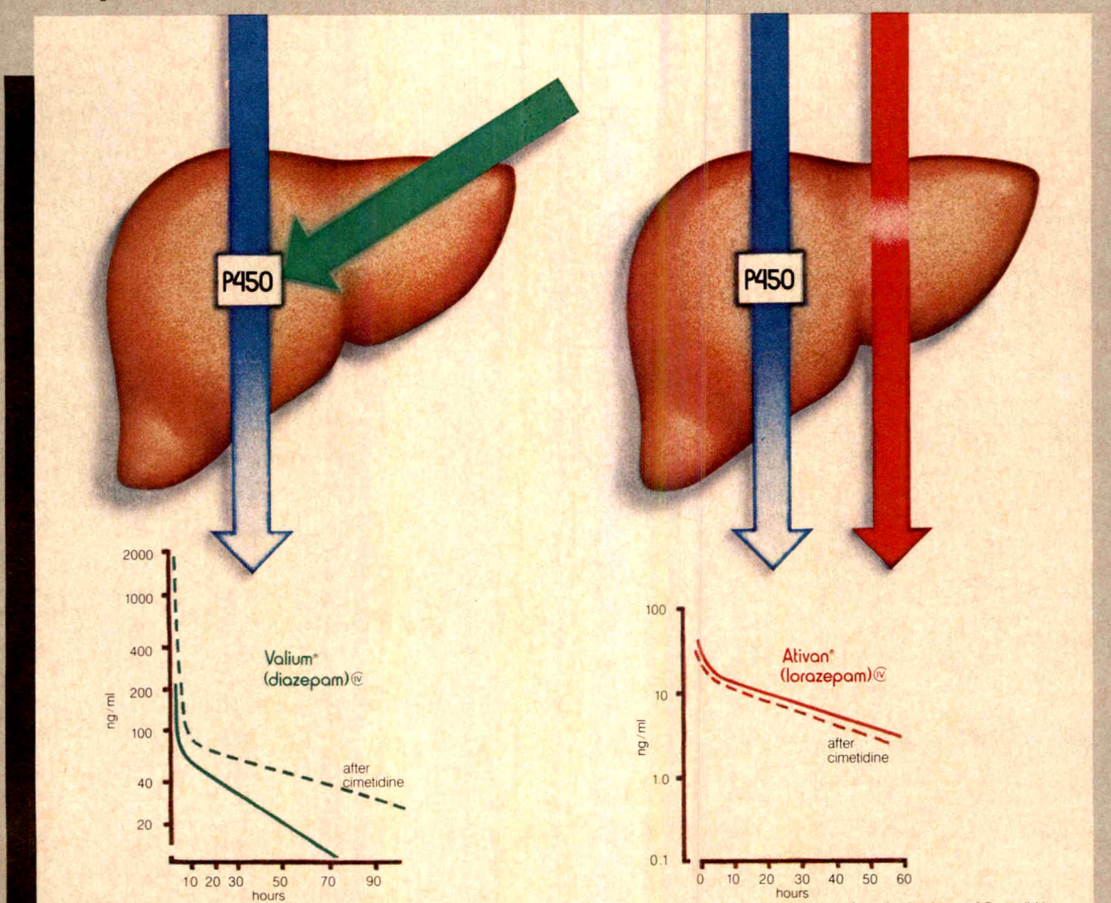
MICHAEL K. KYRIAKIDIS, COSTAS B. KOUROUKLIS, JOHN T. PAPAIOANNOU, STAMATIS G. CHRISTAKOS, GEORGE P. SPANOS, and DIMITRIS G. AVGOUSTAKIS

Coronary angiograms of 309 consecutive patients undergoing coronary angiography were reviewed to investigate the blood supply to the sinus node area. Blood was supplied from the right coronary artery in 59% of cases, from the left coronary artery in 38%, and from both coronary arteries in 3%. The posterior sinus node artery was demonstrated in 32 patients (27% of the 119 patients with the sinus node artery originating from the left circumflex and 10.5% of all patients).

**751 Beneficial Effects of Ibuprofen in Pacing-Induced Myocardial Ischemia**

PAUL WALINSKY, J. BRYAN SMITH, ALLAN M. LEFER, and LESLIE WIENER

The effect of ibuprofen on cathepsin D, a marker of lysosomal membrane leakiness, and on thromboxane $B_2$, a marker of platelet activation, was evaluated in 44 patients with angina pectoris. Coronary sinus and systemic arterial blood were analyzed for cathepsin D, thromboxane $B_2$ and lactate before and after atrial pacing to 140 beats/min for 4 minutes. Ibuprofen (800 mg) or placebo was administered orally 2 hours before catheterization. There were 4 subgroups based on administration of ibuprofen or placebo and based on demonstration of lactate extraction or production. Patients with lactate production given placebo had a significant increase in thromboxane $B_2$ level and in cathepsin D activities after atrial pacing. In contrast, patients with lactate production given ibuprofen and patients with lactate extraction had no significant efflux of either thromboxane $B_2$ or cathepsin D after pacing. These findings suggest that ibuprofen stabilizes lysosomal membranes and prevents platelet activated release of thromboxane $A_2$ in pacing-induced myocardial ischemia.



**755 Improved Exercise Ventilatory Responses After Training in Coronary Heart Disease During Long-Term Beta-Adrenergic Blockade**

NEIL F. GORDON, PIETER E. KRÜGER, and JONES F. CILLIERS

Exercise ventilatory responses of 7 men with well-documented myocardial infarction receiving long-term beta-adrenergic blockade were studied before and after 4 months of endurance training. Observations were obtained during graded levels of upright treadmill exercise continued until 85% of the predetermined symptom-limited heart rate (working heart frequency limit) was obtained. This submaximal testing procedure revealed a significant slowing of the heart rate ($p < 0.005$) together with an increased oxygen pulse ($p < 0.05$) after training, for what was previously a maximal work load for the working heart frequency limit. In addition, all patients achieved an increased exercise duration and work load, accompanied by significant increases in maximal oxygen uptake ($p < 0.01$), oxygen pulse ($p < 0.025$), and respiratory exchange ratio, for their working heart frequency limit after exercise conditioning. These results show that prolonged physical training results in physiologic adaptations to cardiac rehabilitation in the presence of long-term beta-adrenergic blockade.

# Ativan®. Agent of Change
(lorazepam)

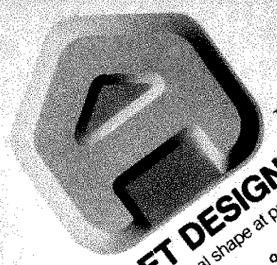
Plasma concentration of diazepam after a single dose of 0.1 mg/kg IV to a single subject administered before (—) and after (---) pretreatment with cimetidine—5 X 200 mg orally q6h. (Adapted from Klotz U, Reimann I: N Engl J Med *302*:1012-1014, 1980.)

Plasma concentration of lorazepam after single dose of 2 mg IV in 8 normal subjects before (—) and after (---) 7 days of treatment with cimetidine, 300 mg orally qid. (Adapted from Patwardhan RV, Yarborough GW, Desmond PV, et al: Gastroenterology *79*:912-916, 1980.)

## because it doesn't utilize the P450 system

All drugs inactivated by oxidative metabolism, including cimetidine and most benzodiazepines, utilize the cytochrome P450 oxidase enzyme system and, therefore, compete for it when given concomitantly. Patients on cimetidine, for example, are apt to experience excessive drowsiness when taking a benzodiazepine dependent on this system—because benzodiazepine clearance is delayed and plasma levels increase.

Ativan® (lorazepam) is inactivated by simple, one-step glucuronidation and is not subject to N-dealkylation or hydroxylation by the P450 system—unlike diazepam, chlordiazepoxide, clorazepate and prazepam, all CIV.



And, since Ativan does not compete for the P450 system, its elimination is not appreciably affected by concomitant use of cimetidine... one more reason why Ativan is becoming the anxiolytic of choice for an increasing number of physicians.

**NEW TABLET DESIGN 0.5 mg and 1 mg**

(2 mg tablet retains original oval shape at present)

**Brief Summary of Prescribing Information.**

**Indications and Usage:** Management of anxiety disorders or short-term relief of symptoms of anxiety or anxiety associated with depressive symptoms. Anxiety or tension associated with stress of everyday life usually does not require treatment with an anxiolytic.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

**Contraindications:** Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

**Warnings:** Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

**Precautions:** In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation. Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions. Observe usual precautions with impaired renal or hepatic function. Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component. Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (about 6 times maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatrics requires caution and frequent monitoring for symptoms of upper G.I. disease. Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug. In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

**Adverse Reactions,** if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

**Overdosage:** In management of overdosage with any drug, bear in mind multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

**Ativan® (IV) for (lorazepam) Anxiety**

**DOSAGE: Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.**

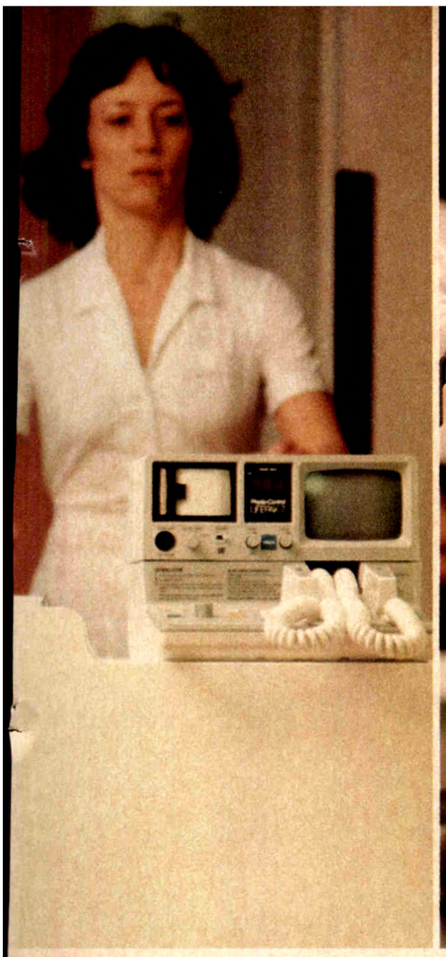
**HOW SUPPLIED: 0.5, 1.0 and 2.0mg tablets.**

**Wyeth Laboratories**
Philadelphia, PA 19101

## NOTICE OF PUBLIC SALE

NOTICE is hereby given that JOHN and LINDA VALENTINE as the secured party in possession of their collateral furnished to them by their debtor, Bomed Medical Manufacturing, Ltd., will sell that collateral, for cash, at public sale on Tuesday, April 5, 1983, at 10:00 A.M. at the offices of Drummy Garrett King & Harrison at 3200 Park Center Drive, Suite 1000, Costa Mesa, California. The collateral is generally described in the Financing Statement filed with the Office of the California Secretary of State as "(a) all of Debtor's right to manufacture, sell and license others to manufacture and sell three devices (the "devices") developed by Debtor commonly known as (1) the Heart Rate Monitor, (2) the Depil-X, and (3) the Bioimpedance Analyzer; (b) that certain Patent for Accelerated Electrolysis issued June 11, 1974, being Patent No. 3815603 relating to the Depil-X; and (c) all proceeds of the foregoing Collateral."

This personal property is owned by Bomed Medical Manufacturing, Ltd. and is located at 130 McCormick Avenue, Suite 109, Costa Mesa, California and is subject to that certain Security Agreement dated June 23, 1982 between it and JOHN and LINDA VALENTINE, that certain Financing Statement dated June 23, 1982 filed in the Office of the Secretary of State of the State of California on June 28, 1982, and that certain Notice of Assignment and Assignment of Patent for Security Purposes Only dated June 23, 1982 and filed in the office of the Commissioner of Patents and Trademarks in Washington, D.C., on June 28, 1982.



The sale is being held to enforce the rights of JOHN and LINDA VALENTINE as secured party in possession of their collateral under and pursuant to the above-mentioned Security Agreement, Financing Statement, Notice of Assignment and the California Uniform Commercial Code.

For additional information concerning the above sale, and the Heart Rate Monitor, Depil-X, and Bioimpedance Analyzer, please contact Alan I. White of Drummy Garrett King & Harrison, attorneys for JOHN and LINDA VALENTINE, at P.O. Box 5080, Costa Mesa, CA 92626, or at the following telephone number: (714) 850-1800.

**CARDIOLOGIST**—IMMEDIATE OPENING FOR A BOARD CERTIFIED OR ELIGIBLE CANDIDATE AT THE KING-DREW MEDICAL CENTER, LOS ANGELES. MUST QUALIFY FOR ACADEMIC APPOINTMENT AT UCLA AT ASSISTANT OR ASSOCIATE PROFESSOR LEVEL. CALL AND SEND RESUME TO: Dr. Ravi Prakash, Professor and Chief of Cardiology, 12021 S. Wilmington Ave., Los Angeles, CA 90059 213/603-4567.

## ACADEMIC CARDIOLOGIST

Director of Nuclear Cardiology is sought for an expanding program in a large teaching hospital on Long Island, New York. This position is geographic, full-time, and the compensation is attractive. Applicant should be Board Certified in Internal Medicine and in Cardiovascular Diseases. Qualifications for the academic rank of Associate Professor or higher is desirable. Outstanding, enthusiastic teacher/clinician with proven administrative and research ability is sought. Send CV in confidence to Steven M. Zeldis, M.D., Acting Chief of Cardiology, Nassau Hospital, 259 First Street, Mineola, L.I., New York 11501.

# The end of the "one-defibrillator-meets-all-needs" theory.

From the field to the various departments in the hospital, cardiac care offers more problems and situations than one system can efficiently handle.

Which is why Physio-Control has a family of LIFEPAK® defibrillator/monitors. Each one gives you specialized features designed to meet your specific needs.

You can depend on the whole LIFEPAK family for ease of operation and outstanding reliability. And service from the best in the industry. Physio-Control.

## ARRHYTHMIAS AND CONDUCTION DISTURBANCES

**759 Disopyramide: Evaluation of Electrophysiologic Effects and Clinical Efficacy in Patients With Sustained Ventricular Tachycardia or Ventricular Fibrillation**

BRUCE B. LERMAN, HARVEY L. WAXMAN, ALFRED E. BUXTON, and MARK E. JOSEPHSON

The efficacy of disopyramide was evaluated by programmed ventricular stimulation in 50 patients who had a history of sustained ventricular tachyarrhythmias. Disopyramide prevented induction of sustained ventricular tachycardia in one third of patients studied and remained effective therapy in 80% of those discharged on the drug. Regardless of response to disopyramide, plasma levels, ventricular refractory periods, QRS and Q-Tc durations did not differ significantly. Although minor side effects developed in 20% of patients receiving disopyramide, the major factor limiting its use was myocardial depression. This occurred only in patients with preexisting ventricular dysfunction.

**765 Effects of Oral Digoxin on Ventricular Ectopy and Its Relation to Left Ventricular Function**

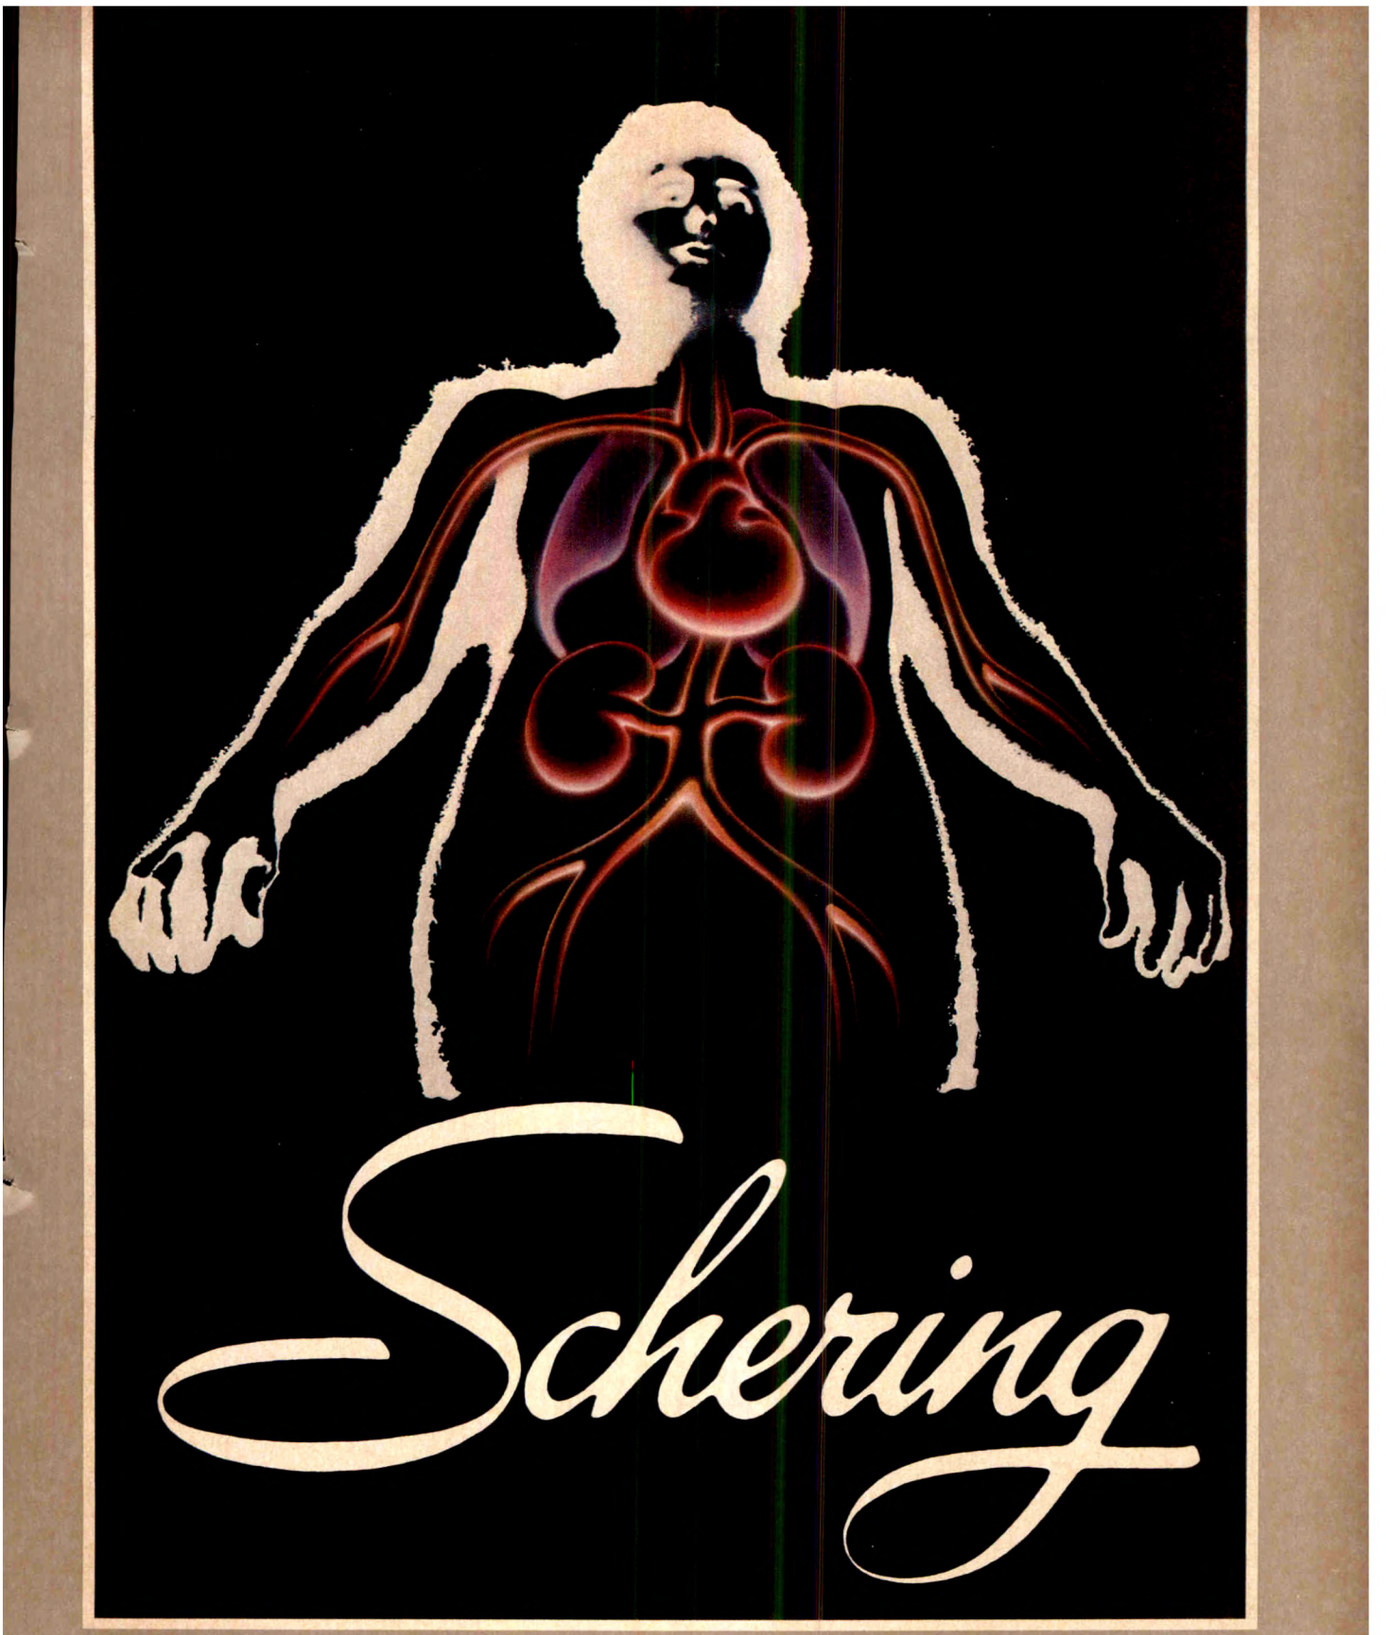
ALAN H. GRADMAN, MOIRA CUNNINGHAM, MARY A. HARBISON, HARVEY J. BERGER, and BARRY L. ZARET

The ventricular antiarrhythmic properties of oral digoxin were examined in 13 patients with chronic ventricular ectopy using serial 24-hour electrocardiographic monitoring. For the group as a whole, mean premature ventricular contraction frequency (per 1,000 normal beats) decreased from 56.1 ± 46.6 during the placebo period to 40.0 ± 27.2 (difference not significant) and 24.8 ± 17 ($p < 0.05$) during daily administration of digoxin, 0.25 and 0.375 mg, respectively. Radionuclide left ventricular ejection fraction was measured during the placebo period. Both mean premature ventricular contraction and couplet frequency decreased significantly in the 7 patients with normal left ventricular performance, while the patients with abnormal resting ejection fractions showed no significant reduction in arrhythmia occurrence after digoxin administration. This study indicates that digoxin is a moderately effective ventricular antiarrhythmic agent, and that its effects are greatest in patients with normal overall left ventricular function.

**770 Cardiac Electrophysiologic Effects of Flecainide Acetate for Paroxysmal Reentrant Junctional Tachycardias**

KEVIN J. HELLESTRAND, ANTHONY W. NATHAN, RODNEY S. BEXTON, ROWORTH A. J. SPURRELL, and A. JOHN CAMM

Intravenous flecainide acetate was administered to 18 patients with a direct accessory atrioventricular (AV) pathway and 15 patients with functional longitudinal A-H dissociation (dual A-H pathways). Flecainide was given to 14 patients during sustained AV reentrant tachycardia and to 9 patients during sustained intra-AV nodal reentrant tachycardia. AV reentrant tachycardia was successfully terminated in 12 patients, due to retrograde accessory pathway block in 11 and AV nodal block in 1. Tachycardia reinitiation was not possible in 6 patients. Flecainide significantly increased both anterograde and retrograde accessory pathway effective refractory periods. Intra-AV nodal reentrant tachycardia was successfully terminated in 8 patients, due to retrograde "fast" A-H pathway block in 7 patients and anterograde "slow" A-H pathway block in 1. Reinitiation was not possible in 4 patients. Flecainide selectively prolonged the retrograde effective refractory period of the fast A-H pathway only. Flecainide acetate effectively terminates reentrant junctional tachycardias by increasing accessory AV pathway and retrograde fast A-H pathway refractoriness.



**777 Cardiac Effects of Treatment With Quinidine and Digoxin, Alone and in Combination**

KARIN SCHENCK-GUSTAFSSON, TOMAS JOGESTRAND, LARS-ÅKE BRODIN, ROLF NORDLANDER, and RUNE DAHLQVIST

Systolic time intervals ($QS_2$-I and LVET-I) and echocardiographically determined ejection fraction and velocity of circumferential fiber shortening were recorded in 10 healthy volunteers, as measures of inotropic effect during sequential maintenance treatment with the following drug regimens: (1) quinidine alone, 1,200 mg daily, (2) digoxin alone, (3) combined treatment with quinidine and digoxin, (4) digoxin alone with increased dose to produce the same steady-state level as during the combined quinidine-digoxin treatment. Quinidine prolonged while digoxin caused a dose-related shortening of systolic time intervals. The addition of quinidine to digoxin treatment further shortened $QS_2$-I. By correcting for the negative inotropic effect of quinidine itself, the molar effect of digoxin on systolic time intervals was the same, irrespective of absence or presence of quinidine. Drug effects on echocardiographic measurements were less marked but followed the same directions as the systolic time intervals. This study performed under steady-state conditions demonstrates that the quinidine-induced increase in steady-state serum digoxin concentration will, with due consideration to quinidine's own pharmacodynamic properties, be accompanied by increased cardiac effects. This indicates that quinidine is not interfering with active receptor sites in the heart for digoxin.

PICKER INTERNATIONAL

# Picker International is the source for cardiography systems.

# To you, this is important.

Having a single source dedicated to meeting all of your cardiography equipment needs can save time in your decision making process.

And, a single source for your service and supply needs can save you time after your purchase, as well.

This three channel ECG with its versatile interactive memory is just one of the exciting new products available from our Cambridge Medical Instruments Group. Others include automatic and manual single channel ECG's; conventional and computer assisted stress test systems; ambulatory and telemetry monitoring systems; and the first truly portable ultrasound system.

We'd like to tell you more about our cardiography systems. Please write Picker International, Inc., 73 Spring St., Ossining, NY 10562; Telephone 914/941-8100 or Telex 137337.

## SYSTEMIC HYPERTENSION

**783 Immediate Hemodynamic Effect of a New Calcium-Channel Blocking Agent (Nitrendipine) in Essential Hypertension**

HECTOR O. VENTURA, FRANZ H. MESSERLI, WILLIE OIGMAN, FRANCIS G. DUNN, EFRAIN REISIN, and EDWARD D. FROHLICH

The immediate hemodynamic effects of nitrendipine were studied in 12 patients with mild essential hypertension. Patients were classified as responders (decrease ≥ 10 mm Hg, 7 patients) or nonresponders (≤ 10 mm Hg, 5 patients) according to the observed decreases in mean arterial pressure. The decrease in arterial pressure in responders was associated with a significant decrease in total peripheral resistance and a significant increase in heart rate, cardiac index, and left ventricular ejection rate. Plasma norepinephrine was significantly increased in the responders. It is concluded that nitrendipine lowered arterial pressure as a result of arteriolar dilatation associated with a reflexive increase in heart rate and cardiac index. Furthermore, nitrendipine combined with beta-blockers would be beneficial for the treatment of arterial hypertension.

**787 Predictability of Blood Pressure Response to Isometric Stress**

ROBERT H. CHANEY and STEPHAN ARNDT

Since there is marked individual variation in blood pressure (BP) response to isometric stress, a study was designed to determine whether such response could be predicted by readily measured clinical variables. BP, heart rate (HR), electrocardiographic findings, and symptoms were recorded during maximal isometric as well as dynamic exercise in 270 office patients. Multiple regression analyses of several potential predictors demonstrated that isometric systolic BP was best predicted by resting systolic BP, and this in combination with age, sex, and maximal treadmill systolic BP yielded 70% predictability. Isometric diastolic BP was best predicted by resting diastolic BP, and this with handgrip strength, treadmill HR, systolic BP, and diastolic BP allowed 66% prediction. Isometric testing was also found safe and practical if monitored for electrocardiogram, symptoms, and BP.

## CONGESTIVE HEART FAILURE

**791 Clonidine in Congestive Heart Failure: A Vasodilator With Negative Inotropic Effects**

JAMES B. HERMILLER, RAYMOND D. MAGORIEN, MARK E. LEITHE, DONALD V. UNVERFERTH, and CARL V. LEIER

Fourteen patients with moderately severe congestive heart failure were given oral clonidine (0.2 and 0.4 mg doses) in order to determine the hemodynamic effects of a typical central-acting vasodilator. The 0.2 mg dose significantly reduced systemic (15%), pulmonary (20%), and pulmonary capillary wedge pressures (27%). The reductions in systemic and pulmonary vascular resistance were comparatively modest secondary to a diminished cardiac output. Heart rate decreased 11% and stroke volume remained unchanged. The 0.4 mg dose augmented these reductions but increased stroke volume modestly (15%). After both doses, isovolumic developed pressure/duration of isovolumic contraction decreased dramatically (≥23%) and the preejection period increased substantially (≥18%). Compared with currently employed vasodilators, the central-acting agent clonidine appears unique in that drug-induced reductions of afterload are not accompanied by a commensurate improvement in ventricular function. This lack of improvement appears to be secondary to negative inotropic effects.

## CARDIOVASCULAR PHARMACOLOGY

**796 In Vivo Quantitation of Platelet Deposition on Human Peripheral Arterial Bypass Grafts Using Indium-111–Labeled Platelets. Effect of Dipyridamole and Aspirin**

CHARLES W. PUMPHREY, JAMES H. CHESEBRO, MRINAL K. DEWANJEE, HEINZ W. WAHNER, LARRY H. HOLLIER, PETER C. PAIROLERO, and VALENTIN FUSTER

Indium-111–labeled, autologous platelets injected 48 hours after operation were used to quantitate platelet deposition in vivo and to assess the effect of platelet-inhibitor therapy. Dacron® double-velour (Microvel®) aortobifemoral artery grafts were placed in 16 patients and unilateral polytetrafluorethylene femoropopliteal grafts were placed in 10 patients. Half of the patients in each group received dipyridamole before and dipyridamole plus aspirin after operation; the rest of the patients served as controls. Scintigrams of the graft region were taken with a gamma camera interfaced with a computer 48, 72, and 96 hours after injection of the labeled platelets. Platelet deposition was estimated from the radioactivities of the grafts and expressed as counts per 100 pixels per microcurie injected. Platelet deposition on vascular grafts can be quantitated in vivo by noninvasive methods. Therapy with dipyridamole and aspirin significantly reduced platelet deposition on Dacron aortofemoral artery grafts. Platelet deposition was low on polytetrafluoroethylene grafts in the femoropopliteal position.

Continued on Page A49

Burdick has a well-earned reputation for high quality engineering in cardiac care instruments. These two new Holter ambulatory ECG recorders are offered in that tradition.

Choose either 25-hour reel-to-reel or 24/48-hour cassette, depending on need or preference, providing compatibility with major Holter scanners.

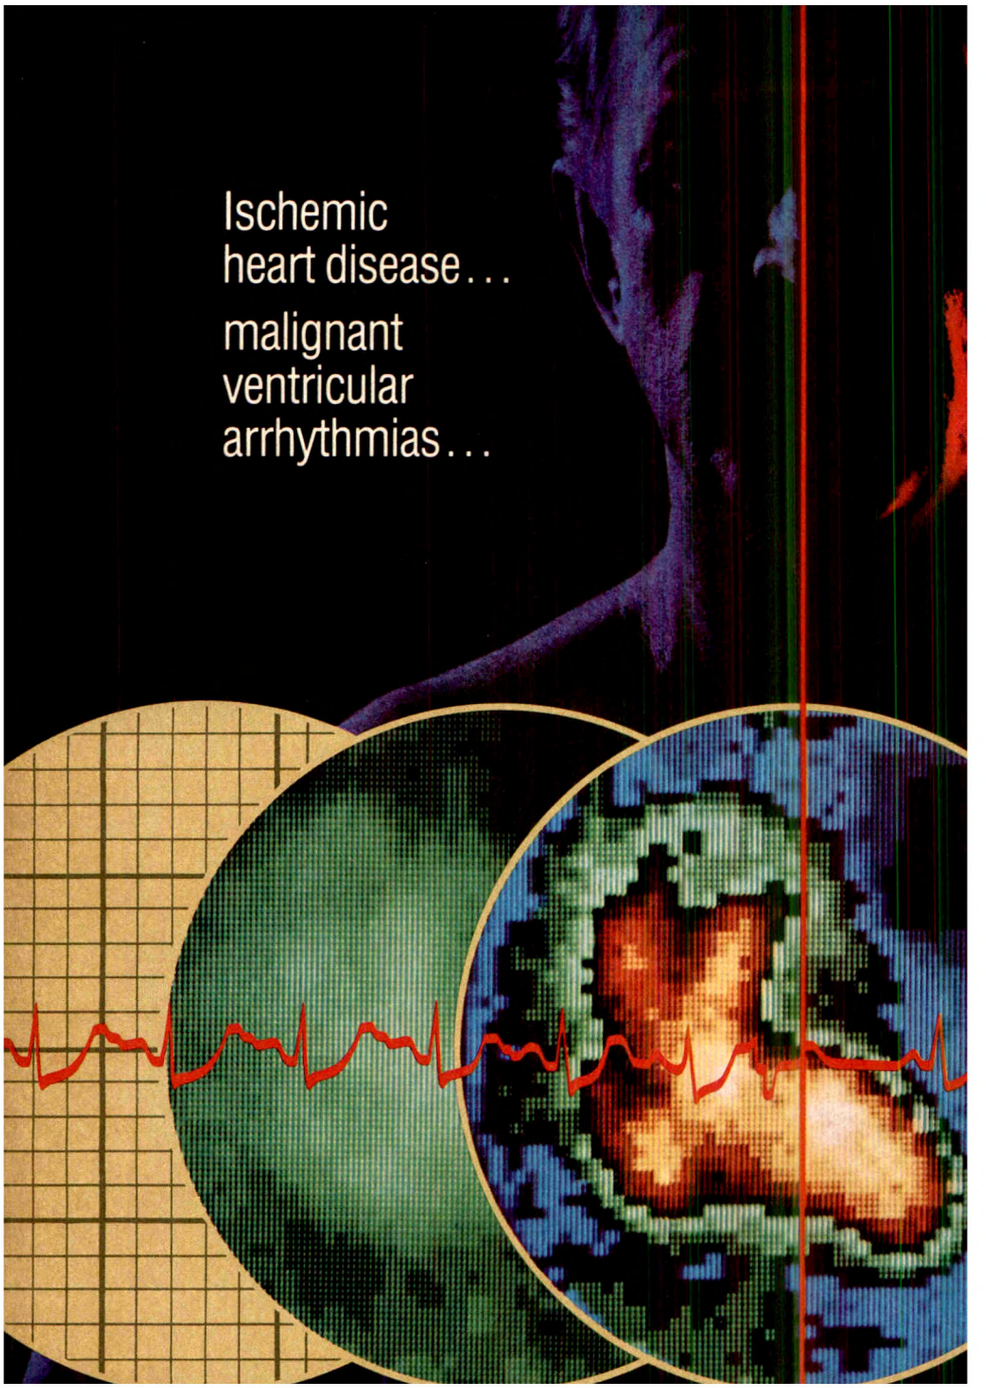
Burdick offers several advantages over other Holter recorders. For instance, these Burdick Holter recorders have the patient cable permanently attached to minimize "noisy" ECGs due to loose contacts. They're powered by a single 9V alkaline battery, have two recording tracks, built-in push-button calibration, and timing accuracy of better than ±1% for diagnostic precision.

Not only that, their lightweight aluminum cases are so rugged they're virtually impact-proof.

Of course, you expect Burdick to deliver the latest technology at affordable prices. And back every product with dependable service.

If you're expanding your patient services to include Holter monitoring or adding to your present system, you owe it to yourself to take a look at the new Burdick recorders. Call or write for more information or a demonstration.

# Of course you expect these new Holter recorders to be superior.



# They're from Burdick.

# ZEROING IN ON THE CANDIDATE AT RISK

Frequent and complex forms of PVCs sharply increase the risk of sudden cardiac death (SCD) in patients with ischemic heart disease, especially in the presence of left ventricular dysfunction.[1,2]

## To reduce the risk of potentially fatal arrhythmias in such patients

# QUINAGLUTE® 324 mg DURA-TABS®

## (quinidine gluconate)

- If initially tolerated, can usually be taken successfully over long periods.[3]
- Demonstrated by programmed ventricular stimulation to be effective in accepted "standard" doses.[4]
- BID or TID dosage helps improve compliance while providing 24-hour antiarrhythmic activity.
- "As a rule, GI toxicity associated with quinidine gluconate is less frequent and less severe than that associated with quinidine sulfate."[5]

**QUINAGLUTE® (quinidine gluconate) DURA-TABS®**

**INDICATIONS AND USAGE:** Quinaglute (quinidine gluconate) Dura-Tabs are indicated in the prevention and/or treatment of:

**1. Ventricular arrhythmias:** Premature ventricular contractions, ventricular tachycardia (when not associated with complete heartblock).

**2. Junctional (nodal) arrhythmias:** A-V junctional premature complexes, paroxysmal junctional tachycardia. **3. Supraventricular (atrial) arrhythmias:** Premature atrial contractions, paroxysmal atrial tachycardia, atrial flutter, atrial fibrillation (chronic and paroxysmal).

**CONTRAINDICATIONS:** 1. Idiosyncrasy or hypersensitivity to quinidine. 2. Complete A-V block. 3. Complete bundle branch block or other severe intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. 4. Digitalis intoxication manifested by A-V conduction disorders. 5. Myasthenia gravis. 6. Aberrant impulses and abnormal rhythms due to escape mechanisms.

**WARNINGS:** 1. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine.

2. Recent reports indicate that plasma concentrations of digoxin increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored. Reduction of digoxin dosage may have to be considered.

3. Manifestations of quinidine cardiotoxicity such as excessive prolongation of the Q-T interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring.

4. In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function such as hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals.

5. Quinidine should be used with extreme caution in patients with incomplete A-V block since complete block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication. 6. Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in plasma leading to toxicity.

7. Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or plasma levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal.

8. A few cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported in patients taking quinidine. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4-8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.

**PRECAUTIONS: General:** The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and possible determination of plasma quinidine levels is indicated when large doses are used, or with patients who present an increased risk.

**Drug Interactions:**

| *Drug* | *Effect* |
|---|---|
| Quinidine with anticholinergic drugs | Additive vagolytic effect |
| Quinidine with cholinergic drugs | Antagonism of cholinergic effects |
| Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics | Alkalinization of urine resulting in decreased excretion of quinidine |
| Quinidine with coumarin anticoagulants | Reduction of clotting factor concentrations |
| Quinidine with tubocurare, succinylcholine and decamethonium | Potentiation of neuromuscular blockade |
| Quinidine with phenothiazines and reserpine | Additive cardiac depressive effects |
| Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin) | Decreased plasma half-life of quinidine |
| Quinidine with digoxin | Increased plasma concentrations of digoxin (see WARNINGS) |

**Carcinogenesis, Mutagenesis and Impairment of Fertility:** Long-term studies in animals have not been performed to evaluate the carcinogenic potential of quinidine. There is currently no evidence of quinidine-induced mutagenesis or impairment of fertility.

**Pregnancy:** *Teratogenic Effects:* Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinaglute (quinidine gluconate) Dura-Tabs should be given to a pregnant woman only if clearly needed. *Nonteratogenic Effects:* Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.

**Nursing Mothers:** Caution should be exercised when Quinaglute (quinidine gluconate) Dura-Tabs are administered to a nursing woman due to passage of the drug into breast milk.

**Pediatric Use:** There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinaglute (quinidine gluconate) Dura-Tabs in children.

**ADVERSE REACTIONS:** Symptoms of cinchonism, ringing in ears, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal in nature. These gastrointestinal effects include nausea, vomiting, abdominal pain and diarrhea.

Less frequently encountered adverse reactions:

**Cardiovascular:** Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism and hypotension.

**Hematologic:** Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenia (purpura), agranulocytosis.

**Central Nervous System:** Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis.

**Dermatologic:** Rash, cutaneous flushing with intense pruritus, urticaria. Photosensitivity has also been reported.

**Hypersensitivity Reactions:** Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity, including granulomatous hepatitis (see WARNINGS). Although extremely rare, there have also been reports of lupus erythematosus in patients taking quinidine. A positive association with quinidine therapy has not been established.

# CONTENTS

**802 Cardiovascular Effects of a Newly Synthesized Cardiotonic Agent (TA-064) on Normal and Diseased Hearts**

MASAYA KINO, YUZO HIROTA, SHOJI YAMAMOTO, KENICHI SAWADA, MASATOMO MORIGUCHI, MASAHIRO KOTAKA, SHINICHIRO KUBO, and KEISHIRO KAWAMURA

A positive inotropic effect was confirmed echocardiographically in both healthy volunteers (n = 8) and patients with congestive heart failure (CHF) (n = 9) who were on a maximal medical regimen. Mean velocity of circumferential fiber shortening increased (healthy, 1.29 ± 0.05 to 1.60 ± 0.11 circ/s [$p < 0.05$]; patients with CHF, 0.69 ± 0.08 to 0.93 ± 0.09 circ/s [$p < 0.01$]) and ejection fraction increased (healthy, 68 ± 2 to 75 ± 2% [$p < 0.05$]; patients with CHF, 37 ± 4 to 45 ± 5% [$p < 0.01$]) without change in heart rate.

## CARDIOMYOPATHY

**811 Vulnerability of Patients With Obstructive Hypertrophic Cardiomyopathy to Ventricular Arrhythmia Induction in the Operating Room. Analysis of 17 Patients**

KELLEY P. ANDERSON, EDWARD B. STINSON, GERALDINE C. DERBY, PHILIP E. OYER, and JAY W. MASON

Seventeen patients with obstructive hypertrophic cardiomyopathy (HC) and 5 control patients underwent programmed electrical stimulation in the operating room. Of the 17 patients with HC, 14 had inducible sustained ventricular tachycardia or ventricular fibrillation, whereas none of the control patients had an inducible sustained ventricular arrhythmia. Unsustained ventricular tachycardia was induced in 1 patient in each group. The differences in the 2 groups with respect to ventricular tachyarrhythmia induction was significant ($p < 0.001$). Patients with obstructive HC are unusually vulnerable to ventricular tachyarrhythmia induction which may, in part, account for their propensity for sudden death.

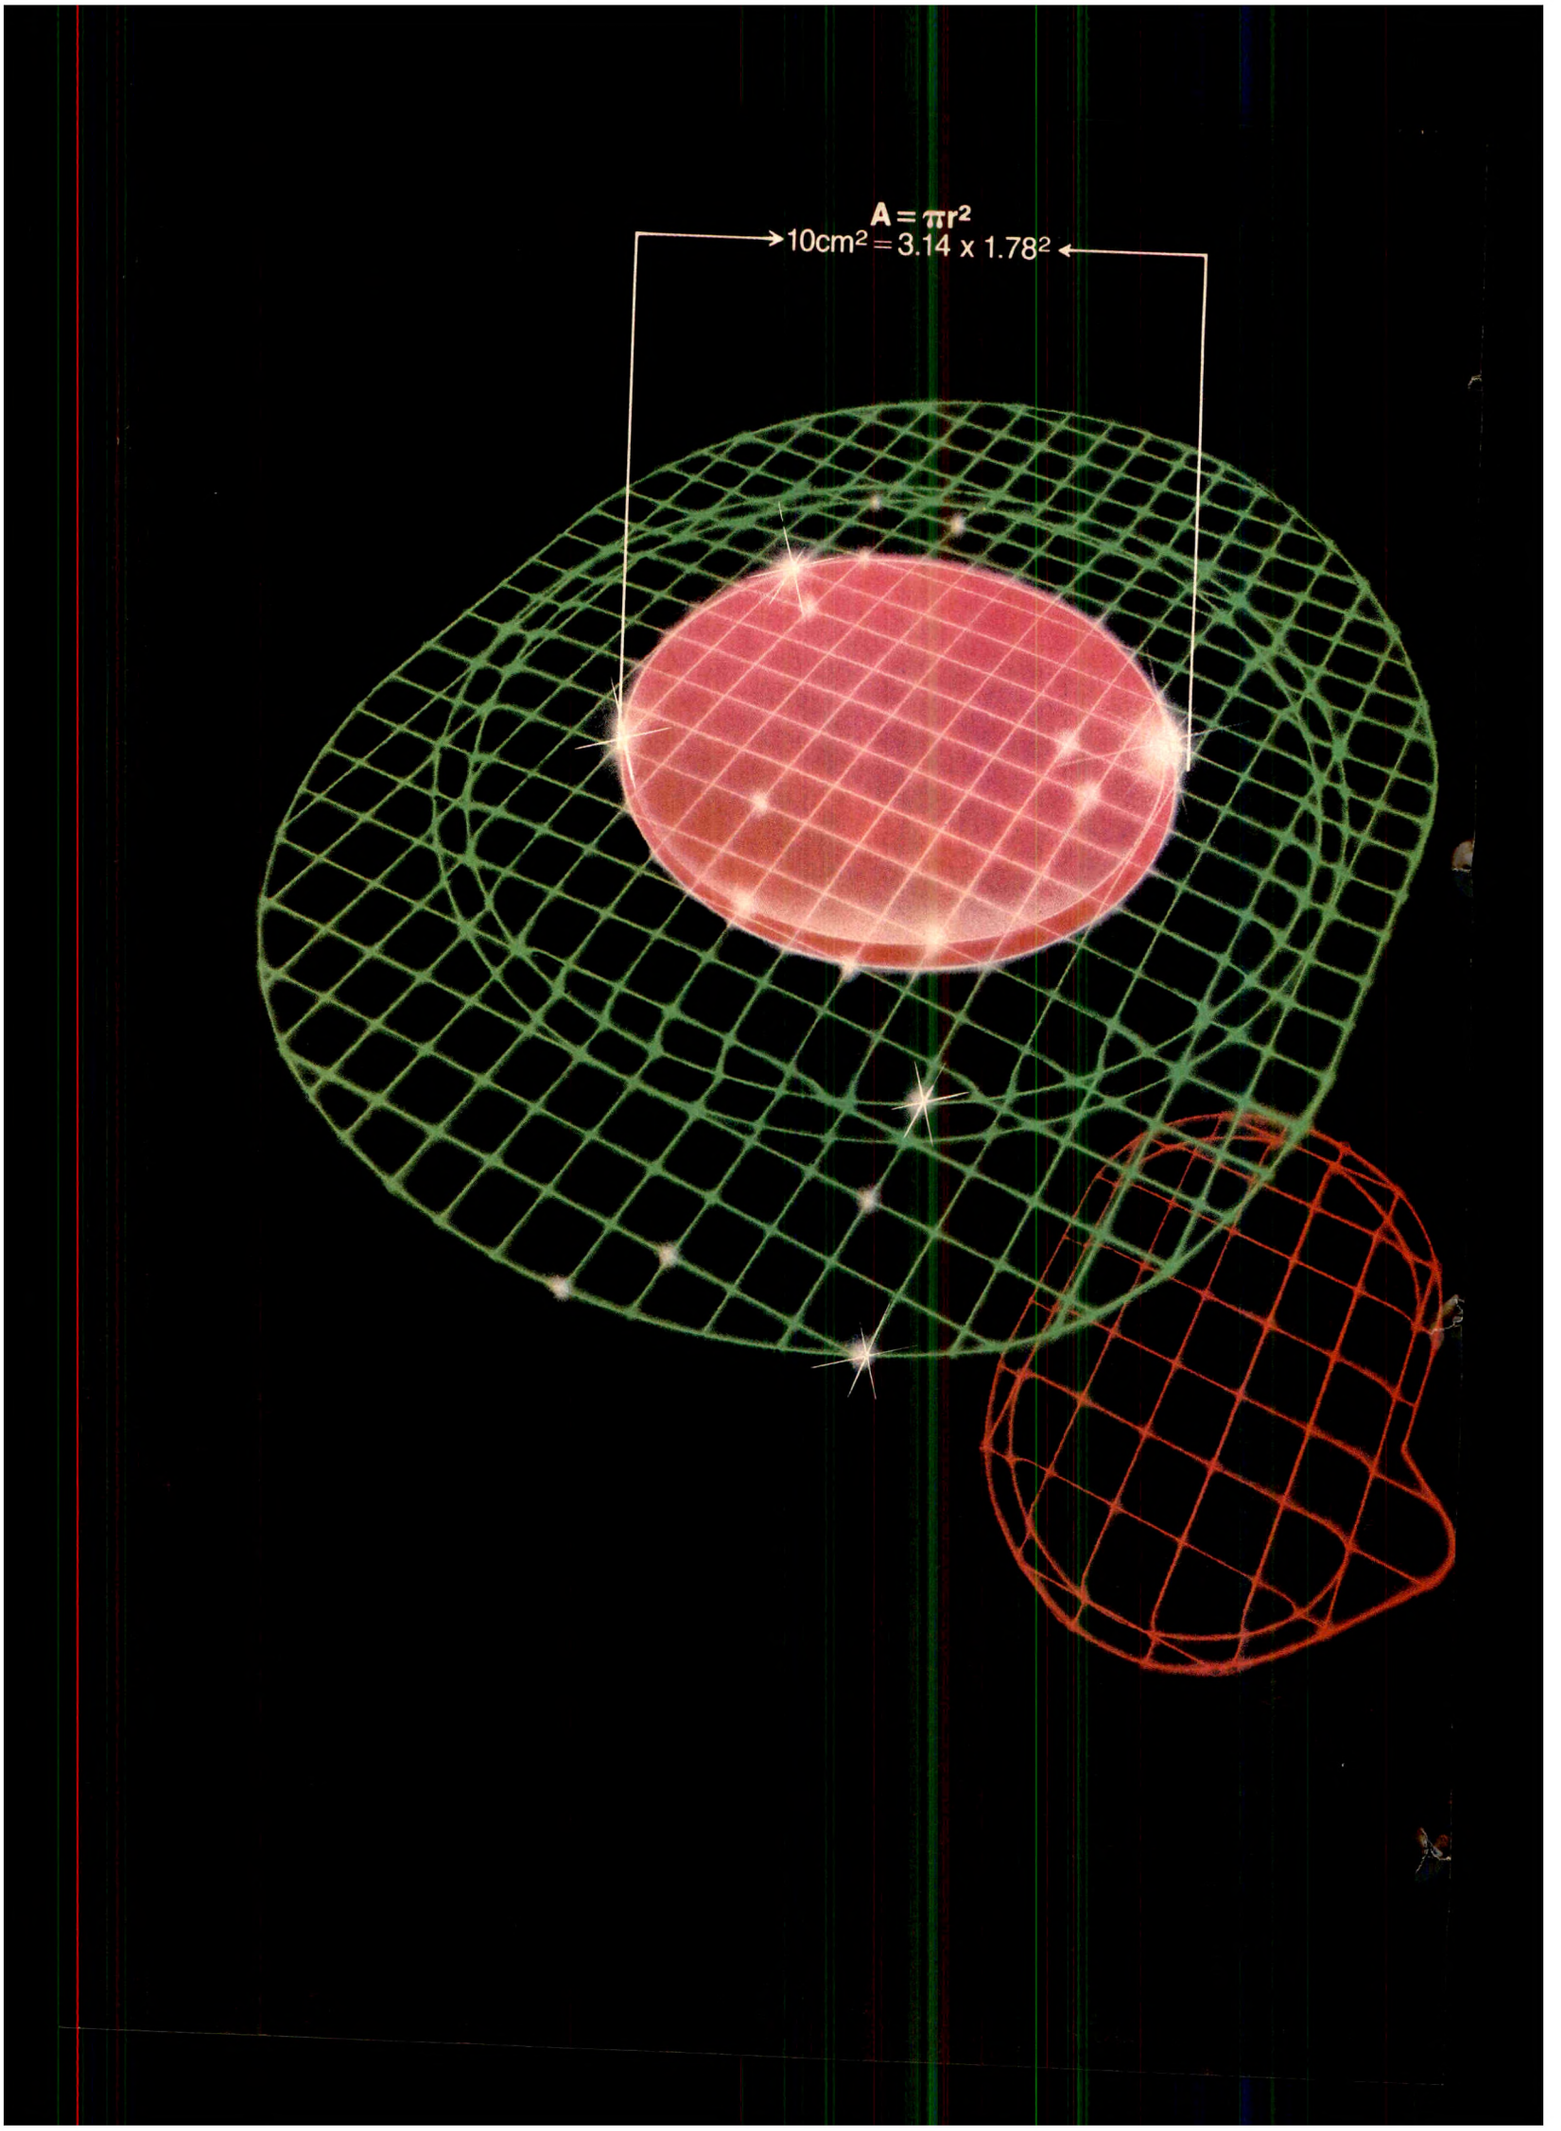
**817 Myocardial Texture Characterization by Two-Dimensional Echocardiography**

ANIL K. BHANDARI and NAVIN C. NANDA

Twenty-four normal subjects and 181 patients with various cardiac disorders (36 autopsies) were studied by 2-dimensional echocardiography. All patients with infiltrative disorders (amyloidosis and Pompe's disease) showed multiple, discrete, and small highly refractile echoes (HREs) in the myocardium. However, this finding was nonspecific and was observed in many other conditions. In the noninfiltrative group, HREs in the autopsied cases were shown to result from gross fibrosis/endocardiofibroelastosis utilizing in vitro echocardiographic studies and metallic probe guided biopsies, whereas HREs in the autopsied cases with cardiac amyloidosis could be correlated only with amyloid deposits since fibrosis was absent. Larger HREs presenting as broad patches or long linear echoes in the myocardium were seen in old myocardial infarctions and congestive cardiomyopathy and were correlated with large areas of myocardial fibrosis.

**826 Sensitivity of Technetium-99m–Pyrophosphate Scintigraphy in Diagnosing Cardiac Amyloidosis**

RODNEY H. FALK, VICTOR W. LEE, ALAN RUBINOW, WILLIAM B. HOOD, Jr., and ALAN S. COHEN



Technetium pyrophosphate scintigraphy, performed prospectively in 20 patients with systemic primary amyloidosis, demonstrated myocardial uptake of equal or greater intensity than that of the ribs in 8 of 9 subjects with heart failure and 9 of 11 with abnormal echocardiograms. None of 10 control patients with nonamyloid, nonischemic heart failure had positive findings on scintigraphy. Increased left ventricular wall thickness measured by M-mode echocardiography correlated with myocardial pyrophosphate uptake. In the presence of an abnormal echocardiogram, technetium pyrophosphate scintigraphy is a sensitive and specific test in the diagnosis of cardiac amyloidosis.

**831 Survival in Men With Severe Chronic Left Ventricular Failure Due to Either Coronary Heart Disease or Idiopathic Dilated Cardiomyopathy**

JOSEPH A. FRANCIOSA, MARY WILEN, SUSAN ZIESCHE, and JAY N. COHN

A greater misunderstanding of the course of congestive heart failure (CHF) is needed. In this study 182 patients with refractory CHF due to coronary artery disease (95 patients) or idiopathic dilated cardiomyopathy (87 patients) were followed up. Total mortality was 34% at 1 year, 59% at 2 years, and 76% at 3 years. The incidence of sudden death was 45%, and did not differ between groups. Mortality was worse in coronary artery disease than idiopathic dilated cardiomyopathy (46 versus 23% at 1 year, and 69 versus 48% at 2 years, $p < 0.01$). At entry hemodynamic abnormalities were more severe in patients who did not survive.

# Designed with the patient in mind.

**People move, bend, stretch, perspire.**
When we designed Nitro-Dur™ (nitroglycerin) Transdermal Infusion System, we designed it with features to accommodate these human factors. Because of the size of Nitro-Dur it has features that other nitroglycerin systems don't have.

**It's big because it's the only one with a wide adhesive strip.**
If angina patients were supine for 24 hours, adhesion would be a minor concern. But people move, bend, stretch, and turn while awake and asleep. A system has to stay put throughout all these movements.

In developing Nitro-Dur, we tested dozens of tapes before we settled on a microporous tape known for its excellent adhesion, one that doesn't leave the skin macerated and is relatively painless on removal.

The Nitro-Dur adhesive strip is wider than that on any other system. Wide enough to stay put during a 24-hour day of walking, showering, bending, standing or sleeping. Wide enough to prevent leaking or falling off.

**It's big because it's the only one with an absorbent pad.**
Because perspiration could affect adhesion, we added an absorbent pad behind the matrix. Nitro-Dur is the only system with this feature.

**Surface area determines the dose.**
The stratum corneum regulates the absorption of cutaneously applied nitroglycerin. Therefore, as the surface area of application is increased the dose of nitroglycerin also increases. To insure a fixed surface area, we offer a solid—a gel polymer matrix that contains the active drug.

**The only transdermal to offer you greater dosage flexibility.**
Nitro-Dur has four dosage strengths—5, 10, 15 and 20 $cm^2$. Other systems limit your options to two strengths.

**The only place it's smaller—the cost to your patients.**
Your patients can save up to $75 a year using Nitro-Dur rather than competitive products. Considering that they may be taking the product for years, that's a very important advantage.[1]

The human factor made us big. You made us the largest-selling transdermal nitroglycerin system.

**The most widely prescribed transdermal nitroglycerin system.**

**Nitro-Dur™**
(nitroglycerin)
Transdermal Infusion System

Please see next page for a summary of prescribing information.

# Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

**DESCRIPTION:** The Nitro-Dur Transdermal Infusion System contains nitroglycerin in a gel-like matrix composed of glycerin, water (purified), lactose, polyvinyl alcohol, povidone and sodium citrate to provide a continuous source of the active ingredient. Nitro-Dur is available in dosage sizes 5cm², 10cm², 15cm² and 20cm², containing 26 mg, 51 mg, 77 mg and 104 mg of nitroglycerin, respectively, thereby providing precise dosing levels of nitroglycerin. Nitro-Dur has a rated release *in vivo* of approximately 0.5mg/cm²/24 hours. Each unit is sealed in a polyester-foil-polyethylene laminate. The bandage portion consists of a medical grade non-woven, heat sealable, microporous tape.

**CLINICAL PHARMACOLOGY:** When the Nitro-Dur system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In bioavailability studies[2] transdermal absorption of nitroglycerin from the gel-like matrix achieved steady state venous plasma levels comparable to that of sublingual nitroglycerin and maintained these levels for 24 hours. Therapeutic effect is achieved within 30 minutes after application of the unit, and persists about 30 minutes after removal of the unit.

**INDICATIONS AND USAGE:** Prevention and treatment of angina pectoris due to coronary artery disease.

**CONTRAINDICATIONS:** Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

**WARNINGS:** The Nitro-Dur system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of angina patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

**PRECAUTIONS:** Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced.

Nitro-Dur is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

**ADVERSE REACTIONS:** Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing Nitro-Dur therapy. If headache persists, the Nitro-Dur dosage should be reduced.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the Nitro-Dur dosage should be reduced or use of the product discontinued.

**HOW SUPPLIED:** Nitro-Dur Transdermal Infusion System, 5cm², 10cm², 15cm² and 20cm², is available in unit dose packages of 28.

**CAUTION:** Federal law prohibits dispensing without a prescription.

**PATIENT INSTRUCTIONS FOR APPLICATION:** Patient instructions are furnished with each unit dose package.

# MYOCARDIAL REVASCULARIZATION

## MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

## The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

## Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

## METHODS

**837 Evaluation of Left Ventricular Performance Using Digital Subtraction Angiography**

MARVIN W. KRONENBERG, RONALD R. PRICE, CLYDE W. SMITH, ROSE MARIE ROBERTSON, JAMES M. PERRY, DAVID R. PICKENS, MICHAEL J. DOMANSKI, C. LEON PARTAIN, and GOTTLIEB C. FRIESINGER

Cardiac applications for digital subtraction angiography appear promising. Thus, left ventricular volume, ejection fraction, and regional wall motion by digital subtraction angiography were evaluated after intravenous injection of 40 ml of iodinated contrast medium and after left ventricular injection of 5 to 10 ml. A film-based system of the authors' own design was used. Results were compared with those after 40 ml direct left ventricular contrast injection. The ventriculograms after intravenous injection showed close correlation with direct left ventricular injections for ejection fraction, volume, and regional wall motion. After small-volume left ventricular injections, the ventricular image was enhanced markedly by digital subtraction, and correlations between small and large volume ventriculograms were close for left ventricular ejection fraction, volume, and regional wall motion. Thus, digital subtraction angiography improves the visibility of the left ventricle after either intravenous or small-volume direct left ventricular injection. Digital images produce excellent estimates of left ventricular volume and should have considerable usefulness for the study of cardiac performance and anatomy.

**843 Evaluation of Intracardiac Thrombus With Computed Tomography**

HARUO TOMODA, MITSUMOTO HOSHIAI, HIDEO FURUYA, SACHIO KURIBAYASHI, MAKOTO OOTAKI, SEIYA MATSUYAMA, SHIROSAKU KOIDE, SHIAKI KAWADA, and AKIRA SHOTSU

Left atrial and left ventricular thrombus was evaluated by computed tomography in 56 patients: Group I, 28 patients with mitral valve disease; and Group II, 28 patients with myocardial infarction. Computed tomography, 2-dimensional echocardiography, angiocardiography, and open-heart surgery or autopsy were performed in these patients. The sensitivity in detecting left atrial thrombus was 100% with computed tomography, 60% with 2-dimensional echocardiography, and 70% with angiocardiography. The specificity in detecting left atrial thrombus was 91% with computed tomography, 86% with 2-dimensional echocardiography, and 88% with angiocardiography. Left ventricular thrombus was visualized by computed tomography with similar or greater accuracy than other diagnostic methods, although the sensitivity and specificity were not ascertained because surgery or autopsy was performed in only a minority of Group II patients.

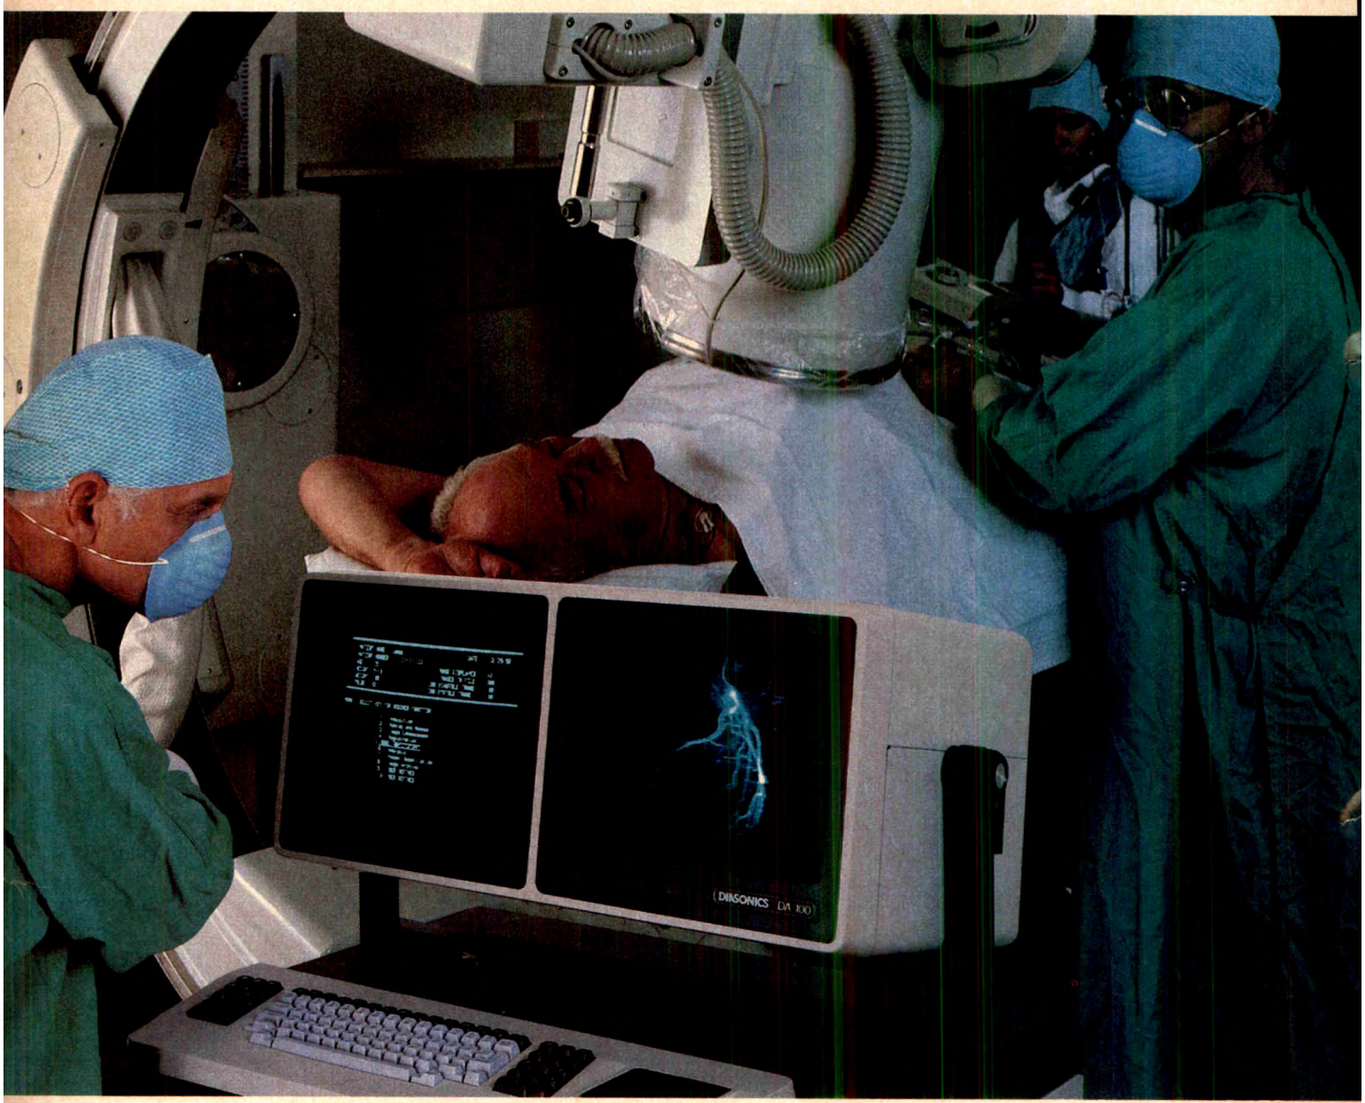
**853 Absolute Left Ventricular Volume From Gated Blood Pool Imaging With Use of Esophageal Transmission Measurement**

ALAN H. MAURER, JEFFRY A. SIEGEL, BARRY S. DENENBERG, BLASE A. CARABELLO, ARNOLD K. GASH, JAMES F. SPANN, and LEON S. MALMUD

A new method for determining absolute left ventricular volume from equilibrium gated blood pool images was validated by comparing gated blood pool imaging with contrast ventriculography. The technique is geometry-independent and is the first to correct for tissue attenuation utilizing an in vivo point source. An orally administered capsule containing 1 to 2 mCi of technetium-99m sulfur colloid is used for this purpose. Left ventricular volumes are determined by dividing attenuation- and background-corrected count rates obtained from semiautomated left ventricular regions of interest by the count rate per milliliter from a blood sample.

**859 Effect of Exercise Protocol on the Left Ventricular Response to Exercise**

CARL FOSTER, DUNCAN S. DYMOND, JAMES D. ANHOLM, MICHAEL L. POLLOCK, and DONALD H. SCHMIDT, *With the technical assistance of* JOHN G. CARPENTER



The effect of exercise protocol on the left ventricular ejection fraction response to exercise was evaluated in a sample of 120 healthy male volunteers. When first-pass radionuclide angiograms were obtained during peak upright graded bicycle exercise with >85% of age-predicted maximal heart rate attained, there was no net change in ejection fraction from rest to exercise. When exercise was submaximal, either through failure to attain at least 85% of the age-predicted maximal heart rate or through the use of postexercise imaging, the ejection fraction increased significantly from rest to exercise. If exercise was supermaximal and was presented abruptly, either with or without warm-up, the ejection fraction decreased from rest to exercise. The results suggest that interpretation of exercise radionuclide angiograms on the basis of reported values for normal and abnormal responses is dependent on careful replication of exercise protocol.

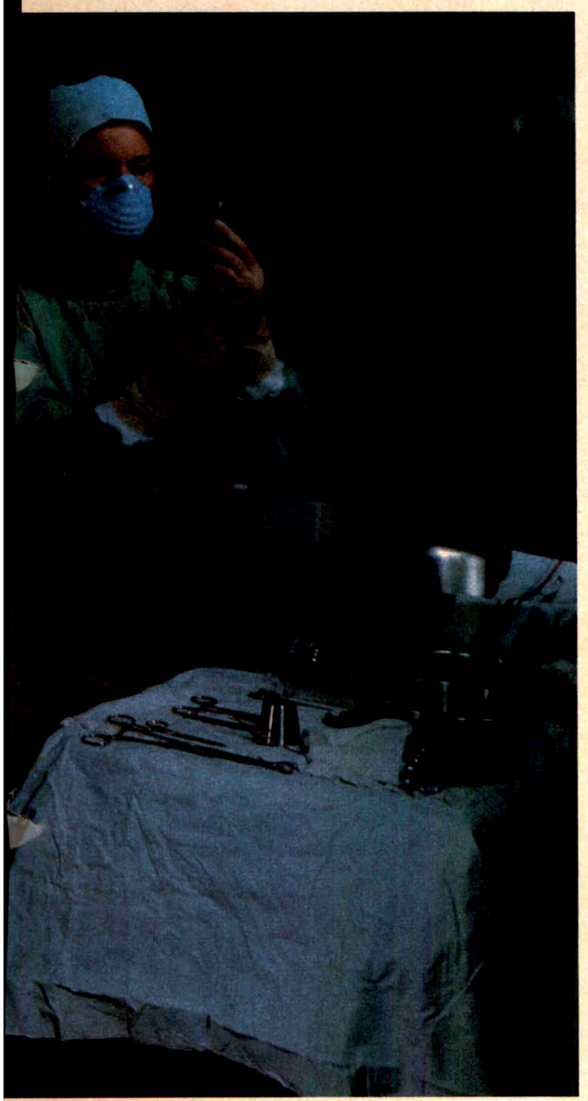
# DIASONICS



# *TOTALLY DIGITAL CORONARY*

## *Superior images with high frame*

# *IT'S WHERE IMAGING IS GOING...*

# ARTERY IMAGING...AngioVue.™
## rate processing and image enhancement.

### Coronary artery imaging with a totally digital system.

Diasonics' new AngioVue Digital Angiography System produces digital images clinically equivalent to cine film through digital image manipulation and image enhancement algorithms. The AngioVue allows clear visualization of coronary arteries with fine detail. It's all possible through Diasonics' unique pulsed mode digital acquisition gated at 8/fps with 512x512 resolution—and totally digital storage.

### Faster, more accurate, quantitative ventriculography.

By combining superior digital images acquired at 30 fps and powerful computer analysis, faster, more accurate ventriculography is performed.

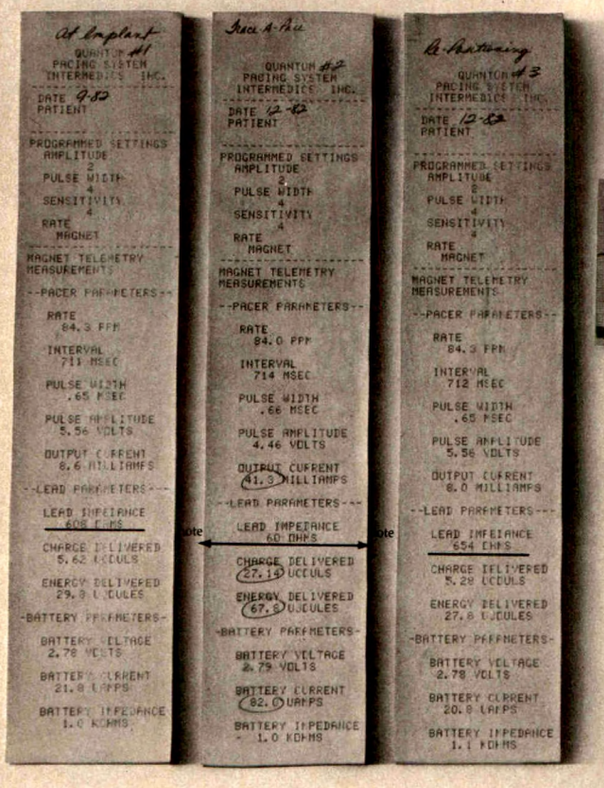
Through standard area length techniques and densitometry, AngioVue provides easy calculation of ejection fraction, C.O. and C.I. Diasonics' advanced software allows segmental wall motion and functional image analyses. And, with its 256x256 matrix, ventriculography is performed with better resolution than nuclear cardiology.

### Now, digital angiography for all cath lab imaging procedures.

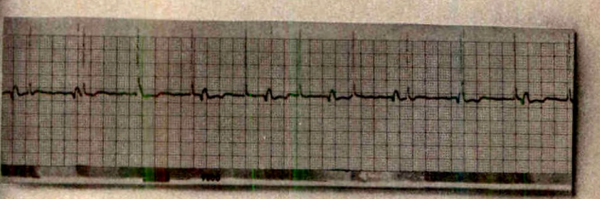
With the Diasonics AngioVue, you can more effectively perform functional studies, PTCA, drug therapy and vascular imaging. You use less dye permitting more injections with less risk to the patient. And AngioVue interfaces directly with your existing equipment and can provide dual room and biplane capabilities.

**DIASONICS**

*DIASONICS, INC.*
*1545 Barber Lane, Milpitas, CA 95035*
*(408) 946-9001*



### Consult a Diasonics professional.



AngioVue brings to the cath lab the most advanced digital imaging technology available, with all the benefits of computerized analysis and the flexibility to meet your future needs. For a complete review of the AngioVue, consult the Diasonics professional in your area.

# QUANTUM: THE PROBLEM SOLVER

## Indication For Pacing: Intermittent Heartblock, Sinus Arrest.

*ECG: Loss of capture*

*This is the second in a series of case histories demonstrating the Quantum system's unique ability to help physicians diagnose the condition of a pacemaker patient.*

**An Actual Case History***

Patient: MALE
Age: 67 YEARS
Indication for Pacing: INTERMITTENT HEARTBLOCK, SINUS ARREST

The patient received a bipolar Quantum™ pulse generator with a transvenous bipolar lead. Intraoperative fluoroscopy and postoperative telemetry indicated satisfactory lead position.

Several months later, during routine telephone follow-up through Intermedics' Trace-A-Pace™ service, the patient's transtelephonic telemetry readout displayed abnormally low lead impedance values. A subsequent ECG strip indicated intermittent pacing, although the patient had experienced no discomfort.

Reexamination revealed insulation fractures of the lead that probably were causing intermittent shorting of the electrode. Access to the lead was gained via the pacer pocket and the repair was effected by medical adhesive and a suture sleeve tied in place. Postrepair pacing is normal with telemetry indicating acceptable lead impedance values.

*This is just one example of how Quantum helped pinpoint the exact source of a patient's problem. The complete Quantum pacing system, including a Decoder, Printer, Transmitter, Intermedics Programmer and three pacemaker models, represents the most sophisticated technology available today. By providing you with more information, Quantum helps you better manage your pacemaker patients.*

*This actual case history is on record at Intermedics, Inc. For more information, contact the Marketing Dept., Intermedics, Inc.

## EXPERIMENTAL STUDIES

**865 Influence of Aortic Stenosis on the Hemodynamic Importance of Coronary Artery Narrowing in Dogs Without Left Ventricular Hypertrophy**

ROBERT L. FELDMAN, WILMER W. NICHOLS, JAMES R. EDGERTON, C. RICHARD CONTI, and CARL J. PEPINE

This study evaluated coronary hemodynamic effects of both controlled left ventricular outflow obstruction simulating aortic valve stenosis and graded coronary artery diameter narrowing in open-chest dogs without left ventricular hypertrophy. Mean coronary flow during aortic stenosis increased an average of 17%, as did the percentage of flow occurring during diastole. However, there was a concomitant decrease in the endocardial/epicardial ratio. During reactive hyperemia, values with no coronary narrowing during aortic stenosis were similar to peak hyperemic flows with 60% coronary narrowing during control. With coronary narrowings estimated at 90%, mean coronary flow decreased with or without aortic stenosis. At this time transmural flow distribution also decreased but was consistently lower during aortic stenosis. These data suggest that in a model of aortic stenosis without left ventricular hypertrophy, the changes in aortic and left ventricular pressures during aortic stenosis periods were sufficient to influence total coronary flow and transmural distribution. The addition of a coronary narrowing produced further coronary effects.

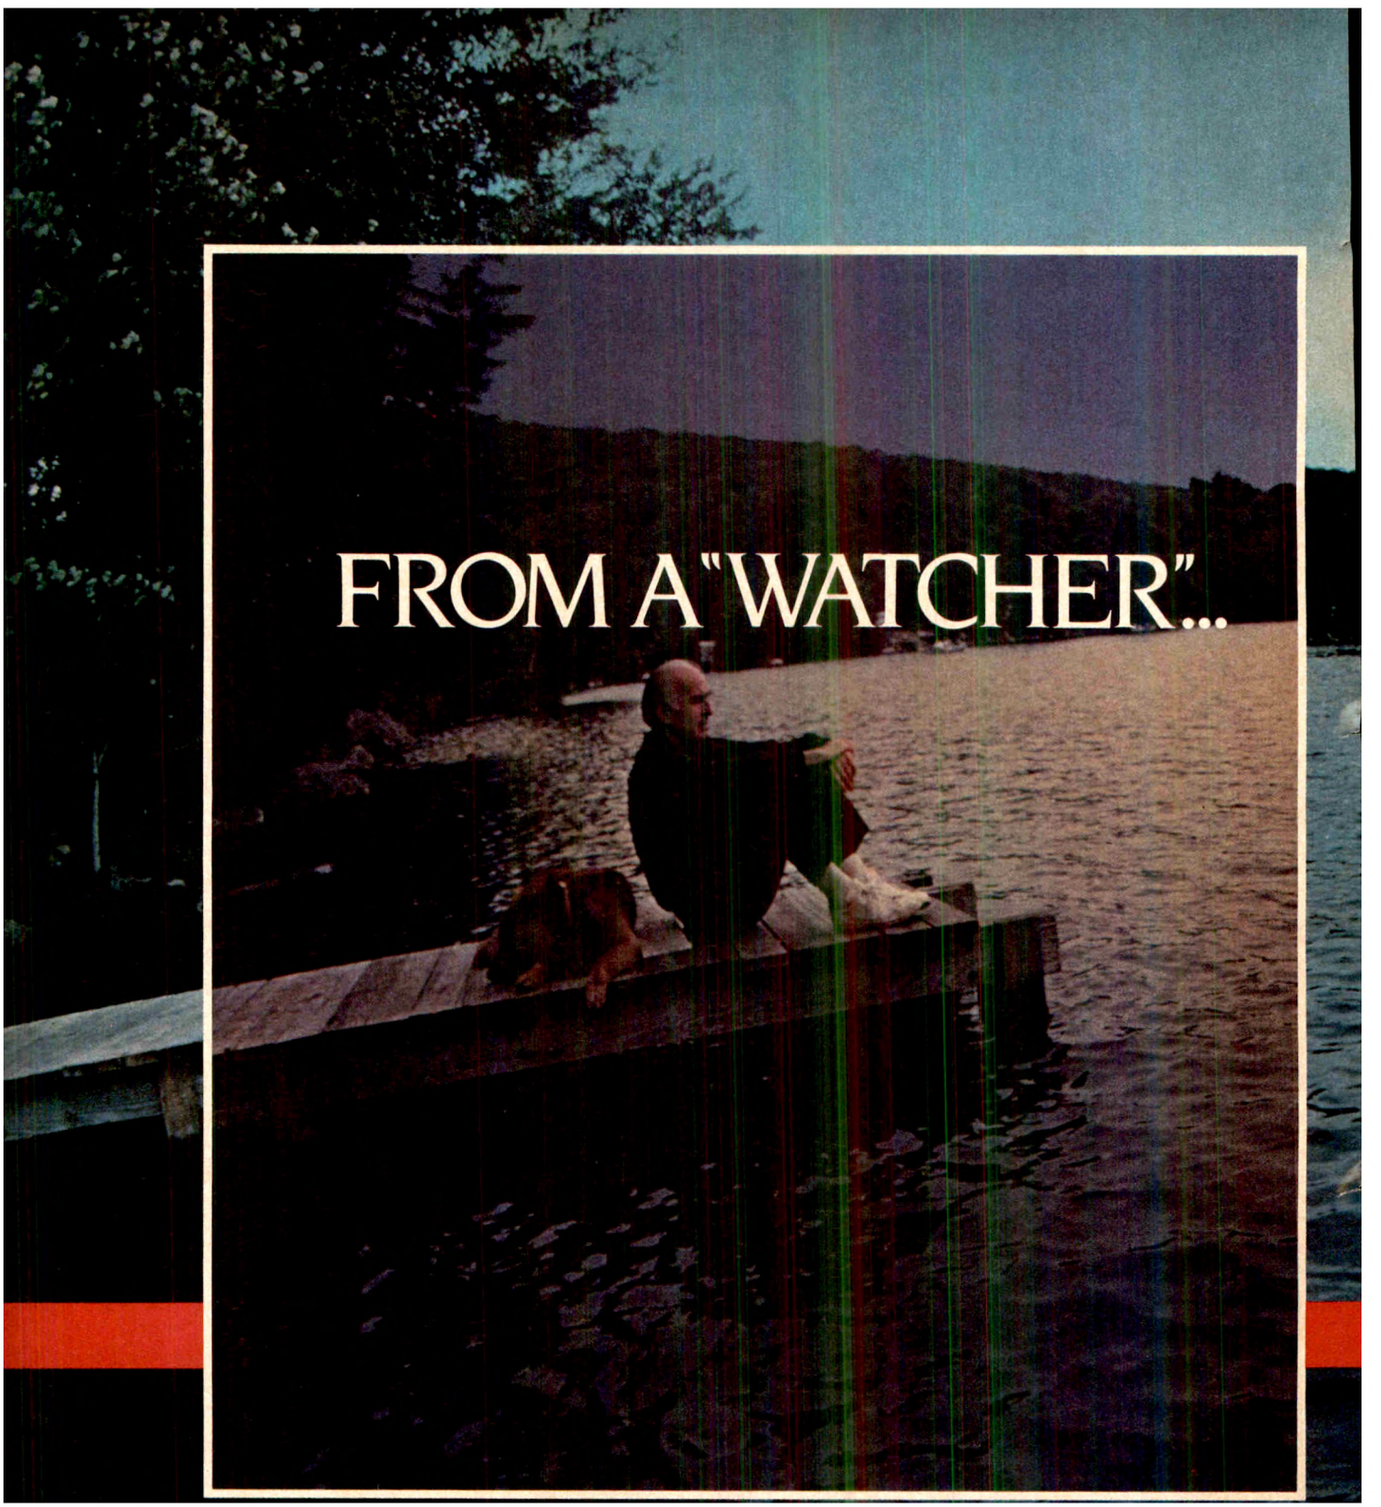
**872 Topographic Changes in the Left Ventricle After Experimentally Induced Myocardial Infarction in the Rat**

CHARLES S. ROBERTS, DEREK MACLEAN, EUGENE BRAUNWALD, PETER R. MAROKO, and ROBERT A. KLONER

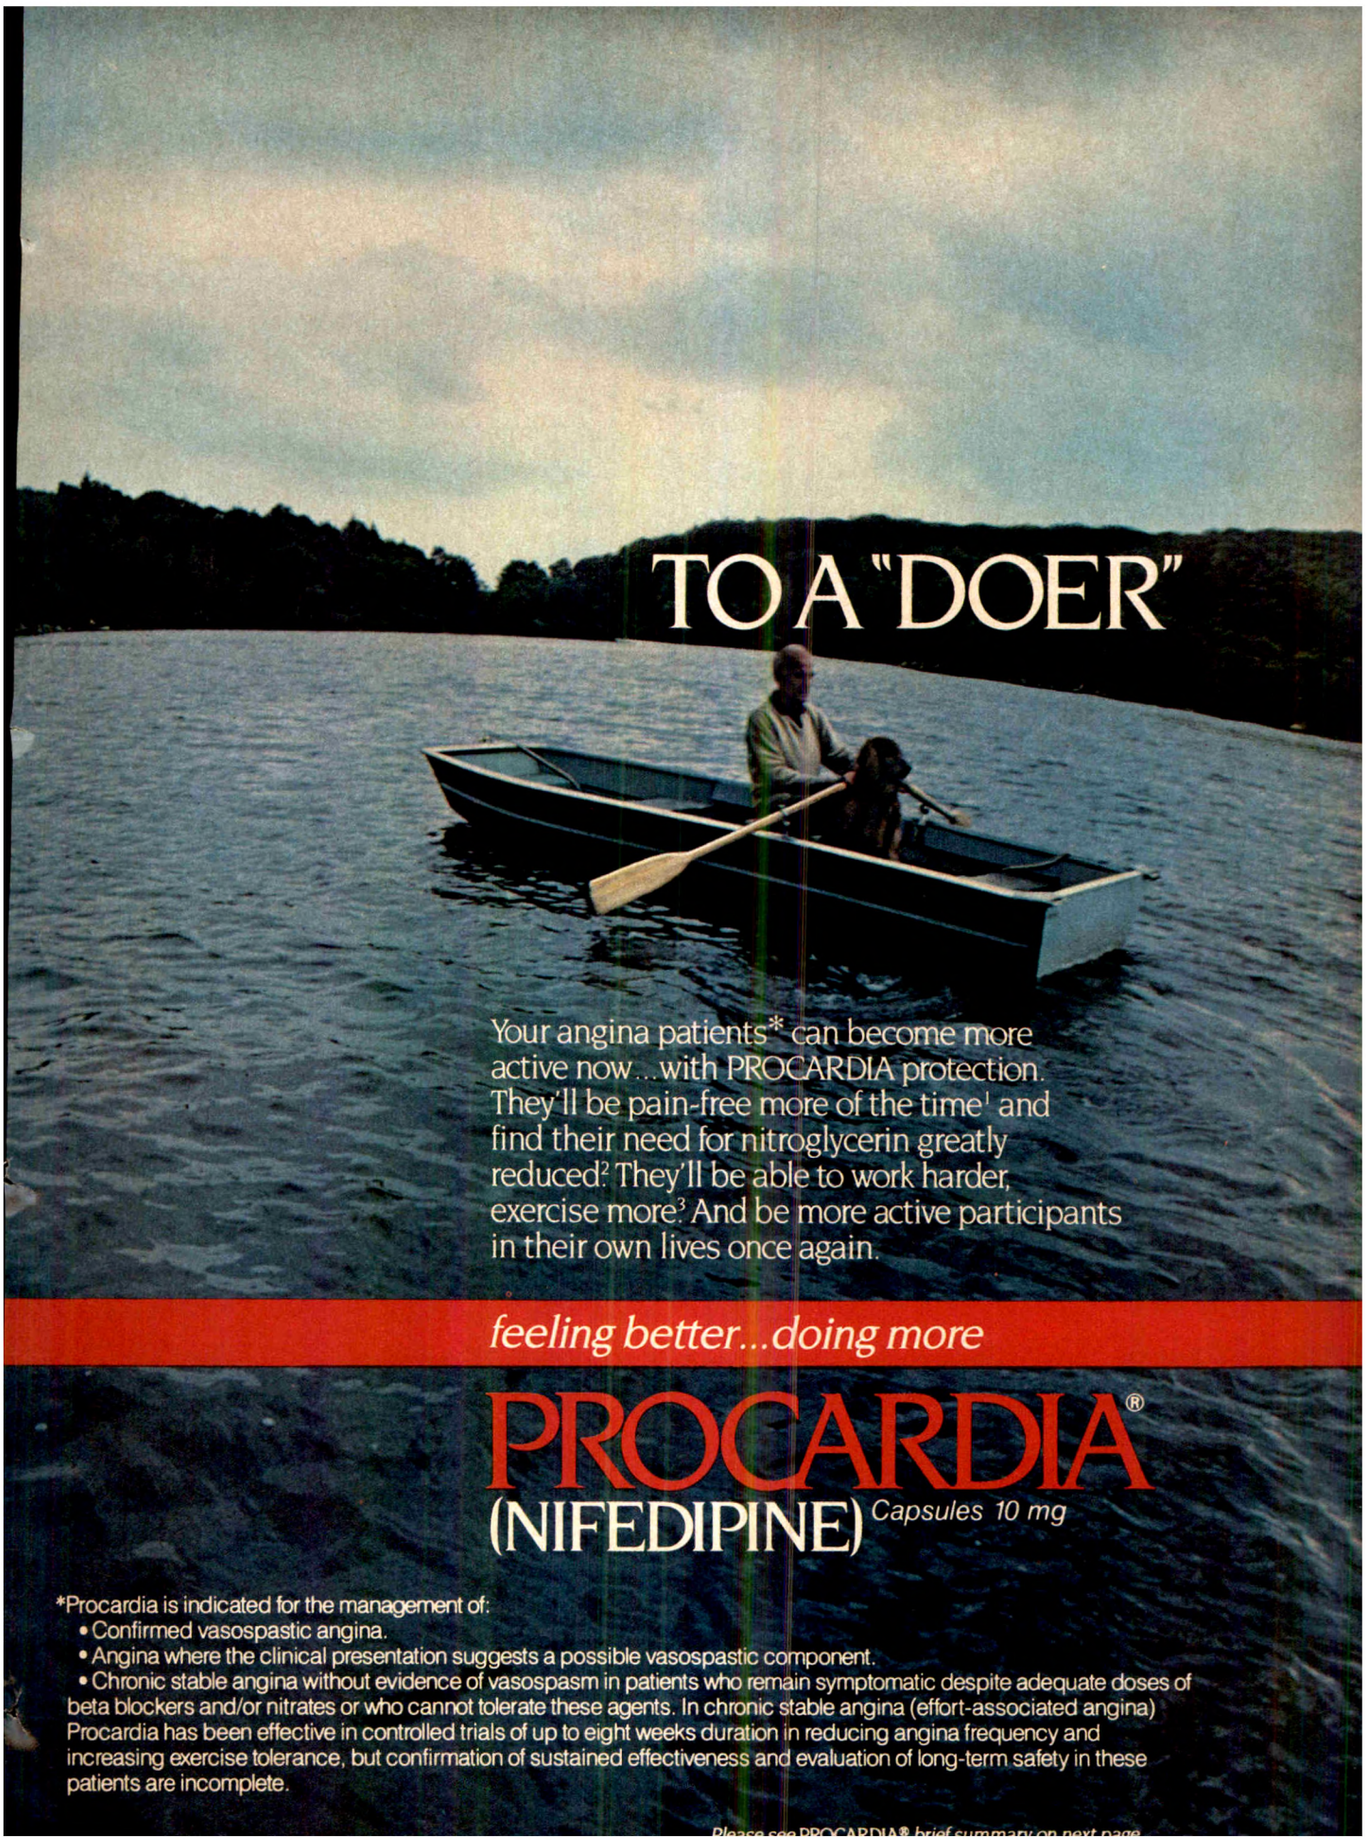
The factors which determine the thickness of transmural myocardial infarctions are unknown. Therefore, the relation between size and thickness of transmural infarcts was studied in 67 rats 21 days after occlusion of the left main coronary artery. Septal wall thickness was similar in rats with transmural infarcts and in sham-operated rats. There was no significant correlation between infarct size and thickness ($r = 0.10$) or circumferential length of infarct ($r = 0.17$). Large infarcts resulted in a 23% greater loss of myocardial tissue ($p < 0.001$), greater expansion of the left ventricular (LV) cavity area ($18 \pm 9$ mm$^2$ compared with $14 \pm 1$ mm$^2$ in small infarcts, $p < 0.005$), and lengthening of the noninfarcted septal wall ($7.2 \pm 1.1$ mm and $6.7 \pm 1.0$ mm in large and small infarcts, respectively [$p < 0.05$], and $6.3 \pm 0.1$ mm in shams). Increase in cavity area and noninfarcted septal length in infarcted ventricles suggested a volume overload hypertrophy, which at 3 weeks was nonetheless inadequate to provide as much normal muscle as was present in sham-operated rats. In an additional 9 rats with subendocardial infarctions (involving <75% of the LV wall from endo- to epicardium), the LV walls were thicker ($94 \pm 5$% of septal wall thickness, compared with $35 \pm 1$% for transmural infarcts, $p < 0.001$), and there was an inverse correlation between infarct size and thickness.

**877 Scar Thinning Due to Ibuprofen Administration After Experimental Myocardial Infarction**

EDWARD J. BROWN, Jr., ROBERT A. KLONER, FREDERICK J. SCHOEN, HAIM HAMMERMAN, SHARON HALE, and EUGENE BRAUNWALD



While much attention has been directed toward interventions which reduce myocardial infarct size, the effect of such agents on the healing phase of myocardial infarction is largely unknown. The effect of ibuprofen and aspirin on the healing of experimental canine myocardial infarctions was investigated. After coronary artery ligation, dogs received either saline solution, aspirin, high-dose ibuprofen or low-dose ibuprofen. Six weeks after coronary artery ligation the animals were killed and the hearts were removed for analysis of scar thickness. The myocardial infarct scars of the animals receiving ibuprofen were thinned compared with those of the control animals. Animals receiving aspirin demonstrated no scar thinning. Thus, ibuprofen increases the incidence of scar thinning after myocardial infarction.



**884 Effects of Flurbiprofen in Altering the Size of Myocardial Infarcts in Dogs: Reduction or Delay?**

DAVID E. CHAMBERS, DEREK M. YELLON, DAVID J. HEARSE, and JAMES M. DOWNEY

Anti-inflammatory agents such as flurbiprofen have been reported to reduce myocardial infarct size. In the present study, a closed-chest model of permanent coronary occlusion was used. Groups of dogs were subjected to either 6 or 24 hours of elapsed ischemia. Flurbiprofen (1 mg/kg) was given immediately after occlusion and thereafter every 6 hours. Risk zone to infarct size ratios for the 24 hour group revealed that flurbiprofen treatment had no effect on infarct size. In contrast, when hearts were examined after only 6 hours of ischemia, infarct size was considerably reduced in the flurbiprofen-treated group. These results indicate that during myocardial ischemia, flurbiprofen may delay but not prevent tissue injury.

FROM A "WATCHER"...

Your angina patients* can become more active now...with PROCARDIA protection. They'll be pain-free more of the time[1] and find their need for nitroglycerin greatly reduced.[2] They'll be able to work harder, exercise more.[3] And be more active participants in their own lives once again.

*feeling better...doing more*

# PROCARDIA®
## (NIFEDIPINE) *Capsules 10 mg*

*Procardia is indicated for the management of:

- Confirmed vasospastic angina.
- Angina where the clinical presentation suggests a possible vasospastic component.
- Chronic stable angina without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or nitrates or who cannot tolerate these agents. In chronic stable angina (effort-associated angina) Procardia has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

*Please see PROCARDIA® brief summary on next page*

*feeling better...doing more*

# PROCARDIA®
# (NIFEDIPINE) *Capsules 10 mg*

## *–Usual effective dosage is 30-60 mg/day*

For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely.

Because Procardia decreases peripheral vascular resistance, careful monitoring of blood pressure during initial administration and titration is suggested. Close observation is especially recommended for patients taking medication known to lower blood pressure.

## *–Offers a favorable safety profile*

Most frequently reported side effects, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%.

**BRIEF SUMMARY**
**PROCARDIA® CAPSULES** For Oral Use
(nifedipine)

**INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA** (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

**II. Chronic Stable Angina (Classical Effort-Associated Angina):** PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in those patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See Warnings.)

**CONTRAINDICATIONS:** Known hypersensitivity reaction to PROCARDIA.

**WARNINGS: Excessive Hypotension:** Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been reported in patients receiving PROCARDIA together with a beta blocking agent who underwent coronary artery bypass surgery using high dose fentanyl anesthesia. The interaction with high dose fentanyl appears to be due to the combination of PROCARDIA and a beta blocker, but the possibility that it may occur with PROCARDIA alone, with low doses of fentanyl, in other surgical procedures, or with other narcotic analgesics cannot be ruled out.

**Increased Angina:** Occasional patients have developed well documented increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases. The mechanism of this response is not established but could result from decreased coronary perfusion associated with decreased diastolic pressure with increased heart rate, or from increased demand resulting from increased heart rate alone.

**Beta Blocker Withdrawal:** Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

**Congestive Heart Failure:** Rarely, patients, usually receiving a beta blocker, have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

**PRECAUTIONS: General: Hypotension:** Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See Warnings.)

**Peripheral edema:** Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

**Drug interactions:** Beta-adrenergic blocking agents: (See Indications and Warnings.) Experience in over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

Digitalis: Administration of PROCARDIA with digoxin increased digoxin levels in nine of twelve normal volunteers. The average increase was 45%. Another investigator found no increase in digoxin levels in thirteen patients with coronary artery disease. In an uncontrolled study of over two hundred patients with congestive heart failure during which digoxin blood levels were not measured, digitalis toxicity was not observed. Since there have been isolated reports of patients with elevated digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing PROCARDIA to avoid possible over- or under-digitalization.

Carcinogenesis, mutagenesis, impairment of fertility: When given to rats prior to mating, nifedipine caused reduced fertility at a dose approximately 30 times the maximum recommended human dose.

Pregnancy: Category C. Please see full prescribing information with reference to teratogenicity in rats, embryotoxicity in rats, mice and rabbits, and abnormalities in monkeys.

**ADVERSE REACTIONS:** The most common adverse events include dizziness or light-headedness, peripheral edema, nausea, weakness, headache and flushing each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA or concomitant antianginal medication. Additionally, the following have been reported: muscle cramps, nervousness, dyspnea, nasal and chest congestion, diarrhea, constipation, inflammation, joint stiffness, shakiness, sleep disturbances, blurred vision, difficulties in balance, dermatitis, pruritus, urticaria, fever, sweating, chills, and sexual difficulties. Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of the disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

**Laboratory Tests:** Rare, mild to moderate, transient elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT, and SGPT have been noted, and a single incident of significantly elevated transaminases and alkaline phosphatase was seen in a patient with a history of gall bladder disease after about eleven months of nifedipine therapy. The relationship to PROCARDIA therapy is uncertain. These laboratory abnormalities have rarely been associated with clinical symptoms. Cholestasis, possibly due to PROCARDIA therapy, has been reported twice in the extensive world literature.

**HOW SUPPLIED:** Each orange, soft gelatin PROCARDIA CAPSULE contains 10 mg of nifedipine. PROCARDIA CAPSULES are supplied in bottles of 100 (NDC 0069-2600-66), 300 (NDC 0069-2600-72), and unit dose (10x10) (NDC 0069-2600-41). The capsules should be protected from light and moisture and stored at controlled room temperature 59° to 77°F (15° to 25°C) in the manufacturer's original container.

891 **Effects of Reduced Coronary Flow on Thallium-201 Accumulation and Release in an In Vitro Rat Heart Preparation**

SAMUEL Z. GOLDHABER, JOHN B. NEWELL, JOANNE S. INGWALL, GERALD M. POHOST, NATHANIEL M. ALPERT, and ERIC T. FOSSEL

To study the relation between myocardial thallium-201 uptake, thallium-201 release, and reduced coronary flow, isolated Langendorff rat hours (n = 8) were perfused for 3 hours at constant flows ranging from physiologic (12 ml/min) to severely ischemic (1.5 ml/min); thallium activity was monitoring with a scintillation probe. Each heart was perfused for 1 hour with thallium buffer, followed by 2 hours with thallium-free buffer at the same flow rate. Accumulation curves for all 4 flows were monoexponential. However, release curves during the 2 hours of washout with thallium-free buffer demonstrated a biexponential configuration. The early fast release component decreased with reductions in coronary flow, and the later slow release component did not vary significantly with flow. These data show that thallium clearance has at least 2 components: a rapid (possibly extracellular) component related to coronary flow and a slow (possibly intracellular) component independent of coronary flow. These findings should be useful in providing a better understanding of thallium redistribution observed clinically.

CORONARY HEART DISEASE

# Influence of Partial Sympathetic Denervation on the Results Of Myocardial Revascularization in Variant Angina

AMADEO BETRIU, MD, JOSE LUIS POMAR, MD, MARTIAL G. BOURASSA, MD, and CLAUDE M. GRONDIN, MD

**Poor results of the aortocoronary bypass graft operation in the treatment of variant angina have been ascribed to recurrent vasospastic activity due to autonomic imbalance. Cardiac sympathetic denervation (plexectomy) may represent a rational approach in the prevention of vasospasm. To test the value of plexectomy in the treatment of variant angina, 31 patients were studied, 17 of whom (Group 1) underwent conventional coronary artery grafting whereas the remaining 14 (Group 2) underwent cardiac sympathetic denervation also. The 2 groups were similar with respect to age (54 ± 8 versus 50 ± 7 years), sex distribution (male/female ratio 12/5 versus 9/5), prevalence of coexisting effort angina (10 versus 12 patients), previous myocardial infarction (7 versus 4 patients), and duration of variant angina (3.3 ± 5.4 versus 2.4 ± 2.7 months). The left ventricular ejection fraction was comparable in both groups (60 ± 11 versus 60 ± 4%) as were left ventricular end-diastolic pressure (15 ± 4 versus 13 ± 5 mm Hg) and extent of coronary artery disease (65 versus 71% prevalence of multivessel disease).**

**The average duration of follow-up was 23 ± 15 months in Group 1 and 22 ± 18 months in Group 2 (p = not significant [NS]). There were no operative deaths. Four patients, 2 in each group, had a perioperative myocardial infarction. Seven patients in Group 1 and 1 patient in Group 2 had recurrent variant angina. There was sudden death and 2 infarcts in Group 1. Actuarial curves showed the cumulative probability of recurrent variant angina to be significantly lower ($p < 0.05$ and $p < 0.001$ at 6 and 10 months, respectively) in Group 2. This study suggests that cardiac sympathetic denervation may prevent recurrent vasospastic activity in variant angina.**

Calcium channel-blocking agents provide effective control of symptoms in most patients with the variant form of angina pectoris.[1–8] Nevertheless, coronary artery grafting is currently offered to a subset of patients with variant angina who present with fixed severe coronary artery stenoses and show poor response to medical treatment. Unfortunately, aortocoronary bypass grafting appears less successful in the variant form than in the classic form of angina,[9–11] as evidenced by a higher rate of graft occlusion[9,12–15] and of recurrence of symptoms despite graft patency.[1] Coronary artery spasm, the primary pathogenetic mechanism in variant angina[16–18] has been held responsible for the surgical failures.[1,9–11] Recent studies suggest that coronary artery spasm develops by activation of alpha receptors as a result of increased sympathetic activity.[19–21] Thus, the association of sympathetic denervation (plexectomy)

and coronary artery grafting may represent a reasonable surgical approach for patients with variant angina and obstructive coronary artery lesions.

Plexectomy in the treatment of variant angina was introduced in 1977.[10] Recently, Bertrand et al[11] reported on 22 patients undergoing combined plexectomy and coronary artery bypass grafting. To our knowledge no other clinical study dealing with cardiac denervation in the management of variant angina has been reported. To further elucidate the possible advantages of myocardial revascularization associated with plexectomy over the former procedure alone we studied 31 consecutive patients, 14 of whom had combined coronary artery bypass grafting and partial sympathetic denervation.

## Methods

**Patient group:** During a 5-year period ending in December 1981, 31 patients presenting with the variant form of angina underwent myocardial revascularization at the Montreal Heart Institute. Variant angina was defined as that occurring at rest and associated with a transient elevation of the S-T segment of ≥0.2 mV and no subsequent evidence of myocardial infarction. Surgery was performed because of failure of medical treatment to control the chest pain or because of the severity and location of coronary artery lesions, or both. Seventeen patients (Group 1) underwent aortocoronary bypass operation alone; the remaining 14 (Group 2) underwent, in addition to coronary artery grafting, partial sympathetic denervation.

**Clinical characterization (Table I):** The mean age of Group 1 was 54 years (range 42 to 66) and that of group 2 was 50 years (range 35 to 64). There were 12 men and 5 women in Group 1 and 9 men and 5 women in Group 2. Differences in age and sex distribution between the 2 groups were not statistically significant. Coexisting angina on effort was present in 10 patients in Group 1 and in 12 in Group 2 (NS). The prevalence of previous myocardial infarction (7 patients in Group 1 and 4 patients in Group 2) was similar in both groups. Recent onset variant angina (≤1 month in duration) was found in 9 patients in Group 1 and 6 in Group 2 (NS). Three patients in Group 1 and 2 in Group 2 were treated with long-acting nitrates and propranolol, whereas the remaining 26 patients (14 in Group 1 and 12 in Group 2) received calcium antagonists. The choice of a particular calcium-channel blocking agent depended on its availability at the time.

**Hemodynamic and angiographic data:** Left ventricular end-diastolic pressures were comparable in both groups (14.8 ± 4.2 mm Hg in Group 1 and 13.2 ± 4.5 mm Hg in Group 2) as were the left ventricular ejection fractions (60.1 ± 11.1% in Group 1 and 60.2 ± 4.2% in Group 2). Coronary artery disease was considered significant when the luminal diameter was narrowed by ≥50%. Stenoses of the diagonal or the marginal branches were considered lesions of the left anterior descending or the circumflex coronary artery.

Single-vessel disease was present in 7 patients (41%) in Group 1 and 6 patients (43%) in Group 2, whereas double- and triple-vessel disease, respectively, were found in 3 (18%) and 6 (35%) patients in Group 1 and in 7 (50%) and 2 (14%) patients in Group 2. Three patients in Group 1 and 1 in Group 2 had left main coronary artery stenosis, associated in 3 instances with lesions in other coronary arteries. Differences in the incidence of single-, double-, and triple-vessel disease and those found between single- and multiple-vessel involvement did not reach statistical significance.

**Surgical procedures:** The electrocardiogram (lead $CM_5$) was monitored throughout the procedure. A nitroglycerin drip infusion was started at induction of anesthesia and continued for at least 24 hours postoperatively. Standard cardiopulmonary bypass and systemic hypothermia (24°C) was used. Intermittent crystalloid cold cardioplegia and topical hypothermia were used for myocardial protection. Distal anastomoses were performed first through a single aortic cross clamping. A mean of 2.3 grafts per patient was inserted in Group 1, whereas an average of 1.7 ± 0.6 grafts were inserted in patients in Group 2 (NS). Partial sympathetic denervation was carried out after completion of the proximal anastomosis, with the heart fibrillating and the aorta unclamped, according to a technique previously described.[10] Briefly, the procedure involves removal of the adventitia of the ascending aorta, of the anterior and superior aspect of the main pulmonary artery and its right and left branches, and the inferior aspect of the aortic arch including the triangle of tissue overlying the carina and left main bronchus underneath the aortic arch. Histologic examination showed the presence of ganglion cells and nerve fibers in all instances.

Perioperative myocardial infarction was diagnosed when both enzymatic (myocardial-specific creatine kinase [CK-MB]) and electrocardiographic criteria were present. Serial blood samples for enzyme determination were withdrawn the day before operation, at the beginning of cardiopulmonary bypass, 6 and 8 hours postoperatively, and daily for the 5 following days. The upper limit of normally expected postoperative CK-MB activity was considered 120 IU/liter. This corresponds to the 95% confidence limits of the mean peak CK-MB activity (61.18 ± 28.41 IU/liter) of a series of 79 patients undergoing uneventful simple coronary artery bypass grafting in our institution. Standard 12-lead electrocardiograms were obtained the day before and immediately after operation, daily for 5 days, and before hospital discharge. Electrocardiograms were also obtained as deemed clinically appropriate. The electrocardiographic criterion for a new infarction was the appearance of a Q wave of at least 0.04 second in duration in 2 or more adjacent leads.

**Follow-up:** After discharge, each patient returned to the outpatient clinic at 1 month, 3 months, and every 6 months thereafter. On each visit a standardized questionnaire, physical examination, and electrocardiogram were recorded. Mean follow-up was 23.12 ± 15.2 months in Group 1 and 22.43 ± 18.3 months in Group 2 (NS). Two patients in Group 1 were lost to follow-up at 9 and 18 months.

**Statistical analysis:** Data are expressed as mean ± standard deviation. Clinical and angiographic data were compared by using the unpaired $t$ test or the chi-square test when appropriate. Actuarial curves were plotted with the follow-up data. Cardiac death, myocardial infarction, and variant angina were considered endpoints. The difference between groups was assessed by the Mantel-Haenszel test.[22] A probability (p) value $<0.05$ was considered significant.

## Results

**Group 1:** There were no surgical deaths. In 2 patients (Cases 5 and 6) a perioperative anterior myocardial infarction developed. Patient 5, who had a single bypass to the left anterior descending coronary artery for a 60% stenosis of the main left stem, again underwent cardiac catheterization 3 weeks after the infarct. His bypass graft was occluded and he underwent a second operation in which a double graft to the left anterior descending and to the circumflex coronary artery was constructed. Three months later, chest pain with transient S-T segment elevation at rest recurred and a second postoperative angiogram was obtained. The bypass graft to the left anterior descending artery was occluded and that of the circumflex was patent. The patient was given nifedipine (20 mg, 4 times a day) and has remained asymptomatic. Patient 6 has been free of symptoms since his perioperative infarct. There were 2 other infarcts in this group, at 3 and 14 months (Cases 9 and 14, respectively) and 1 sudden cardiac death at 20 months (Case 11).

Spontaneous transient S-T segment elevation without further evidence of infarction was documented in 4 patients (Cases 2, 3, 4, and 14) during hospitalization. Patients 4 and 14 showed the electrocardiographic changes shortly after their arrival in the recovery room, whereas Patients 2 and 3 had the attack 1 week after the operation. In all instances the S-T segment elevation occurred in the same leads as in those preoperatively (precordial in Patients 2, 3, and 4 and in the inferior leads in Patient 14) and disappeared after the administration of a bolus dose of nitroglycerin. These patients were given calcium-channel blocking agents for 3 months after discharge from the hospital.

Five patients (Cases 1, 2, 5, 13, and 14) had recurrent chest pain at rest which developed at variable intervals after operation (at 3, 5, 6, 9, and 10 months). All 5 patients were off medication at the time of recurrence and all but 1 (Case 6) were relieved of angina with the use of calcium-channel blocking drugs. Patient 2, who showed both early and late recurrent variant angina, underwent a repeat angiographic study. Although his bypass graft to the left anterior descending coronary artery was patent, a transient occlusion of the distal vessel was elicited by administration of ergonovine. In Patient 13, angiographic evaluation performed shortly after onset of recurrent angina showed patency of the graft and an unchanged coronary anatomy.

**Group 2:** All patients survived the operation. There were 2 perioperative infarctions, anterior in Patient 18 and inferior in Patient 21. Both patients have remained symptom-free. Patient 25 presented with several episodes of S-T segment elevation within the first 48 hours. The first of these episodes occurred in the operating room and subsided after administration of papaverine into the graft to the left anterior descending coronary artery. Subsequent attacks required repeat intravenous bolus doses of nitroglycerin in addition to the permanent drip infusion. Control of these episodes was achieved by the use of calcium-channel blocking agents (through the nasogastric tubing during the first 12 hours). Both diltiazem and nifedipine were administered to this patient until the 7th postoperative day, when unexpected left ventricular failure occurred. The latter responded after several hours to infusion of calcium and dopamine. This patient has been well after cessation of calcium blocking agents.

There was 1 noncardiac death (Patient 24) caused by Australia antigen hepatitis 14 months after operation. No late myocardial infarction or recurrent variant angina was documented in this group. Two asymptomatic patients (Cases 26 and 30) underwent angiography, which demonstrated patent bypasses and no significant change in the coronary arteries.

**Comparison of the 2 groups:** The chi-square test disclosed significant differences between the 2 groups with respect to the overall prevalence of new coronary events ($p < 0.05$), but no difference was found when prevalence of recurrent variant angina or that of peri- and postoperative myocardial infarction and cardiac death were analyzed separately.

Actuarial curves showed the cumulative probability of new coronary events to be significantly different in the 2 groups ($p < 0.01$ at 6 months and $p < 0.001$ at 10 months). Cumulative probability or recurrent variant angina was also different in each group ($p < 0.05$ at 6 months and $p < 0.001$ at 10 months). When only myocardial infarction and death were selected as endpoints, the actuarial analysis failed to show differences between the study groups (Fig. 1).

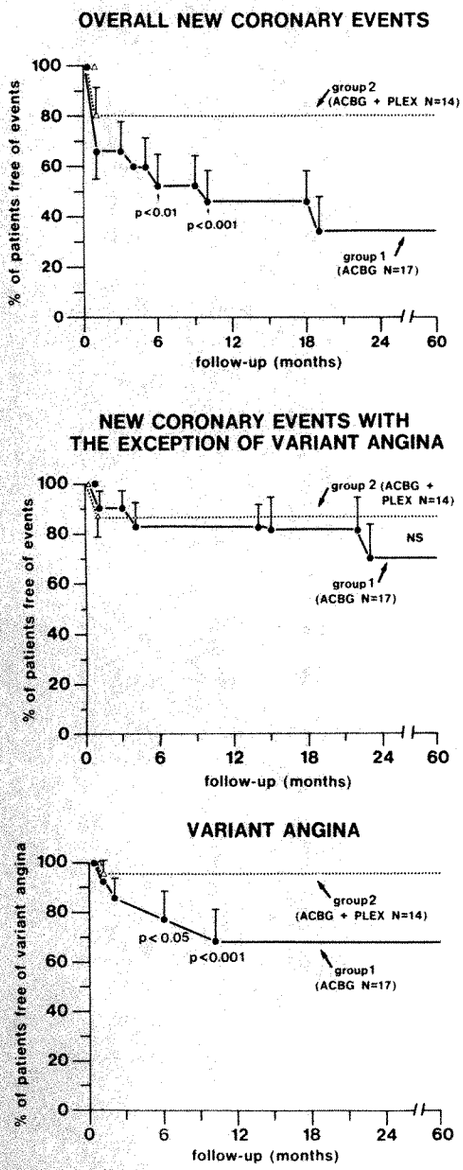

**FIGURE 1.** Actuarial curves with standard error of the mean showing the cumulative probability of overall new coronary events (**top**), that of new coronary events with the exception of variant angina (**middle**), and that of variant angina (**bottom**). Note that when only myocardial infarction and death were selected as endpoints, actuarial analysis failed to show differences in the 2 groups. The differences reach significance at the 6- and 10-month points (**arrow**). ACBG = aortocoronary bypass graft; PLEX = plexectomy.

## Discussion

The cyclic nature of variant angina that includes long asymptomatic time intervals and spontaneous remissions makes assessment of the effectiveness of any treatment quite difficult.[23–25] Recently, calcium-channel blocking agents have proved the therapy of choice in this condition.[3,7,26] Patients in whom spasm and severe coronary artery stenoses coexist are still considered surgical candidates. The results of coronary artery bypass surgery in variant angina are not as gratifying as those obtained in conventional effort angina, as evidenced by the lower patency rate and higher recurrence of symptoms.[9,12–15] In addition, a higher incidence of perioperative myocardial infarction has been reported.[9] Coronary artery spasm, the underlying mechanism of variant angina,[16–18,27–30] conceivably may occur distal to a patent graft and jeopardize the results of an otherwise successful operation. Prevention of coronary spasm therefore appears to be a logical complement to revascularization procedures in the treatment of variant angina. Although the mechanism for coronary spasm remains largely unknown, the autonomic nervous system appears to play an important role. Yasue et al[19] suggested that attacks of variant angina are initiated by enhanced parasympathetic activity, although the parasympathetic neurotransmitter, acetylcholine, causes direct coronary vasodilatation. Acetylcholine also induces release of norepinephrine from the postganglionic sympathetic nerve terminals in the heart which, in turn, causes vasoconstriction of large coronary arteries by activating alpha receptors. Thus, cardiac sympathetic denervation might be a valid approach in the prevention of coronary artery spasm.

Permanent and complete cardiac denervation is difficult to achieve short of allotransplantation. Denervation obtained by autotransplantation[31] is complete, but temporary as fibers ultimately regenerate and cross the suture lines. The heart receives its sympathetic innervation mainly from the cervical ganglia. It has not been clearly demonstrated that the sympathetic system below the stellate ganglion participates in the cardiac innervation. Nonetheless, the sympathetic fibers originating from the lower cervical and upper thoracic ganglia merge with vagal fibers to form cardiac plexuses. The major plexuses are located anterior to the aorta and trachea and behind the left atrium near the interatrial septum. The pretracheal plexus contains several ganglia, including the large and inconsistent ganglion of Wrisberg. Section of the preaortic fibers and removal of the pretracheal plexus may be sufficient to sever connections with the coronary plexus.

Although sympathetic cardiac denervation was used initially to interrupt pain fibers in patients with angina pectoris,[32,33] its use in the treatment of variant angina is recent.[10] It was first performed in 2 patients who

presented with variant angina associated with organic coronary artery lesions. Both remained free of symptoms 12 and 18 months after operation.[10] More recently, Bertrand et al[11] compared the results in 22 patients undergoing combined plexectomy and coronary artery bypass grafting with those obtained in 13 patients who had isolated revascularization procedures. They observed a 5% recurrence rate of variant angina in the former group, versus 18% in the latter. Although these figures suggest that associated plexectomy improves the results of the aortocoronary bypass operation in variant angina, the significance of their findings remains unsettled because no statistical analysis was applied to their data. However, the extent of follow-up was longer in the series of patients without plexectomy, and that may account—at least in part—for the higher rate of recurrent angina observed in this group.

In contrast, the present study concerns only patients whose operations were performed during the same time frame. Because the choice of plexectomy was a medical decision, our study may be regarded as an open-label trial and thus subject to bias. However, the 2 groups were homogeneous with regard to age and sex distribution, prevalence of coexistent effort angina and previous myocardial infarction, and time of onset of variant angina. In addition, left ventricular function, as assessed by left ventricular end-diastolic pressure and ejection fraction, was similar in both groups. As for the extent of coronary artery lesions, no significant differences were found in the 2 study groups, although the incidence of 3-vessel involvement was greater in Group 1 (35% versus 14%); this difference failed to reach statistical significance because of the small sample size. Furthermore, it is not likely that the results could be influenced seriously by differences in the severity of coronary artery disease as the outcome of the 2 groups appears related only to recurrences in variant angina.

Our series did not show an increased operative mortality in variant angina. In 1974, Gaasch et al[9] reported from the literature a 12.5% rate of operative deaths. Composite results from 17 series[10] totaling 126 patients showed an operative mortality of 10%, higher than that generally observed. There was no operative death in the current series, a fact that may be related to improved intraoperative myocardial protection as well as the routine use of intravenous nitroglycerin during operation and the first postoperative day.

The rate of perioperative myocardial infarction in this study (13%) is comparable with that observed in patients undergoing coronary artery grafting before the use of cardioplegia but superior to the current rate with cardioplegia.[34] These findings differ from those of previous reports showing a high incidence of perioperative myocardial infarction in variant angina.[14,15,35] However, the value of these reports is limited as they deal with small population samples. The composite results from 17 series[10] show a perioperative infarction rate of 15%, comparable with that in the current study.

No myocardial infarction was demonstrated in the patient with repeated episodes of S-T segment elevation within 48 hours after plexectomy. Although variant angina could not be demonstrated on long-term follow-up, the early electrocardiographic changes indicate that vasospastic activity could not be prevented by plexectomy. Whether partial sympathetic denervation was adequately achieved or not in this patient is difficult to assess. However, because autonomic dysfunction is certainly not the only cause of spasm, an increase in circulating catecholamines or changes in the coronary vessel walls themselves could account for the recurrent vasospasm.

Although the hypothesis that plexectomy is effective in preventing recurrent vasospastic activity is supported by our data, these must be interpreted with caution. Several methodologic difficulties arise in assessing therapeutic efficacy in the setting of coronary artery spasm. As mentioned earlier, the cyclic nature of the disease is a confounding factor that often magnifies the apparent benefits of any therapeutic intervention. Because patients tend to present to physicians at peak of disease activity, improvement may occur regardless of the therapy used. It should be stressed in this respect that 40% of patients in Group 1 have not manifested evidence of recurrent vasospasm since operation. We did not attempt to elicit vasospasm by ergonovine injection. This test may be negative in asymptomatic patients.[25,26] Because recurrence of pain was the only clinical variable separating the 2 groups of patients, it is conceivable that plexectomy, in fact, leads to interruption of pain fibers rather than to abolition of spasm. Effort angina did occur in both groups, however, which suggests that interruption of afferent pain fibers was not the primary mechanism for the relief of variant angina. Larger series, perhaps with pre- and postoperative ergonovine tests and a longer follow-up, will be required to validate our data. Nonetheless, as plexectomy does not increase the surgical risk, the association of this procedure with aortocoronary bypass grafting may be considered in the management of patients presenting with refractory variant angina. At present, plexectomy is not advocated for patients with variant angina who have no significant obstructive coronary disease.

# Digital Angiography in Assessment of Ventricular Function And Wall Motion During Pacing in Patients With Coronary Artery Disease

JONATHAN TOBIS, MD, ORHAN NALCIOGLU, PhD, WARREN D. JOHNSTON, MD, ANTHONY SEIBERT, PhD, LLOYD T. ISERI, MD, WERNER ROECK, Eng Grad, and WALTER L. HENRY, MD

**Using digital subtraction angiography, left ventriculograms were obtained with 10 ml of iodinated contrast material in 21 patients both at rest and during atrial pacing. In 15 patients with significant coronary artery lesions (CAD) (>50% diameter narrowing in at least 1 major artery), ejection fraction decreased during atrial pacing from a mean of 62 ± 14% to 51 ± 15% ($p < 0.001$). In 14 (93%) of 15 patients, ejection fraction decreased or was unchanged during pacing. In 6 patients with chest pain but normal coronary arteries, ejection fraction increased from a mean of 66 ± 9% at rest to 72 ± 6% during atrial pacing ($p < 0.01$). Ejection fraction increased by ≥5% during pacing in 5 of 6 patients with normal coronary arteries. Patients with CAD also had an abnormal response in end-systolic volume during atrial pacing (50 ± 31 ml at rest versus 47 ± 24 ml during pacing) compared with patients with normal coronary arteries (46 ± 16 ml at rest versus 26 ± 9 ml during pacing; $p < 0.01$). The digital ventriculograms demonstrated new or increased wall motion abnormalities during atrial pacing in 4 of 5 patients with CAD who had wall motion abnormalities at rest and in 8 of 10 patients with CAD who had normal wall motion at rest. Moreover, these wall motion abnormalities occurred in myocardial wall segments that were supplied by coronary arteries with significant lesions.**

**Thus, because digital subtraction angiography allows multiple left ventriculograms to be obtained during routine cardiac catheterization, intervention studies such as atrial pacing can be used to obtain a functional assessment of the severity of coronary arterial lesions.**

Digital subtraction angiography enhances standard angiographic images by processing the radiographic images through a high-speed digital computer. The enhancement is such that adequate visualization of major arterial systems can be obtained with low concentrations of iodinated contrast material.[1] Because lower concentration provides adequate visualization, standard doses (30 to 40 ml) of contrast material can be injected intravenously, which is different from traditional angiography in which the same amount of contrast material must be injected directly into the arterial circulation. Several investigators have reported their results with digital angiographic imaging of carotid, renal, and other peripheral arteries,[2–5] whereas others have actively been employing this technology in cardiac imaging.[6–9] We recently reported our results comparing digital first-pass left ventriculograms obtained after intravenous administration of 30 to 40 ml of contrast material with standard left ventriculograms obtained during cardiac catheterization with intraventricular injection of the same amount of contrast material.[10] There were close correlations between the 2 techniques for ventricular volume and ejection fraction.

Another potential application of this technology is to use the digital subtraction technique to process images so that less contrast material is needed for each intraventricular injection during routine cardiac catheterization. For example, it is possible to use digital

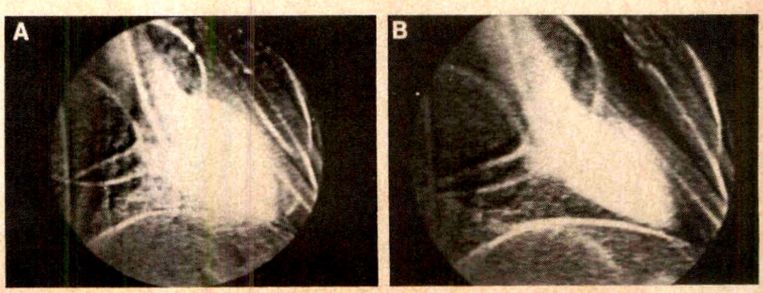
angiography to obtain left ventriculograms with one fourth the usual amount of contrast material. Therefore, 4 times as many digital left ventriculograms can be performed compared with standard cineangiograms without increasing either the total amount of contrast material or the radiation exposure to the patient.[6] This capability of obtaining additional left ventriculograms might permit the angiographer to assess the functional capacity of myocardial segments supplied from specific coronary arteries by performing ventriculography before and after a stressful intervention during routine cardiac catheterization.

This study assesses whether small-dose left ventriculograms obtained with digital angiography at the time of routine cardiac catheterization could be used before and during atrial pacing to determine the functional significance of coronary artery disease (CAD) as defined by changes in ejection fraction and the development of wall motion abnormalities.



## Methods

**Digital angiographic technique:** Digital angiography was performed using the method of mask mode subtraction.[11,12] This technique involved the acquisition of fluoroscopic images of the heart before and during contrast injection. Each 1/30 second fluoroscopic image was digitized by an image processing computer (Cardiac 1000, American Edwards Laboratories, Irvine, California) into a 512 by 512 by 8 bit matrix. Each picture element (pixel) in the matrix was capable of differentiating 256 shades of gray. Because the memory of the image processing computer was large enough to allow computer storage of a 512 by 512 by 12 bit matrix, 16 frames of the 512 by 512 by 8 bit images were summated and stored in memory for the mask. This mask image contained data about the soft tissues and bone structures of the chest. After the mask was obtained, each new 1/30 second video fluoroscopic image was digitized and the stored mask was subtracted from it in real time. If perfect subtraction occurred, the resultant image signals would cancel out and not reveal any soft tissue or bone structures. If iodinated contrast media were injected after the mask was obtained and during fluoroscopy, the soft tissues and bones would be subtracted but the iodine signal would be maintained so that low concentrations of contrast material in the heart could be visualized more clearly.

Our catheterization laboratory is equipped with a Siemens Cardioskop U-arm x-ray unit. Images were focused on a 7-inch cesium iodide image intensifier and the images were converted into an electrical signal by a Plumbicon television camera. The video output signal from the television camera was connected to the image processing computer where it was logarithmically amplified before computer digitization. The subtracted images were processed in real time and displayed on television monitors in the catheterization laboratory. For this study, the fluoroscopic exposure level was set at 8 mA and 70 to 90 kVp depending on the size of the subject. The 8 mA setting is 2 to 3 times the electrical current typically used in fluoroscopy. A 5-mm thick aluminum filter was used to eliminate low-energy radiation. The measured incident exposure rate on the image intensifier was 2 to 17 $\mu$R/frame depending on the kVp. After mask mode subtraction processing, the images were reconverted to analog format for storage on videotape (Sony Betamax, model SL0323MD, 1/2-inch recorder) (Fig. 1). After the study, analog images could be replayed through the computer and the image redigitized. This postprocessing of the images permitted manipulation of the contrast and gray scale levels through the computer to enhance visualization and boundary detection. The computer contained software programs to calculate left ventricular volume and ejection fraction using the area-length method.[13] A more comprehensive description of our imaging system is presented in a previous report.[10]

**Clinical studies:** Patients undergoing left ventriculography during routine cardiac catheterization for clinically indicated reasons were asked to participate in this study. Patients with left main coronary artery obstruction and those with unstable angina were excluded from the study. Informed consent was obtained for each patient who agreed to participate. Drugs such as long-acting nitrates and beta-adrenergic antagonists were withheld for 24 hours before the study. Twenty-one patients (14 men and 7 women) who had a clinical history of chest pain were evaluated by atrial pacing. The mean age was 54.3 years (range 38 to 70) and the mean weight was 82.4 kg (range 54.5 to 120.5). Fifteen patients had at least 1 anatomically significant coronary artery lesion. Significant coronary artery stenosis was defined as $\geq$50% diameter narrowing of the coronary artery in at least 1 projection. Two or more projections were obtained for each coronary artery in standard and caudocranial views. At least 2 of these projections were orthogonal. The lesions were as follows: 9 in the left anterior descending artery, 8 in the circumflex system, and 11 in the right coronary artery. Six patients had normal coronary arteries as defined by <25% diameter narrowing of all coronary branches. Percent coronary artery stenoses in each patient are presented in Table I.

After coronary angiography was completed, a 7-French Cordis pigtail catheter was passed retrograde across the aortic valve into the left ventricle. A digital left ventriculogram was taken at rest in the 30° right anterior oblique position by injecting 10 ml of Vascoray® or Hypaque® 75 at a rate of 5 ml/s. A 6-French Cordis bipolar temporary pacemaker wire was passed from the right femoral vein under fluoroscopic control and placed against the lateral border of the right atrium. The pacemaker wire was connected to a Medtronic external pulse generator (model 5375). The right atrium was stimulated at

REAL TIME SUBTRACTION

**FIGURE 1.** End-diastolic (**A**) and end-systolic (**B**) images obtained by injecting 10 ml of contrast material over 2 seconds into the left ventricle. The video signals are processed in real time by the method of mask mode subtraction. Images are recorded on videotape and displayed in real time on a television monitor.

2 mA, initially at a rate of 20 beats/min above the patient's resting heart rate. The rate was increased in increments of 10 beats/min every minute until the patient experienced chest pain or until 85% of the maximal predicted heart rate was reached. If atrioventricular Wenckebach heart block developed, 1 mg atropine was administered intravenously and the pacing study was continued. When the end-point heart rate was achieved, another 10 ml digital left ventriculogram was performed. The pacemaker was then turned off. To correct for magnification, an 8 by 8 cm grid was placed on the x-ray table after the study was performed at a height corresponding to one half the patient's anteroposterior thoracic dimension. The image intensifier and x-ray tube were adjusted to the position used in the study and the grid was fluoroscopically imaged and recorded on videotape for subsequent analysis of ventriculograms.

Left ventricular pressure was recorded through the fluid-filled 7-French pigtail catheter using a Statham P23ID transducer. Left ventricular end-diastolic pressure was measured from the pressure tracing as the point after the "a" wave where the rapid upstroke of the left ventricular pressure curve began. Pressure was recorded before the digital angiography studies, after the initial resting 10-ml digital study, and then after the 10-ml digital study obtained during atrial pacing. In the latter 2 situations, left ventricular pressure was recorded within 3 minutes after the contrast material was injected. The mean end-diastolic pressure at rest and after the baseline 10-ml digital study was compared using Student's $t$ test.

Electrocardiographic (ECG) monitoring was performed at rest and during atrial pacing using leads II and $V_6$. Acute ischemic changes were interpreted as 1 mm horizontal S-T depression persisting 0.08 second after the J point.

**Analysis:** The rest and pacing images recorded on videotape were reviewed and the heart beats in which the greatest concentration of dye was seen in the left ventricle were chosen for analysis. Images from these cardiac cycles were redigitized by the computer system so that the boundary of the left ventricle could be electronically traced directly on the video image. An end-diastolic frame was chosen by identifying the image with the largest iodinated area and the end-systolic frame was identified as the image with the smallest contrast-filled area. End-diastolic and end-systolic volumes at rest and during atrial pacing were calculated by the computer using the area-length method corrected for magnification by the grid.[13,14] Ejection fractions were computed from the volume calculations. Statistical analysis was performed with Student's $t$ test for paired data comparing end-diastolic volumes, end-systolic volumes, and ejection fractions at rest with those obtained during atrial pacing.

Coronary arteriograms were reviewed for the presence and significance of atherosclerotic lesions. Lesions were defined as anatomically significant when the diameter at the stenosis was measured by calipers to be >50% narrowed compared with the arterial segment proximal to the lesion. A panel of 3 cardiologists reviewed all the coronary angiograms. Wall motion abnormalities at rest or induced by atrial pacing were qualitatively assessed. Digital ventriculograms were interpreted by 1 member of the panel and reviewed by the other 2 members. The panel was not specifically blinded to the results of the coronary angiograms. However, in over 75% of the cases, wall motion analysis was made without knowledge of the coronary angiogram interpretation. Regions of normal and abnormal wall motion seen on digital ventriculograms were related to the presence or absence of anatomically significant coronary artery narrowing in the artery supplying those myocardial regions. Arterial lesions were defined as functionally significant if rest- or pacing-induced wall motion abnormalities were appreciated.

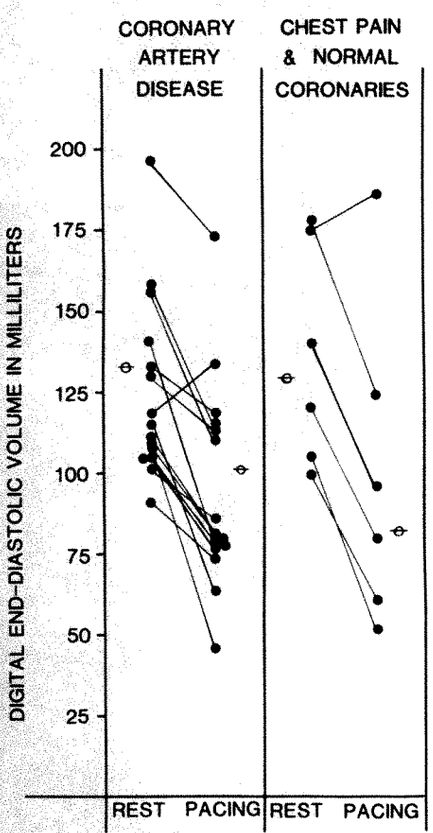

**FIGURE 2.** Comparison of left ventricular end-diastolic volume obtained with 10 ml digital subtraction angiography before and after atrial pacing. The patients were divided after coronary angiography into those with significant coronary artery disease (≥50% diameter narrowing) and those with normal coronary arteries.

## Results

**Patient characteristics:** Table I summarizes our patient data and includes the heart rate and ejection fraction data at rest and during atrial pacing in 21 patients. Twelve of the 15 patients with CAD had New York Heart Association class III or IV symptoms of angina. However, all patients were free of pain ≥24 hours before catheterization. The mean heart rate at rest was 66 ± 11 beats/min in patients with CAD and 71 ± 12 in those with normal coronary arteries (p = NS (not significant)). The mean heart rate achieved during atrial pacing was 124 ± 15 beats/min (range 108 to 150) in the group with CAD. Patients with normal coronary arteries were paced to a mean rate of 132 ± 15 beats/min (range 120 to 150) (p >0.2 compared with the paced heart rate achieved in patients with CAD). In 1 patient with CAD a complication developed during electrical stress testing. This patient had transient (6 seconds) complete heart block but suffered no sequelae.

**Hemodynamic effects:** The mean resting left ventricular end-diastolic pressure was 18 ± 8 mm Hg in patients with CAD and the left ventricular end-diastolic pressure was 17 ± 3 mm Hg in those with normal coro-

nary arteries (p = NS). After the baseline 10-ml digital left ventriculogram, no significant change was noted in left ventricular end-diastolic pressure which was 18 ± 8 mm Hg in patients with CAD and 18 ± 3 mm Hg in those with normal coronary arteries.

**Angiographic results:** Figure 2 demonstrates end-diastolic volumes before and during pacing in 15 patients with CAD and in 6 patients with chest pain but normal coronary arteries. Left ventricular end-diastolic volume decreased during atrial pacing in 14 of 15 patients with CAD. Mean end-diastolic volume was 125 ± 28 ml at rest and decreased to a mean volume of 95 ± 35 ml ($p < 0.001$) during pacing. In the 6 patients with normal coronary arteries, end-diastolic volume decreased from a mean of 137 ± 34 ml at rest to a mean of 99 ± 49 ml ($p < 0.02$) during atrial pacing. There was no significant difference between mean end-diastolic volumes at rest or during pacing between the 2 groups. Also, there was no significant difference in the percent change in mean end-diastolic volume from rest to pacing between the 2 groups.

Left ventricular end-systolic volume decreased during atrial pacing in all 6 subjects with normal coronary arteries (Fig. 3), whereas end-systolic volume decreased in only 8 of 15 patients with CAD. In patients with CAD, mean end-systolic volume was 50 ± 31 ml at rest and 47 ± 24 ml during atrial pacing ($p > 0.2$ compared with that at rest). In patients with normal coronary arteriograms, the mean resting end-systolic volume was 46 ± 16 ml, and decreased during atrial pacing to a mean end-systolic volume of 26 ± 9 ml ($p < 0.01$ compared with that at rest). Although end-systolic volumes at rest were similar in the 2 patient groups, the decrease in end-systolic volume was significantly greater in patients with normal coronary arteries compared with those with CAD ($p < 0.05$).

Ejection fraction data in the 2 groups of patients are shown in Figure 4. In the 15 patients with CAD, mean ejection fraction at rest was 62 ± 14 and decreased an average of 11 percentage points to 51 ± 15 during atrial pacing ($p < 0.001$). Ejection fraction decreased or was unchanged in 14 of the 15 patients. In the 6 patients with chest pain but normal coronary arteries, resting ejection fraction was 66 ± 9% (no significant difference compared with that of the group with CAD) and increased during pacing to 72 ± 6 ($p < 0.01$ compared with that in patients with CAD). During atrial pacing, the ejection fraction increased by at least 5 percentage points in 5 (83%) subjects and decreased in 1 subject.

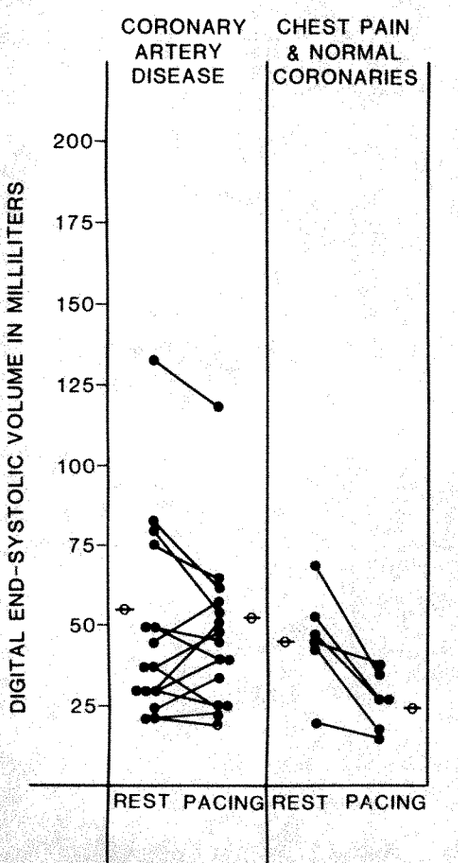

**FIGURE 3.** Comparison of left ventricular end-systolic volumes obtained with 10 ml digital subtraction angiography before and after atrial pacing.

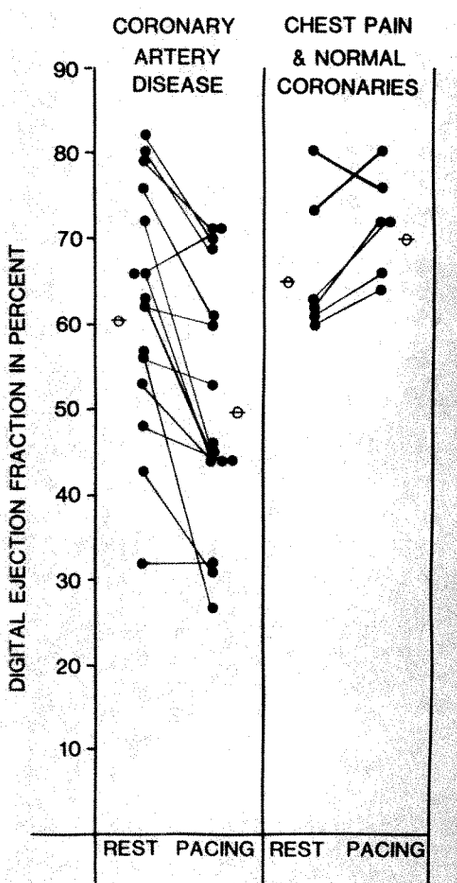

**FIGURE 4.** Comparison of left ventricular ejection fractions obtained with 10 ml digital subtraction angiography before and after atrial pacing. Fourteen of 15 patients with coronary artery disease had a decrease or no change in ejection fraction, compared with 5 of 6 patients with normal coronary arteries who had an increase in ejection fraction.

**Wall motion abnormalities:** The resting digital angiograms demonstrated wall motion abnormalities in all 5 patients who had dysfunctional contraction patterns visualized on standard cineangiogram. The areas of abnormal wall motion at rest and after pacing are listed in Table I.

Four patients had inferior wall dysfunction at rest and each of these patients had severe right coronary artery obstruction. During atrial pacing, more extensive impairment of inferior wall motion developed in these 4 patients and dyskinesia of the inferior wall developed in 2. One patient had extensive anteroapical akinesia at rest with an ejection fraction of 32%. He developed chest pain at a paced heart rate of 110 beats/min but did not develop new areas of wall motion dysfunction despite the presence of significant disease in 4 vessels. In the 10 patients with CAD who had normal wall motion at rest, 8 patients developed new areas of abnormal contraction in muscle segments that were supplied by coronary arteries with significant anatomic obstruction. In 4 of these 8 patients, the new area of wall motion abnormality was located in the anterior wall and was associated with significant obstruction in the proximal left anterior descending coronary artery. In 2 of the 8 patients, the new area of wall motion abnormality was located in the inferior wall and was associated with significant obstruction in the right coronary artery. In 2 patients abnormal wall motion developed in both the anterior and inferior walls corresponding to significant disease in both the left anterior descending and right coronary arteries.

One patient (Patient 6 in Table I) with normal wall motion at rest had a decrease in ejection fraction of 12 percentage points, but no segmental wall motion abnormality was visualized in the right anterior oblique projection. The only significant anatomic obstruction in the patient was in the circumflex artery. One patient with significant 3-vessel disease (Patient 4 in Table I) had an increase in ejection fraction of 5 percentage points during atrial pacing with normal wall motion during both studies. In this patient chest pain developed at a paced rate of 110 beats/min and the digital ventriculogram was taken within 30 seconds of the onset of chest pain.

## Discussion

It is well described that coronary angiography may underestimate the extent of coronary artery narrowing or even completely miss significant lesions due to overlapping or foreshortening of vessels.[15–17] Special angulated views help to reduce this problem.[18–20] However, it is not unusual for angiographers to disagree as to the severity of a coronary lesion on the basis of visual inspection of the angiograms.[21] A functional assessment of the hemodynamic effects of a specific lesion would be useful in that it might aid in evaluating the severity of that lesion.

One way to assess clinically the presence of myocardial ischemia is to measure ejection fraction during stress intervention such as exercise.[22] Borer et al[23] found that a decrease in ejection fraction measured by radionuclide angiography during supine bicycle exercise was more sensitive and specific than ischemic electrocardiographic changes detected during standard treadmill stress testing. Moreover, they demonstrated that wall motion abnormalities could be detected on radionuclide angiograms when myocardial ischemia developed. However, it is sometimes difficult to relate wall motion abnormalities visualized by radionuclide angiography to specific coronary artery lesions because they frequently are obtained from different views with markedly different image resolution and at different times. Previous reports have shown that atrial pacing can be used to induce angina or ischemic electrocardiographic changes when the same pressure-rate product is achieved compared with exercise stress tests.[24–26]

In the present study, we used digital angiography and atrial pacing to assess ventricular volume, global ejection fraction, and segmental wall motion in the catheterization laboratory at the same time and in the same view that 1 of our coronary arteriograms was taken. A dose of 10 ml of contrast material and high fluoroscopic exposure levels were used which made it possible to obtain multiple ventriculograms without deleterious hemodynamic effects from excessive amounts of contrast material.[27] We did not attempt to evaluate ventricular function in patients with intermediate (25 to 50%) diameter narrowing of the cornary arteries because we wanted a comparison in lesions in which the anatomic severity is accepted as being hemodynamically significant. Therefore, only patients with moderate or severe coronary artery stenosis, (that is, >50% diameter narrowing) were included in the CAD group.

In response to atrial pacing, ejection fraction decreased or did not change in 14 of 15 (93%) patients with anatomically significant coronary artery lesions, whereas 5 of 6 (83%) patients with normal coronary arteries had an increase in ejection fraction of at least 5 percentage points. Moreover, digital angiograms revealed the development of new or the exacerbation of existing wall motion abnormalities during atrial pacing in all but 2 patients with significant CAD who had either no change or a decrease in ejection fraction. The wall motion abnormalities corresponded to ventricular muscle segments that were perfused by significantly narrowed coronary arteries. Of the 2 patients who had no change or a decrease in the ejection fraction without developing a new segmental wall motion abnormality in the right anterior oblique projection, 1 had significant stenosis of the circumflex artery. Because we did not obtain ventriculograms in the left anterior oblique projection during atrial pacing, we could not assess lesions affecting primarily the lateral wall of the left ventricle. The patient with CAD who had no change in ejection fraction during pacing (Patient 3) had a low ejection fraction at rest with diffuse anteroapical akinesis. In this patient chest pain developed at a heart rate of 110 beats/min. There also was 1 other patient who had significant 3-vessel disease in whom an increase in ejection fraction and no wall motion abnormality developed during atrial pacing. Chest pain developed in this patient at a relatively low pacing rate of 110 beats/min and the digital ventriculogram was taken within 30 seconds of the onset of chest pain. Occasionally during atrial pacing it is difficult to determine if the patient is subjectively experiencing angina or just dis-

comfort from the unusual sensation of induced tachycardia. In the previous 2 patients, a positive response might well have been achieved if atrial pacing had been continued for a longer period after the onset of chest pain.

Although these results suggest that patients with significant CAD can be identified by atrial pacing studies, we must be cautious in this analysis because inadequate visualization of ventricular walls and submaximal stress may produce a negative result. In addition, other conditions besides CAD can produce wall motion abnormalities and a decrease in ejection fraction during stress, such as cardiomyopathy and valvular heart disease.[28] Also, this study has a bias in its patient selection in that patients were excluded if they had left main artery disease, unstable angina, valvular heart disease, or cardiomyopathy with normal coronary arteries. However, the patients that were entered into the study represent the typical distribution for our hospital population of patients with symptoms of ischemic heart disease.

There was so significant difference at rest in regard to end-diastolic or end-systolic volume between patients with CAD and those with chest pain but normal coronary angiograms. During atrial pacing, 19 of the 21 patients had a decrease in end-diastolic volume. This finding is consistent with other studies which show that atrial pacing decreases the end-diastolic volume.[29] However, the effect of atrial pacing on end-systolic volume was distinctly different between our 2 groups. In the 6 patients with normal coronary arteries, the end-systolic volume decreased a mean of 20 ml (43%) from the resting value ($p < 0.01$), whereas in the 15 patients with CAD the mean end-systolic volume did not change significantly during atrial pacing. Therefore, the decrease in ejection fraction seen in patients with CAD was primarily due to the fact that the left ventricle could not contract down to a smaller end-systolic volume when ischemia developed during atrial pacing. Thus, the inability of the myocardium to contract during ischemia is apparently reflected in alterations of end-systolic volume during the stress of increased heart rate, whereas the end-diastolic volume continues to reflect changes in heart rate and ventricular filling despite the presence of ischemia. The implication is that ventricular function can be assessed not only by the response of global ejection fraction to stress but also by the change in end-systolic volume during pacing. These relations are summarized in Figure 5 in which the percent changes in left ventricular volumes and ejection fraction between rest and pacing are plotted for the 2 groups of patients with or without CAD. As can be seen, ejection fraction and, to a lesser degree, end-systolic volume changes during tachycardia induced by atrial pacing

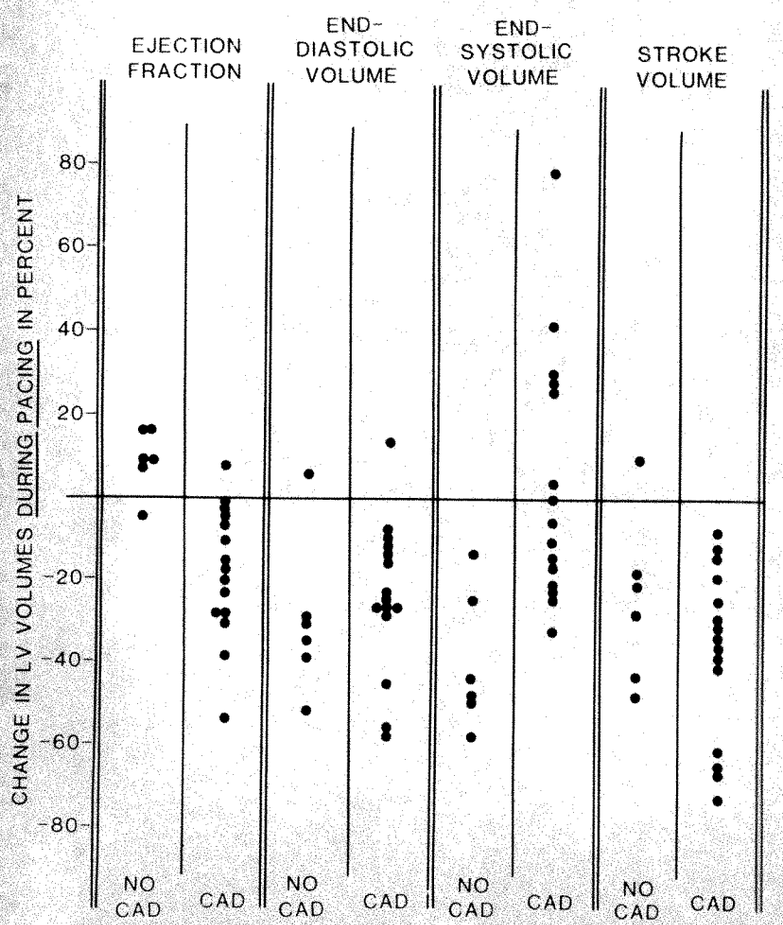

**FIGURE 5.** The percent change in left ventricular volume and ejection fraction during atrial pacing compared with rest is plotted for the patients with coronary artery disease (CAD) versus those with normal coronary arteries (NO CAD). Both the ejection fraction response and the percent change in end-systolic volume tended to discriminate between patients with normal coronary arteries and those with CAD.

were good discriminators of normal patients versus those with CAD.

Atrial pacing precipitated chest pain in 10 patients including 2 with normal coronary arteriograms. In none of the 6 patients with normal coronary arteries did ischemic ECG changes develop during pacing, whereas in only 3 of the 15 (20%) patients with CAD did ischemic ECG abnormalities develop (Table I). One explanation for the low sensitivity of the ECG response in our patients may be that only 2 ECG leads were used. Moreover, our patients achieved a relatively low level of maximal heart rate during atrial pacing. The low maximal heart rate was a result of our decision to stop increasing the atrial pacing rate and immediately perform digital angiography if the patient had chest pain. The fact that the ejection fraction decreased in 14 of the 15 (93%) patients with CAD whereas only 3 of the 15 (20%) had ischemic ECG changes and 8 of the 15 (53%) developed chest pain suggests that ischemia induced by atrial pacing is initially manifested as an abnormality of muscle contraction before either ECG alterations or the subjective sensation of chest pain. Upton et al[30] found similar results concerning the higher sensitivity of wall motion analysis as compared with the development of angina or S-T segment depression in patients undergoing bicycle exercise during radionuclide imaging. Their results for end-diastolic and end-systolic volume differ from ours probably because they used upright exercise whereas we used supine atrial pacing.

*In summary*, digital subtraction angiography permits multiple left ventriculograms to be taken during cardiac catheterization without increasing the amount of contrast or x-ray exposure to the patient and with less alteration in hemodynamics than with the traditional cineangiographic mode. Thus, functional evaluation of coronary artery stenosis is facilitated by permitting assessment of ventricular volumes, ejection fraction, and wall motion at rest and after an intervention such as atrial pacing. Similarly, it should be possible to study pharmacologic interventions or exercise stress with digital angiography in order to assess the functional significance of coronary lesions. This information could be useful in evaluating a patient with suspected or known CAD and in assessing functional improvement after coronary bypass graft surgery.

# Angiographic Changes Produced by Percutaneous Transluminal Coronary Angioplasty

DAVID R. HOLMES, Jr., MD, RONALD E. VLIETSTRA, MB, ChB, MICHAEL B. MOCK, MD, GUY S. REEDER, MD, HUGH C. SMITH, MD, ALFRED A. BOVE, MD, JOHN F. BRESNAHAN, MD, JEFFREY M. PIEHLER, MD, HARTZELL V. SCHAFF, MD, and THOMAS A. ORSZULAK, MD

**Percutaneous transluminal coronary angioplasty (PTCA) is being used with increasing frequency in the treatment of patients with symptomatic coronary artery disease. Balloon inflation results in diverse angiographic findings, reflecting the great variety of anatomic and pathologic changes produced. The long-term effects of inflation on the underlying atherosclerotic lesion and the clinical outcome are unknown but may depend in part on the anatomic changes caused by the dilatation itself. To facilitate communication and evaluation of the results of PTCA, a classification of the angiographic findings and their potential mechanisms is presented. Recognition and analysis of these angiographic findings may be helpful in evaluating the long-term outcome of patients undergoing PTCA.**

Percutaneous transluminal coronary angioplasty (PTCA) has proved a frequently effective means of reducing coronary artery stenosis.[1–3] With this technique, a balloon catheter placed across the stenotic site is inflated to reduce the obstruction. The controlled injury caused by this technique results in a range of anatomic changes manifested as diverse appearances on the angiogram. The immediate and delayed consequences related to the various angiographic appearances are poorly understood. Changes may occur not only in the arterial segment in which dilatation is attempted (angioplasty segment) but also in other parts of the coronary circulation (nonangioplasty segments). Some of these effects are the planned result of the balloon inflation and controlled injury; others may be considered complications of the procedure.

During this initial period of the clinical use of PTCA, we are still trying to understand the early and late consequences of the various vascular effects. To facilitate this understanding, construction of a practical classification of the angiographic results may be helpful. We provide a broad description of the angiographic appearances produced, based on a review of the literature and experience with the first 100 cases of PTCA at the Mayo Clinic seen between October 1979 and November 1981. As PTCA is a relatively new procedure, many of the interpretations offered are speculative. By developing a classification of the many angiographic changes that may be produced by PTCA, we hope to encourage a more orderly evaluation of the clinical results and to identify areas requiring additional investigative efforts.

**TABLE I Angiographic Findings in 100 Consecutive Patients Undergoing Percutaneous Transluminal Coronary Angioplasty**

| Finding | Patients (n)* |
|---|---|
| Changes in angioplasty segment | |
| Immediate | |
| Intraluminal haziness | 17 |
| Smooth-walled dilatation | 41 |
| Intimal flap or intramural split and dissection | 22 |
| No significant change in lesion | 20† |
| Complete occlusion | 7 |
| Intraluminal thrombosis | 0 |
| Coronary artery spasm | 2 |
| Aneurysmal dilatation | 0 |
| Coronary arterial rupture | 0 |
| Delayed—restenosis | 0 |
| Changes remote from angioplasty segment | |
| Immediate | |
| Branch occlusion | 2 |
| Distal embolization or embolic occlusion | 0 |
| Coronary spasm | 6 |
| Aneurysmal dilatation | 1 |
| Intimal flap | 1 |
| Delayed—new stenosis | 1 |

* Some patients had >1 change.
† In 18 of the 20 patients, the balloon catheter could not be passed across the stenosis.

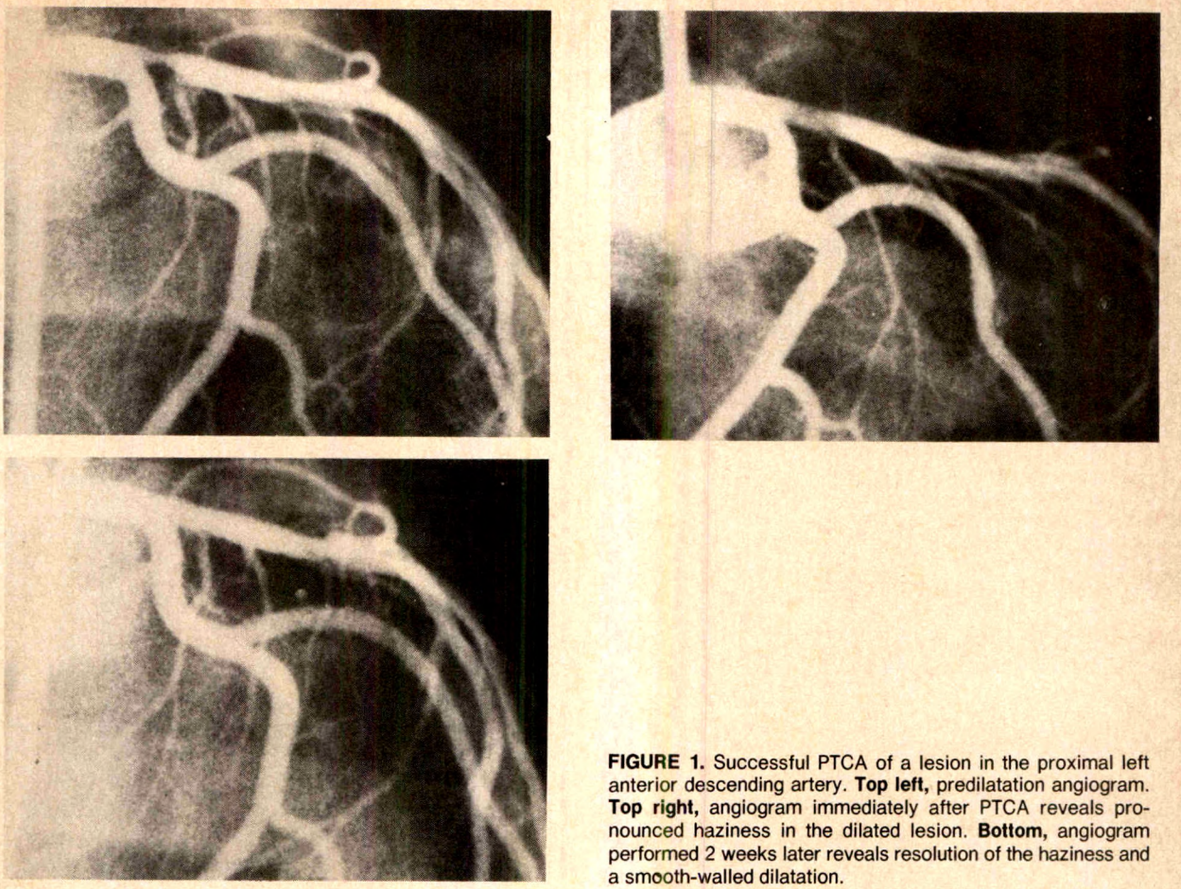

**FIGURE 1.** Successful PTCA of a lesion in the proximal left anterior descending artery. **Top left,** predilatation angiogram. **Top right,** angiogram immediately after PTCA reveals pronounced haziness in the dilated lesion. **Bottom,** angiogram performed 2 weeks later reveals resolution of the haziness and a smooth-walled dilatation.

## Changes in the Angioplasty Segment (Table I)

These may be observed at the time of PTCA (immediate) or at a later restudy (delayed).

**Immediate:** *Intraluminal haziness:* Intraluminal haziness is a frequent angiographic finding in the dilated segment.[4] Quantification and recognition of this haziness may be difficult, owing to the inherent insensitivity of angiography. Pathologically, haziness has been attributed to dispersion of contrast medium down multiple linear channels or fissures in the dilated segment.[5,6] In addition, the presence of platelet thrombi or ragged denuded intima (or both) may have a role in producing this angiographic finding. Usually, this haziness disappears within a few weeks after dilatation. In Figure 1, typical intraluminal haziness can be seen in the proximal left anterior descending artery after successful dilatation.

*Smooth-walled dilatation:* In some patients, a smooth-walled arterial segment is seen after dilatation. This finding was noted in most of our cases (Table I, Fig. 2). The significance of a smooth-walled dilatation with respect to the underlying changes in the vessel wall is unknown. It could reflect endothelial desquamation, compression of a soft atheroma, or stretching of a fibrous plaque instead of intimal fissuring and splitting of an atheromatous plaque. Alternatively, the finding of a smooth dilatation may relate to the inherent insensitivity of angiography in detecting small fissures. Depending on the underlying vessel wall changes, this smooth-walled response to dilatation may have significant implications for the eventual long-term outcome of coronary angioplasty, such as the likelihood of restenosis or remodeling.

*Intimal flap or intramural split and dissection:* The production of an intimal flap or intramural split with balloon dilatation results from splitting and fragmentation of the atheromatous plaque.[6–10] In addition, dissecting hematomas of the outer media have been seen.[4] In our series, 22 patients had evidence of intimal dissection (Fig. 3). A graded angiographic classification from intimal flap to true dissection with persistence of contrast medium in the false channel has been developed and is presently used by the National Heart, Lung, and Blood Institute (NHLBI) Registry. Some authors have concluded that intimal dissection with a small intimal flap should be expected and perhaps is a necessary part of successful PTCA.[11] In these patients, subsequent retraction and remodeling along the fissure lines and intimal dissection may lead to stabilization or actual improvement of the dilated stenosis.[12] Other authors, however, have suggested that any actual dissection may predispose to a higher rate of restenosis.[13]

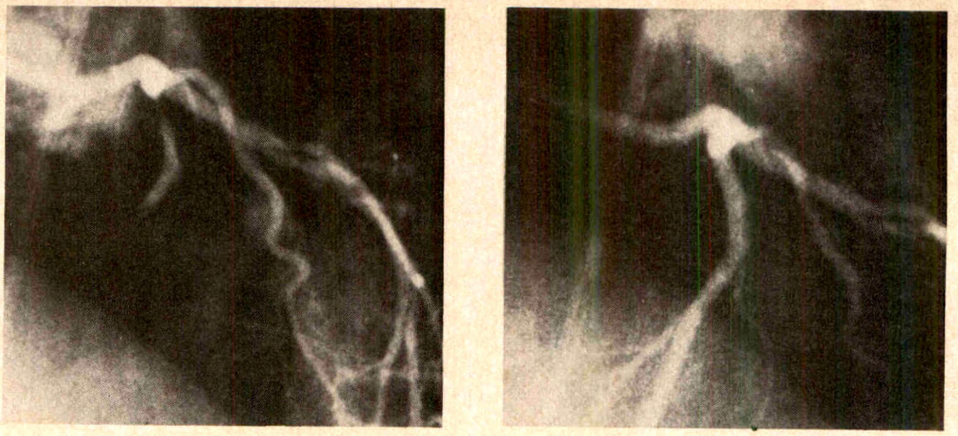

**FIGURE 2.** Successful PTCA in an occluded proximal left anterior descending artery. **Left,** preoperative angiogram. **Right,** immediate post-PTCA angiogram reveals no evidence of haziness or intimal flap.

*No significant change:* The NHLBI Registry has defined unsuccessful PTCA as no change or an improvement of <20% in the stenosis. In these patients, a firm fibrotic or calcified lesion in which the intima cannot be split may account for the lack of success. Once a stenosis has been crossed with the balloon catheter, failure of inflation to significantly decrease the stenosis is uncommon. Such failure has occurred in only 2 of our cases. This type of failure in patients undergoing balloon dilatation may become even less common in the future, with technical advances in catheter construction and less deforming balloons.[14] A more common reason for failure is the inability to intubate the coronary artery or to cross the stenosis with the balloon catheter.

It is important to avoid technical errors that may result in a less than optimal dilatation. It is essential to ensure that the balloon catheter has crossed and straddled the lesion. A number of factors can be overlooked in this regard. During inflation, the balloon may recoil out of the stenosis or be propelled distally. Sometimes, it may also be difficult to determine whether the balloon catheter inflation is being performed in the correct vessel. Problems with this usually can be avoided by constant monitoring of pressure, meticulous observation of transstenotic gradient, multiple roentgenographic views to confirm position, injection of contrast medium through the balloon catheter tip, and high-quality fluoroscopic monitoring of the balloon position during inflation.

Clinical improvement may sometimes occur when the lesion has been crossed, but PTCA has been apparently unsuccessful. Engel et al[15] reported a case in which the stenotic site in the left anterior descending artery improved spontaneously after unsuccessful initial attempts at dilatation. This fascinating observation remains unexplained but is presumably related to the complex, poorly understood remodeling process.

*Complete occlusion:* Complete occlusion is often associated with ischemic pain and electrocardiographic changes. It has been reported to be the most frequent indication for emergency coronary bypass surgery after attempted PTCA.[16] The Mayo Clinic series includes 7 patients with complete occlusion during PTCA.

Potential mechanisms include acute thrombosis, spasm, and dissection with luminal compression. Treatment varies, depending on the clinical setting. When occlusion occurs on initial passage of the dilating catheter into the coronary artery, dissection may be the most common finding. In these patients, prompt surgical intervention may be the best treatment course. Occasionally, occlusion occurs immediately after placement of the catheter across the stenotic site or after initial successful dilatation (Fig. 4). When this occurs, we attempt to reverse the occlusion by the use of intracoronary nitroglycerin and supplemental calcium antagonists. Acute occlusions have been redilated successfully. Therefore, when acute occlusion occurs as a complication of PTCA, additional consideration should be given to probing the occlusion with either a soft guide wire or the dilating catheter itself in an attempt to re-

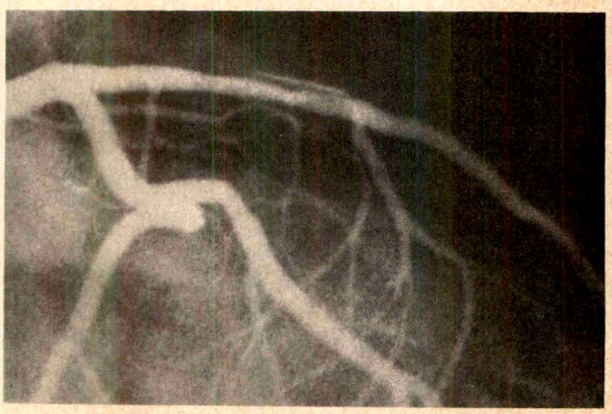

**FIGURE 3.** Angiogram performed immediately after successful PTCA in the middle left anterior descending artery with a long intimal flap.

store flow and successfully complete the dilatation. Care must be taken, however, to avoid delaying prompt surgical intervention and reperfusion.

*Intraluminal thrombosis:* At the site of dilatation, intraluminal thrombosis may occur, resulting in partial or complete occlusion. Potential mechanisms include (1) trauma to the endothelium and exposure of the intima, with subsequent platelet aggregation; (2) stasis from engaging the coronary ostia with a large guiding catheter or impacting the dilating catheter in a tight stenosis; and (3) stasis within the guiding catheter itself, with subsequent thrombus formation and embolization. In addition to anticoagulant treatment, other means of preventing platelet aggregation include the use of aspirin and dipyridamole, low-molecular-weight dextran, and calcium-channel blockers.[17,18] Despite the frequent use of these agents in PTCA, no controlled information exists. When intraluminal thrombus is recognized during dilatation, thrombolytic therapy can be helpful.

Experimental investigators have long recognized the thrombogenic effect of intimal injury. After balloon inflation in canine coronary arteries and rabbit iliac arteries, there is immediate platelet aggregation and adhesion and fibrin deposition at the site of endothelial damage.[6,7,9,19,20] It is not, therefore, surprising that thrombotic occlusion occasionally may complicate PTCA.

*Coronary artery spasm:* Mechanical stimulation of the coronary artery either at the site of the stenosis or distal to the stenosis may precipitate coronary artery spasm during balloon dilatation. The mechanical effect of distention and catheter manipulation appears to be a potent stimulus for spasm which may persist beyond the actual angioplasty. Cowley et al[13] reported that 21% of their patients had evidence of coronary artery spasm during the initial 48 hours after dilatation. Such spasm may occur despite the use of nitrates and calcium antagonists and may necessitate surgical myocardial revascularization. In our experience, 2 patients had spasm during balloon dilatation at the site of the stenosis. Each was treated with supplemental nitrates or calcium antagonists (or both), with resolution of the coronary spasm. However, suspected spasm with subsequent infarction, dysrhythmia, and even death has been reported from the NHLBI PTCA Registry.[3] Spasm also may be 1 factor that influences the occurrence of restenosis. Scholl et al[21] have noted that "variant angina"

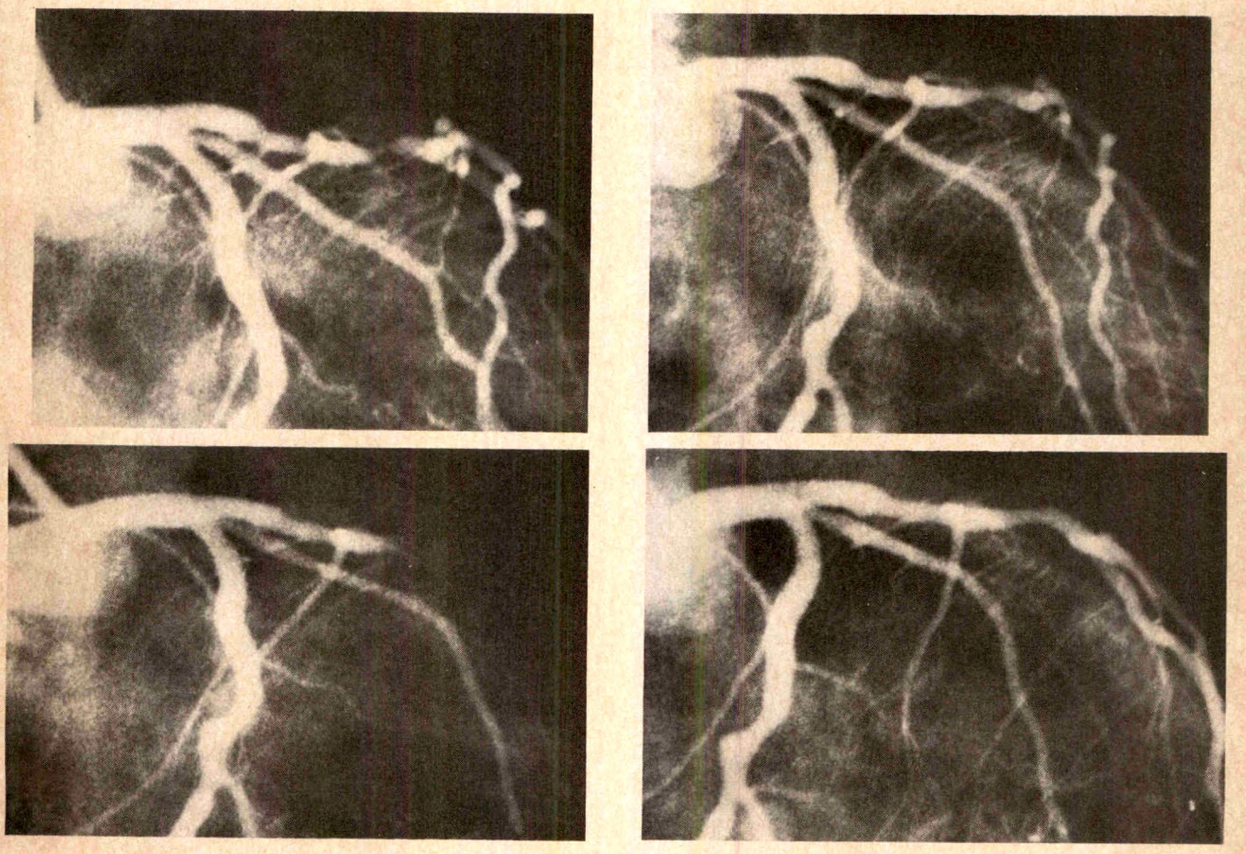

**FIGURE 4. Top left,** high-grade stenosis in the middle left anterior descending artery. **Top right,** initial improvement after PTCA. **Bottom left,** 15 minutes later, the patient had chest pain and angiography documented occlusion of the left anterior descending artery. **Bottom right,** after that, the dilating catheter was passed across the occlusion and successful PTCA resulted.

is associated with an increased incidence of restenosis. To prevent spasm, many angiographers continue treatment with calcium antagonists after angioplasty for from several days to 6 months.

*Aneurysmal dilatation:* A mismatch in size between a balloon catheter and the arterial segment dilated may result in excessive, even aneurysmal, dilatation. This occurred in 1 patient from the inadvertent dilatation of a small but normal diagonal coronary artery. As dilatation in more distal lesions of smaller arterial segments is attempted, aneurysmal changes may be seen more frequently.

Experimentally, an important relation between the size of the stenotic segment and the expanded balloon has been defined.[6] If the balloon is significantly larger than the coronary artery to be dilated, more extensive focal intimal splitting is found microscopically.

*Coronary artery rupture:* The ultimate extension of aneurysmal changes produced by excessive dilatation of a stenosis is frank rupture of the coronary artery. In a postmortem study, Lee et al[8] documented coronary artery rupture from excessive balloon inflation. Dissecting hematomas have been documented after attempted PTCA.[4] While such hematomas have the potential for rupture, to date this has not been noted clinically.

**Delayed:** *Restenosis:* Restenosis occurs in 20 to 30% of successfully dilated segments, usually within 3 to 6 months.[21,22] In the NHLBI PTCA Registry,[23] restenosis was seen in approximately 30% of patients undergoing follow-up angiography. There were no clinical characteristics before dilatation which were associated with an increase in the frequency of restenosis. Scholl et al[21] found, in a group of 11 patients with restenosis, that variant angina and eccentric or calcified lesions had an increased incidence of restenosis. Restenosis is usually heralded by the recurrence of angina pectoris, although some patients continue to be asymptomatic.[21] Whether this is a new lesion or an elastic-like recoil of the old one is not resolved. Fortunately, complete occlusion from restenosis seems rare. We have not yet observed an acute myocardial infarction in a patient who has had restenosis. In patients with restenosis, redilatation usually can be performed successfully.

## Changes in a Coronary Artery Segment Remote From the Angioplasty Site

Changes may be observed at the time of PTCA (immediate) or at later restudy (delayed).

**Immediate:** At dilatation, angiographic changes may be seen in other segments of the arterial tree, either in a different branch or in a different segment in the same vessel undergoing angioplasty. These changes may result from (1) inadvertent entry into a vessel other than the one in which dilatation is attempted, (2) close proximity of the branch vessel to the site of stenosis, and (3) downstream effects. These changes are more aptly considered complications of the procedure rather than planned consequences of the controlled injury by balloon inflation.

*Branch occlusion:* Branch occlusion most commonly results when a branch vessel arises near the stenotic site being dilated. This is particularly likely when the branch vessel has a significant ostial stenosis. In this circumstance, dilatation may further compromise the branch vessel and may result in occlusion, with subsequent infarction (Fig. 5). PTCA might best be avoided in such patients. However, where the branch vessel is small (for example, a small diseased diagonal arising in an area of stenosis in the left anterior descending artery), the benefits of successful dilatation of the large parent vessel may outweigh the risk of an occlusion of the small branch.

*Distal embolization or embolic occlusion:* An early concern with balloon dilatation was the potential for dislodging ragged atheromatous material, causing distal embolization. Although this has been reported, it is infrequent.[13,16] Recently, subsequent to our experience

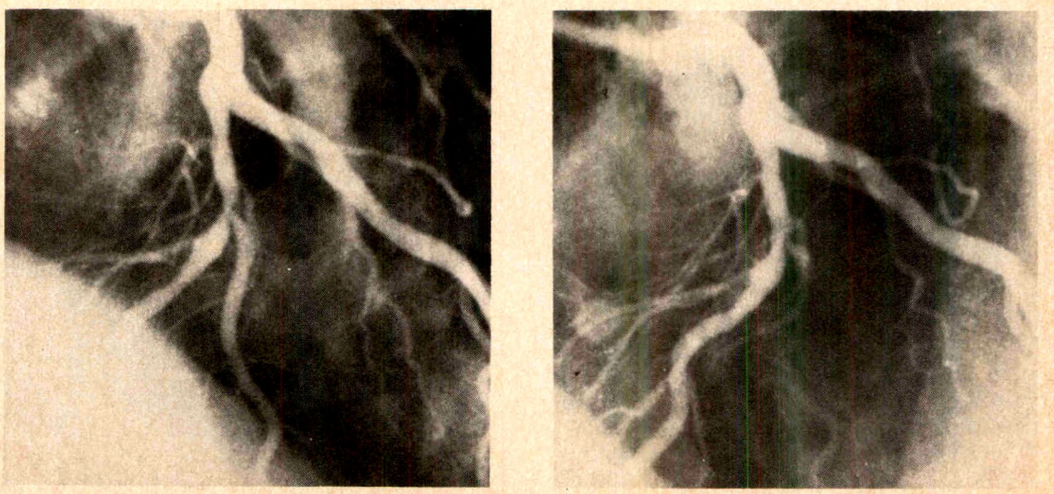

**FIGURE 5. Left,** predilatation angiogram documented a significant lesion in the mid-left anterior descending artery with involvement of a diagonal branch. **Right,** after successful PTCA, there is 100% occlusion of the diagonal branch, with retrograde filling.

with the first 100 patients, we had 1 patient in whom new, small filling defects were seen in the distal segment of the right coronary artery after successful dilatation of a mid-right coronary artery stenosis. Whether these represented embolization of thrombus adherent to an atherosclerotic lesion, atheromatous material itself, or thromboembolism from the guiding catheter is unknown. This patient subsequently had enzymatic and electrocardiographic documentation of a subendocardial infarction.

*Coronary spasm:* As previously discussed, mechanical distention, overinflation, or catheter manipulation may result in coronary spasm at the site of stenosis. Similarly, spasm results if the dilating catheter is inadvertently placed in a branch vessel or distal to the lesion. Distal spasm has been seen in 6 patients. Careful attention to catheter placement and inflation pressure, plus pretreatment with nitrates and calcium antagonists, is currently the most effective method for avoiding spasm.

*Aneurysmal dilatation:* Aneurysmal changes may occur in other segments of the arterial tree where dilatation is inadvertently performed. Dilatation in a small diagonal vessel can result in aneurysmal changes in that vessel (Fig. 6). The long-term results of inadvertent dilatation in a nondiseased or minimally diseased coronary artery are as yet unknown but are potentially adverse. Balloon dilatation has been used experimentally to produce focal atherosclerosis.[24] Fallon[25] pointed out the irony that balloon dilatation is used to treat the atherosclerotic lesions that were originally produced experimentally by balloon inflation itself.

*Intimal flap:* The intimal changes induced in segments of the coronary artery not planned for dilatation have been variable and have ranged from intimal flaps to frank dissection of the coronary artery. These usually are consequences of unsuccessful attempts to intubate the appropriate arterial segment. Figure 7 shows dissection in the circumflex coronary artery in a patient with a significant stenosis of the left anterior descending artery. Entry into the left anterior descending artery was difficult, and during attempts to do so, the circumflex artery was repeatedly entered, with subsequent intimal damage. Improvements in technology, improved patient selection, and increased operator experience with the technique will likely reduce the incidence of these complications.

**Delayed:** *New stenosis:* A new site of coronary artery stenosis remote from the angioplasty segment has been observed in 1 patient during follow-up angiography. We believe this reflects the natural history of the coronary artery disease; however, long-term evaluation must consider the possibility that new remote lesions may be related to previous dilatation.

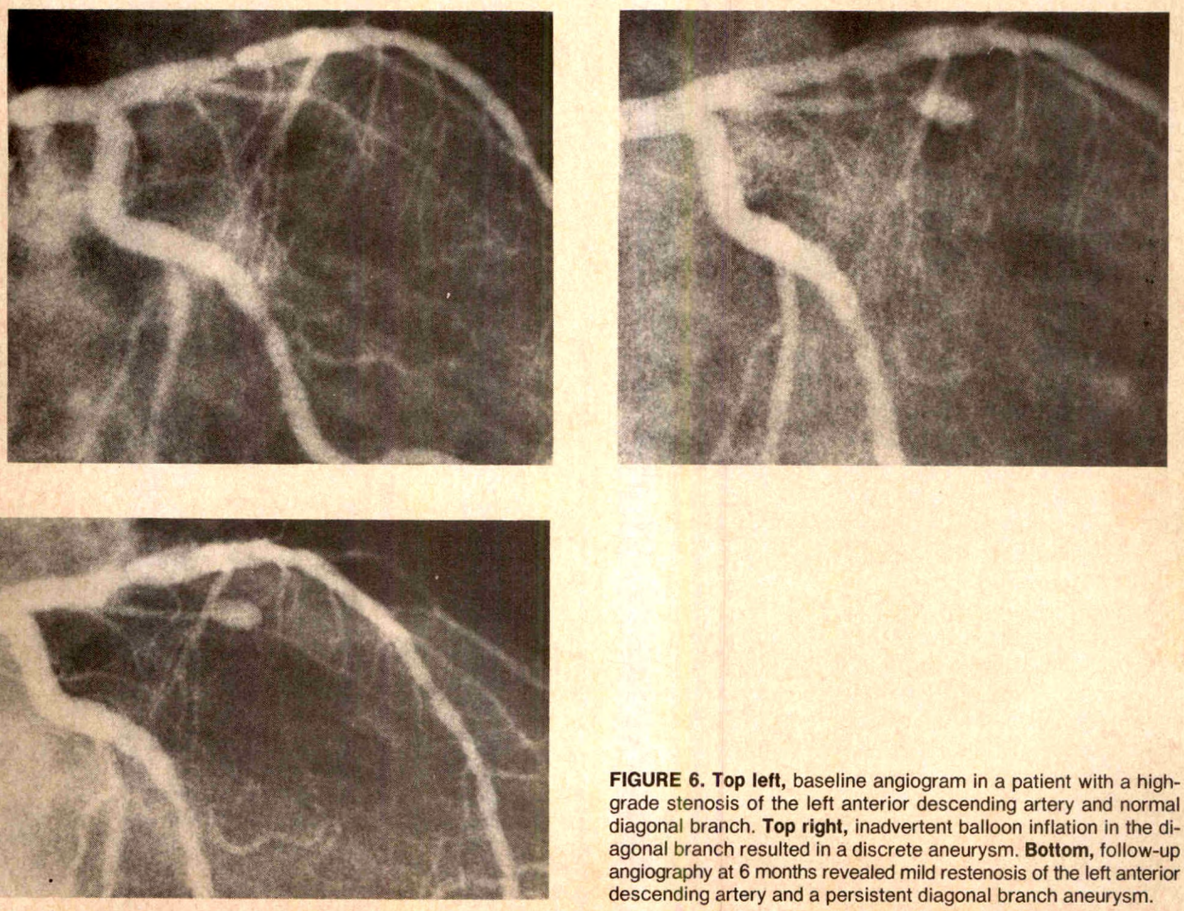

**FIGURE 6. Top left,** baseline angiogram in a patient with a high-grade stenosis of the left anterior descending artery and normal diagonal branch. **Top right,** inadvertent balloon inflation in the diagonal branch resulted in a discrete aneurysm. **Bottom,** follow-up angiography at 6 months revealed mild restenosis of the left anterior descending artery and a persistent diagonal branch aneurysm.

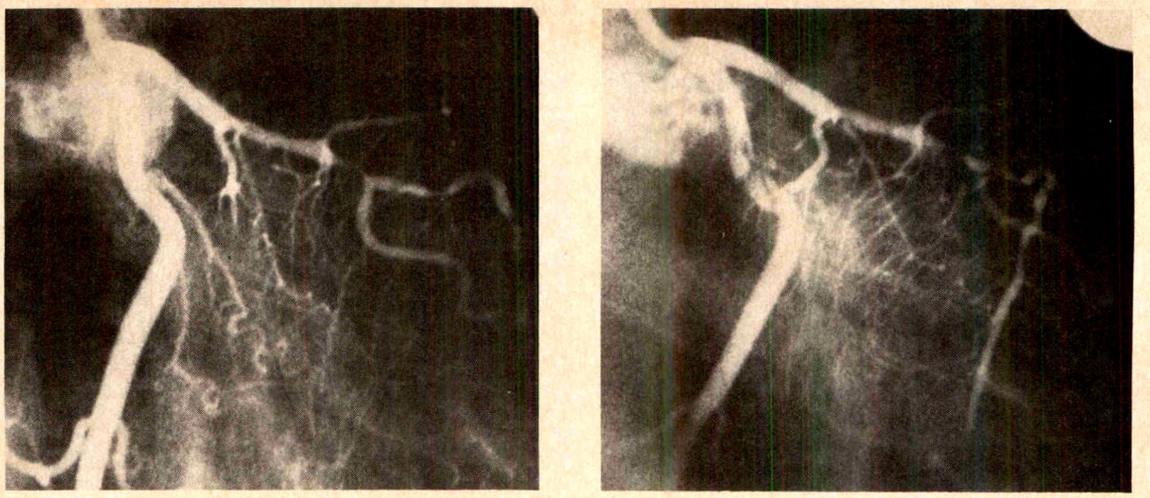

**FIGURE 7. Left,** baseline angiography in patient with a normal circumflex artery and severe stenosis of left anterior descending coronary artery. **Right,** during attempts to intubate the left anterior descending coronary artery, dissection of the circumflex artery occurred.

## Discussion

PTCA has altered the way in which angiographers view the coronary arteries. More attention is now directed to the course of diseased and nondiseased segments, as this may affect the procedure. PTCA also has modified the approach of many cardiologists in patients with symptomatic coronary artery disease. Recognition that the "controlled injury" produced by balloon inflation may result in clinical improvement requires a radical departure from our previous understanding and has led to a reappraisal of our management strategies.

The wide range of angiographic findings that result from coronary angioplasty correlates with the histopathologic findings.[9] These variable angiographic changes may be the result of catheter manipulation or balloon inflation itself. They may be seen both in the nondilated segment of the arterial tree and in the segment undergoing dilatation, and as such they may be considered complications of the technique or simply a manifestation of the controlled injury.

Proper recognition of the wide range of angiographic results is clinically important. This recognition depends on a high-quality x-ray imaging and recording system, as well as on obtaining properly angulated multiple views of all related arterial segments. After initial recognition and classification, long-term follow-up of the different angiographic groups may yield more specific prognostic information as to the outcome of patients undergoing PTCA. An example of this is the significant problem of restenosis, which may occur in as many as 30% of patients undergoing dilatation. At present, little information is available about the determinants of restenosis. Careful classification and follow-up of the diverse angiographic patterns may yield information in this regard, as these patterns reflect in part the underlying anatomic changes in the vessel wall.[9]

The angiographic classification proposed herein does not represent the complete or final statement on the issue. In fact, the terminology currently used—for example, dissection or intramural split—may undergo significant change. The classification is intended to portray some of the angiographic findings observed. Recognition and classification of these findings will become increasingly important in the evaluation of the long-term effects of PTCA and in developing new approaches for avoiding adverse effects. In addition, intensive evaluation of the clinical experiment that PTCA represents eventually may advance our understanding of coronary atherosclerosis.

# Ergonovine Provocation to Assess Efficacy of Long-Term Therapy With Calcium Antagonists in Prinzmetal's Variant Angina

MICHAEL D. WINNIFORD, MD, STACEY M. JOHNSON, MD, DAVID R. MAURITSON, MD, and L. DAVID HILLIS, MD

**In the patient with Prinzmetal's variant angina, the response to therapy with calcium antagonists may be assessed symptomatically, electrocardiographically (that is, by ambulatory electrocardiographic monitoring), or by response to ergonovine provocation. Although some studies have suggested a good relation between anginal frequency and ergonovine responsiveness in these patients, none has compared ambulatory electrocardiographic activity with the results of ergonovine provocation during the long-term administration of calcium antagonists. Therefore, the present study was performed to compare ergonovine responsiveness with both clinical and ambulatory electrocardiographic activity in patients with Prinzmetal's variant angina during long-term therapy with placebo, verapamil, and nifedipine. Accordingly, 27 patients with variant angina (19 men and 8 women, mean age 52 years) received placebo and verapamil for 2 months each, after which 23 of the 27 also received nifedipine for 2 months. All patients kept a diary of chest pains, and all had weekly 24-hour 2-channel ambulatory electrocardiographic (Holter) monitoring, from which episodes of transient S-T segment deviation were quantitated. During the final week of therapy with each agent, ergonovine was administered, beginning at 0.025 mg and incrementally increasing to 0.20 mg. It was discontinued when the patient had chest pain with S-T segment elevation $\geq$0.1 mV or received a total dose of 0.50 mg. Of the 74 tests, 59 were negative; 6 of the negative tests occurred during a treatment period in which the patient had $>$10 chest pains/week and $>$25 episodes of S-T segment deviation/week. Of the 15 positive tests, 8 became positive during administration of $<$0.20 mg ergonovine; 5 of the positive tests occurred during a treatment period in which the patient had no chest pain or S-T segment deviation. Thus, in patients with variant angina, disease activity cannot be monitored reliably by ergonovine provocation because some patients have negative ergonovine tests at a time of marked clinical and electrocardiographic activity, whereas others have positive tests at a time of little (or no) disease activity.**

Ergonovine maleate has been shown to induce coronary arterial spasm in patients with Prinzmetal's variant angina,[1–3] and calcium antagonists have been shown to block such ergonovine-induced spasm.[4,5] Previous reports have demonstrated a good relation between ergonovine responsiveness and anginal frequency during both short-term[6,7] and long-term[8,9] treatment with calcium antagonists. These same studies[8] used ergonovine provocation as a means of detecting spontaneous remissions in disease activity in patients with this syndrome.

Several studies have shown that patients with variant angina have electrocardiographic evidence of ischemia more frequently than they have angina.[10–12] Thus, the patient with this disease may demonstrate numerous episodes of transient S-T segment deviation, most (or all) of which are not accompanied by chest pain. In these persons, ambulatory electrocardiographic (Holter) monitoring is required to ascertain that the disease is not totally quiescent. The present study was performed to compare ergonovine responsiveness with clinical and ambulatory electrocardiographic activity in a group of patients with variant angina during the long-term ad-

From the Department of Internal Medicine, Cardiovascular Division, the University of Texas Health Science Center, Dallas, Texas. This study was supported in part by Ischemic SCOR Grant HL 17669 from the National Institutes of Health, Bethesda, Maryland, and by the Harry S. Moss Heart Fund, Dallas, Texas. ministration of placebo, verapamil, and nifedipine. In so doing, we attempted to address the following questions: (1) Is the response to ergonovine provocation closely linked to other reflectors of disease activity, such as anginal frequency and ambulatory electrocardiographic evidence of ischemia, or, alternatively, (2) is ergonovine responsiveness independent of the symptomatic and electrocardiographic markers of disease activity?

## Methods

**Patient group:** The study group consisted of 27 consecutive patients (19 men and 8 women, average age 52 years, range 33 to 62) with Prinzmetal's variant angina. All had angina at rest in association with transient S-T segment elevation (≥0.2 mV) on a standard 12-lead electrocardiogram. In addition, ergonovine maleate was administered at the time of initial evaluation in 21 of the 27 patients (such provocation was not performed in the remaining 6 because of concern over the presence of severe obstructive coronary artery disease). Of these 21 patients, ergonovine caused typical angina and S-T segment elevation ≥0.2 mV in 20. Simultaneous coronary angiography was performed in 16, demonstrating focal coronary arterial spasm in all. Cardiac catheterization with selective coronary arteriography was performed in 26: 10 had obstructive coronary artery disease (defined as ≥70% luminal diameter narrowing), whereas the remaining 16 had minimal or no coronary artery disease. The criteria for exclusion from the study have been described previously.[11]

**Study design:** After a diagnosis of variant angina was made, informed consent was obtained, and each patient was given open-label verapamil for 1 month, during which the maximal dose of verapamil that did not cause intolerable adverse effects was determined. Subsequently, each patient was randomly assigned to 1 of 2 groups for the next 8 months of the study: four 2-month blocks, with each patient receiving either placebo-verapamil-placebo-verapamil or verapamil-placebo-verapamil-placebo. During this part of the study, neither the physicians nor the patients knew which agent was being administered.

After the 8 months of blinded therapy, 23 patients agreed to receive nifedipine (as an "open-label" medication) for 2 more months. Both verapamil and nifedipine were administered in doses that afforded maximal relief of angina without adverse effects.

**Variables analyzed:** *Clinical and electricardiographic response to therapy:* During the entire study period, each patient maintained a written diary of anginal episodes. In addition, each patient had weekly calibrated 2-channel ambulatory electrocardiographic monitoring for 24 hours, as previously described.[11,12] Transient S-T segment deviations from baseline were said to be present if S-T segment depression or elevation ≥1 mm (0.1 mV) was present for ≥1 minute.[13] Both S-T segment depression and elevation were utilized as electrocardiographic evidence of coronary arterial spasm because patients with variant angina often demonstrate both during therapy with calcium antagonists.[10,11] A period of at least 10 minutes of baseline S-T segment morphology was required between episodes in order for these episodes to be considered separate. For each 24-hour tape, the number of transient episodes of S-T segment deviation was quantitated.

*Ergonovine provocation:* During the final week of blinded treatment periods 3 and 4, 25 of the 27 patients enrolled in the placebo-verapamil comparison had provocative testing with ergonovine maleate. One patient was tested during period 3 but died during period 4 before testing, and another patient refused. Subsequently, all 23 patients who received nifedipine had ergonovine testing during the final week of that treatment period. Thus, during therapy with placebo, verapamil, and nifedipine, 74 ergonovine tests were performed. All tests were done between 10 A.M. and 12 P.M.; they were begun 1.5 hours after a regularly scheduled dose of study medication and at least 12 hours after the last dose of long-acting nitrates. During the 24 hours before ergonovine testing, no sedatives or other cardioactive medications (that is, atropine, adrenergic or antiadrenergic agents, or antihistamines) were administered.

After a baseline 12-lead electrocardiogram and blood pressure were recorded, each patient received intravenous ergonovine maleate every 3 minutes according to the following schedule: 0.025 mg ×4 (cumulative dose, 0.10 mg); 0.05 mg ×2 (cumulative dose, 0.20 mg); 0.10 mg ×1 (cumulative dose, 0.30 mg); and 0.20 mg ×1 (cumulative dose, 0.50 mg). Before each intravenous injection, the patient was questioned about chest pain or other symptoms, and a 12-lead electrocardiogram was recorded. Ergonovine administration was discontinued when one of the following occurred: (1) chest pain in association with electrocardiographic evidence of ischemia (≥0.1 mV of S-T segment elevation), or (2) administration of a cumulative dose of 0.50 mg. All patients with a positive test had chest pain coincident with S-T segment elevation.

**Data analysis:** First, each variable (anginal episodes and S-T segment deviations) was quantitated during the latter 4 months of blinded therapy (2 months placebo, 2 months verapamil) and the 2 months of nifedipine therapy, and the average value for each variable during each 2-month period was compared with the results of ergonovine provocation during the final week of that period. Second, each variable was quantitated during the 7 days in closest temporal proximity to ergonovine provocation, and this value was compared with the ergonovine test results. Finally, these same relations (that is, clinical and electrocardiographic activity compared with ergonovine test results) were examined only in the 16 persons who did not have significant obstructive coronary artery disease and in whom, therefore, angina and S-T segment deviations must have resulted from coronary arterial spasm. For both anginal episodes and S-T segment deviations, the percentage of patients with substantial disease activity (defined as >10 episodes of angina/week and >25 episodes of S-T segment deviation/week) during a treatment period associated with a negative ergonovine test was compared with the percentage of patients with marked disease activity during a period associated with a positive ergonovine test using a chi-square analysis.[14,15]

In comparing the frequency of angina and S-T segment deviations in the 3 treatment periods, a repeated measures analysis of variance was performed. All values are reported as mean ±1 standard deviation. A p value ≤0.05 was considered significant.

## Results

The 27 patients enrolled in the long-term comparison of placebo and verapamil received 450 ± 83 mg/day of verapamil, and the 23 patients who subsequently received nifedipine averaged 71 ± 24 mg/day, both administered in 3 to 4 divided doses.

**Clinical and electrocardiographic response to therapy:** Compared with placebo, both verapamil and nifedipine reduced the frequency of angina and transient S-T segment deviations (Table I).

**Ergonovine provocation:** For the entire group of 27 patients, there were 6 positive tests during placebo therapy, 5 positive tests during verapamil (difference

**TABLE I Clinical and Electrocardiographic Response to Therapy**

| | Anginal Episodes/Week | S-T Segment Deviations/Week |
|---|---|---|
| Placebo | 9.3 ± 23.4 | 21.7 ± 32.7 |
| Verapamil | 2.7 ± 3.6* | 4.6 ± 8.3* |
| Nifedipine | 1.9 ± 2.9* | 5.4 ± 10.1* |

* $p < 0.05$ in comparison with placebo.
All values are mean ± standard deviation.

not significant [NS] compared with placebo), and 4 positive tests during nifedipine (NS compared with placebo and verapamil).

*Disease activity during the entire 2-month treatment period versus ergonovine responsiveness:* Figure 1 shows the relation between anginal episodes and S-T segment deviations for each 2-month treatment period and the results of ergonovine provocation during the final week of each treatment period. Of the 59 negative ergonovine tests, 6 (10%) were performed during periods in which the patient was having >10 episodes of chest pain/week and >25 episodes of S-T segment deviation/week. Of the 15 positive tests, 2 (13%) were done during periods in which the patient noted >10 episodes of chest pain/week (NS) and 4 (27%) during periods in which the patient was having >25 episodes of S-T segment deviation/week (NS).

*Disease activity versus ergonovine responsiveness in close temporal proximity to one another:* Figure 2 shows the relation between anginal episodes and S-T segment deviations during the 7 days in closest proximity to ergonovine provocation and the results of each ergonovine test. Of the 59 negative ergonovine tests, 6 (10%) were performed during a week when the patient had >10 episodes of chest pain, and 5 (8%) were done during a week when the patient had >25 episodes of S-T segment deviation. Of the 15 positive tests, 3 (20%) were done during a week in which the patient had >10 episodes of chest pain (NS) and 4 (27%) during a week in which the patient had >25 episodes of S-T segment deviation (NS).

*Disease activity versus ergonovine responsiveness in the 6 patients with positive ergonovine tests during placebo therapy:* For the 6 patients who had a positive ergonovine test during placebo therapy, the relation between ergonovine responsiveness and disease activity (assessed during both the entire 2-month treatment period as well as the 7 days in closest temporal proximity to ergonovine provocation) was similar to that described for all 27 patients. In this subset of patients, ergonovine provocation was sometimes negative during a period of marked symptomatic or electrocardiographic activity, and, conversely, ergonovine testing was often markedly positive during a period of little or no disease activity.

*Disease activity versus ergonovine responsiveness in patients without significant obstructive coronary artery disease:* Of the 27 patients in the present study, 16 did not have significant obstructive coronary artery disease. In these patients, chest pain and S-T segment deviations are almost always caused by coronary arterial spasm. For these 16, 36 ergonovine tests were negative, and 12 were positive. Of the 36 negative tests, 3 (8%) were performed during a week when the patient had >10 episodes of chest pain and 2 (6%) were performed during a week in which the patient had >25 episodes of S-T segment deviation. Of the 12 positive tests, 2 (17%) were done during a week in which the patient had >10 episodes of angina (NS) and 3 (25%) were done during a week in which the patient had >25 episodes of S-T segment deviation (NS).

## Discussion

Ergonovine maleate has been shown to induce coronary arterial spasm in certain patients with Prinzmetal's variant angina,[1-3] and calcium antagonists have been shown to block ergonovine-induced spasm.[4,5] Over the past few years, several studies utilized ergonovine provocation to assess the adequacy of as well as the need for continued medical therapy in patients with this disease. First, Theroux,[6] Waters,[7] and their co-workers demonstrated an excellent relation between the results of ergonovine provocation and the short-term (2 day) clinical response to therapy with calcium antagonists, and similar findings were reported using methergine (an ergot alkaloid similar to ergonovine maleate)[9] and hyperventilation.[16] Second, Waters et al[7] showed that ergonovine testing within several days of the initiation of calcium antagonist therapy can be used reliably to predict the long-term (1 to 15 month) response to such therapy. Third, these same investigators[8] suggested that some patients with variant angina who are pain-free during long periods of treatment may not require indefinite therapy; ergonovine provocation appears to be a good method of evaluating the status of the disease process in these patients.

In contrast to these reports, the present study demonstrates no relation between the results of ergonovine provocation and disease activity, as assessed during both the entire 2-month treatment period preceding such ergonovine testing (Fig. 1) as well as the 7 days in closest temporal proximity to testing (Fig. 2). Both clinical and electrocardiographic evidence of marked disease activity occurred with similar frequency during periods with a positive ergonovine test and those with a negative test, and there was a wide variation in disease activity during both positive and negative test periods (Fig. 1 and 2). This was true for all 27 patients as well as for the 16 patients without significant obstructive coronary artery disease, a group in which chest pain and S-T segment deviations are almost always caused by coronary arterial spasm. Thus, the results of ergonovine provocation during long-term therapy with verapamil and nifedipine bear no relation to the clinical and electrocardiographic response to therapy.

The present study demonstrates an obvious disparity between ergonovine responsiveness and both clinical and electrocardiographic evidence of disease activity in a group of patients with Prinzmetal's variant angina, but the reasons for this disparity are not clear. The total dose of ergonovine used in the present study—0.50

mg—is lower than that employed by Waters,[6] Theroux,[8] and their associates, but this difference cannot explain the discrepancy in results between the present study and these previous reports. On the one extreme, several patients had positive ergonovine tests at small dosages during periods of little or no clinical or electrocardiographic activity (Fig. 1 and 2); this poor relation cannot be explained by differences in ergonovine dosages. On the other extreme, several other patients had negative ergonovine tests during periods of marked clinical or electrocardiographic activity. Because the cumulative dose of ergonovine given in the present study (0.50 mg) exceeds that in most available reports,[1–3,5,17–20] it is unlikely that the negativity of these tests can be attributed to an insufficient dose of ergonovine. Although it is possible that some of them would have become positive if more ergonovine had been given, the data of Waters,[6] Theroux,[7] and co-workers demonstrate that virtually all clinically active patients have a positive response before receiving a total of 0.50 mg of ergonovine. Thus, the poor relation between clinical activity and the results of ergonovine provocation cannot be explained entirely by differences in ergonovine doses. Similarly, before enrollment in the study, these patients had sufficient coronary arterial spasm to justify a diagnosis of variant angina: all 27 had chest pain at rest in association with reversible S-T segment elevation, and 20 of the 21 given ergonovine had a positive response. It appears unlikely that our patient group was in any way atypical or different from those described by other investigators. For reasons that are unclear at present, therefore, ergonovine responsiveness appears completely independent of the symptomatic and electrocardiographic markers of dis-

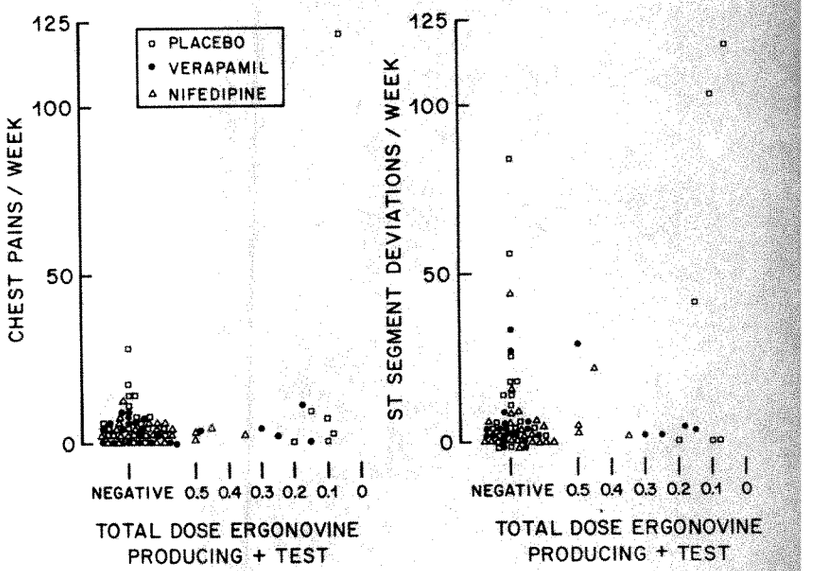

**FIGURE 1. Left panel,** relation between clinical evidence of disease activity, displayed as chest pains/week (during entire 2-month treatment period with each pharmacologic agent), and the results of ergonovine provocation (during the final week of the treatment period). **Right panel,** relation between electrocardiographic evidence of disease activity, shown as S-T segment deviations/week (during the entire 2-month treatment period with each agent) and the results of ergonovine testing (performed during the final week of the treatment period). Note that several patients with negative ergonovine tests had frequent chest pains and S-T segment deviations; conversely, most of the ergonovine tests that were positive at small cumulative doses (≤0.20 mg) were not associated with frequent angina or S-T segment deviations.

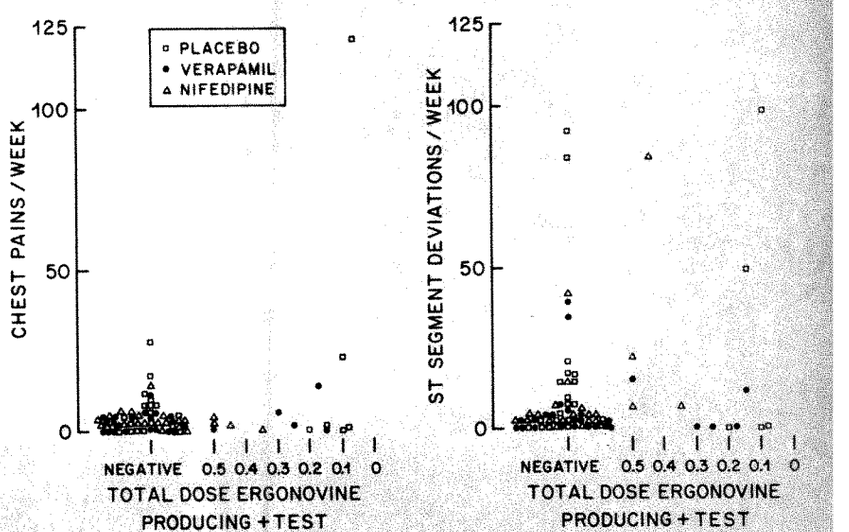

**FIGURE 2. Left panel,** relation between clinical evidence of disease activity, displayed as chest pains/week (during the week in closest proximity to ergonovine provocation), and the results of ergonovine testing. **Right panel,** relation between electrocardiographic evidence of disease activity, shown as S-T segment deviations/week (during the week in closest proximity to ergonovine administration), and the results of ergonovine provocation. Note that several patients with negative ergonovine tests had frequent chest pains and S-T segment deviations, whereas most of the ergonovine tests that were positive were not associated with frequent chest pain or S-T segment deviations.

ease activity in this group of patients with Prinzmetal's variant angina.

All the ergonovine tests in the present study were done under close clinical and electrocardiographic scrutiny, but selective coronary arteriography was not performed during ergonovine administration. Although the relation between ergonovine responsiveness and both clinical and electrocardiographic activity is poor, that between ergonovine responsiveness and the results of coronary arteriography might conceivably be better. Because coronary arteriography was not performed during each ergonovine provocation, we cannot comment on this relation.

In the present study, 74 ergonovine tests were performed without complications during clinical and electrocardiographic monitoring in patients both with and without obstructive coronary artery disease. Although previous reports[20] emphasized the potentially serious side effects of ergonovine administration, such reactions can be minimized if the initial doses of ergonovine are sufficiently small and separated temporally from one another. Specifically, the ergonovine provocation described in the present study is initiated with 4 doses of 0.025 mg each, administered 3 minutes apart. Subsequently, the ergonovine dose is gradually increased, so that a final dose of 0.20 mg is given only after the patient has not responded to smaller amounts.

*Conclusion:* This study demonstrates no relation between ergonovine responsiveness and clinical or electrocardiographic evidence of disease activity in patients with Prinzmetal's variant angina during long-term therapy with calcium antagonists. These data suggest that disease activity cannot be monitored reliably by ergonovine provocation because some patients have negative ergonovine tests at a time of marked clinical and electrocardiographic activity, whereas others have positive tests at a time of little (or no) disease activity. In patients with variant angina, anginal frequency and ambulatory electrocardiographic monitoring are preferable to ergonovine provocation in allowing an accurate assessment of disease activity.

Announcing a major advance
in cardiovascular therapy

# New CARDIZEM™
# (diltiazem HCl)

## CALCIUM CHANNEL BLOCKADE
from Marion Laboratories

**Potent coronary vasodilation with a distinctive hemodynamic profile**

Please see full prescribing information on last p

# INCREASES EXERCISE TOLERANCE, REDUCES ANGINAL FREQUENCY WITH A LOW INCIDENCE OF SIDE EFFECTS

CARDIZEM™ (diltiazem HCl) produces changes in cardiovascular hemodynamics and coronary blood flow that are of benefit in myocardial ischemia.

These changes provide effective therapy with a low incidence of side effects.

**Indications**

(1) Cardizem is indicated in the treatment of angina pectoris due to coronary artery spasm.

(2) Cardizem is indicated in the management of chronic stable angina (classic effort-associated angina) in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents.

## ANTIANGINAL MECHANISM OF ACTION

- Produces relaxation of coronary vascular smooth muscle
- Dilates both large and small coronary arteries at drug levels that cause little or no negative inotropic effect
- Produces dose-dependent decreases in peripheral resistance
- Resting heart rate is usually unchanged or slightly reduced

**Reduces the pressure/rate product for any given work load in patients with effort-associated angina**

© 1983, Marion Laboratories, Inc.

# CARDIZEM™ (diltiazem HCl) offers a distinctive profile of effects

(1) Vascular smooth-muscle relaxation with a potent effect on the coronary arteries.[1]

(2) Mild effect on afterload reduction.

(3) In normotensive patients at rest, recommended dosage levels producing coronary vasodilation result in only a mild reduction in diastolic blood pressure and no change in heart rate.

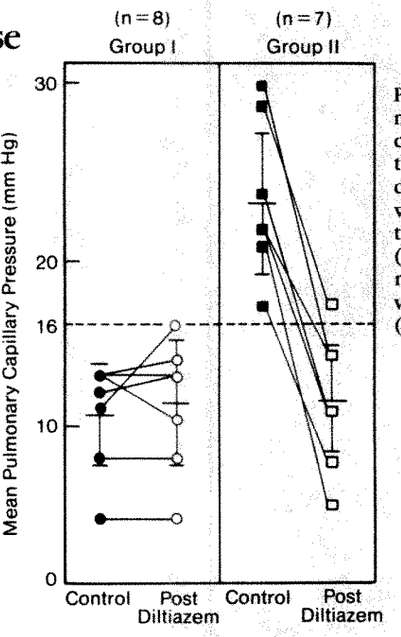
(4) At submaximal exercise, it causes a reduction in heart rate and mean blood pressure compared with placebo, thus reducing myocardial oxygen demand and permitting patients to exercise significantly longer.

(5) Increases coronary blood flow.

(6) Little or no negative inotropic effect at recommended doses while providing a powerful inhibition of coronary artery spasm.

(7) A positive effect on left ventricular function in patients with reduced left ventricular ejection fraction.[2]

(8) Increases ejection fraction at both submaximal and maximal exercise. Exercise ejection fraction is especially increased in patients with poor ventricular function.[3]



**While Cardizem tends to prolong AV conduction,* only rarely has there been an increase in PR intervals outside of normal limits.**

*See Contraindications and Warnings.

# CARDIZEM™ (diltiazem HCl) tends to normalize stress-induced increases in pulmonary capillary pressure (PCP)

The effect of a single 120-mg† dose of Cardizem was evaluated on symptom-limited upright exercise in 15 patients with effort angina.[4]

†It should be noted that this study employed a single 120-mg dose of diltiazem for hemodynamic measurement purposes. The approved maximum dose for Cardizem is 240 mg given in divided doses, three to four times daily.

**CHANGE IN FILLING PRESSURE AT MAXIMAL EXERCISE[4]**

Patients with control PCPs in normal range at maximal exercise showed little change in these values following diltiazem (Group I). Patients with markedly elevated control PCPs at maximal exercise (>16 mm Hg) showed dramatic reductions in these values following diltiazem (Group II).

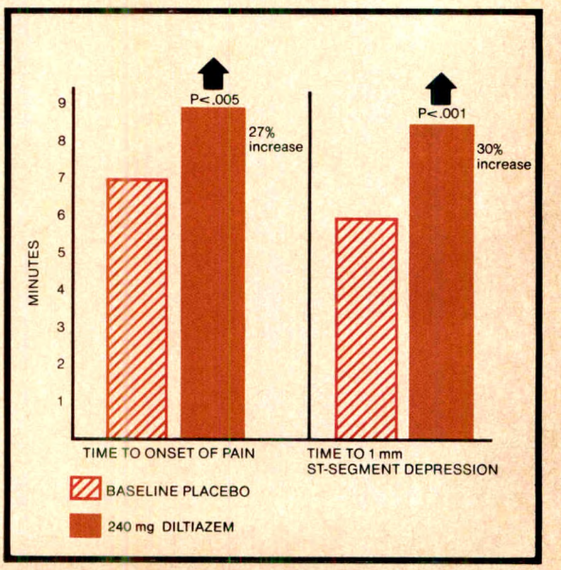
# EXCELLENT CLINICAL RESPONSE TO CARDIZEM™ (diltiazem HCl) IN THE MANAGEMENT OF CLASSIC EFFORT ANGINA

CARDIZEM™ (diltiazem HCl) allows angina patients to significantly prolong exercise tolerance, even in demanding Bruce protocol exercise tests[5] (n=15)*

## Protocol:

A Bruce protocol with a run-in stage was used. Each stage lasts three minutes.

Succeeding stages represent such an increase in speed and slant of the treadmill that each minute spent in a succeeding stage represents a highly significant increase in metabolic equivalents (METS). For example, METS expenditure in run-in stage of the protocol (0 to 3 min) is 1.5. METS expenditure of stage 1 (3 to 6 min) is 4.0. Stage 2 (6 to 9 min) expenditure is 6.5, and stage 3 (9 to 12 min) is 10.



The study[5,6] was double-blind, randomized, triple cross-over comparing diltiazem with placebo, lasting 7 weeks.

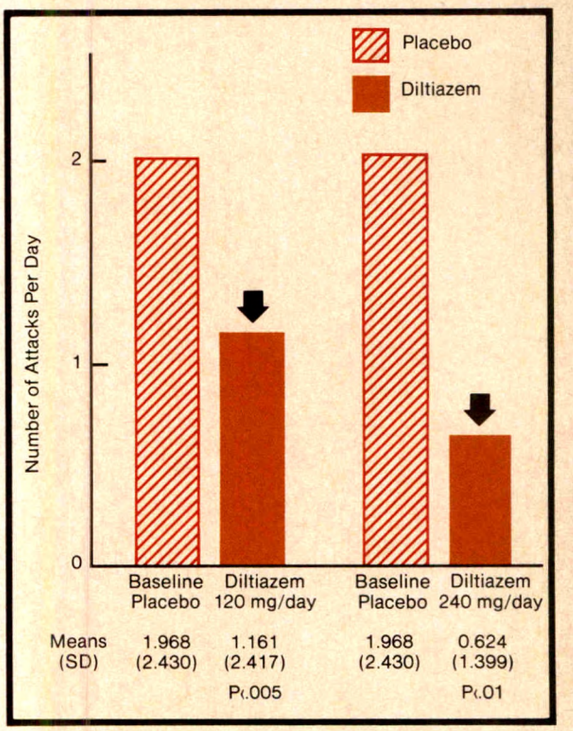
## CARDIZEM™ (diltiazem HCl) produced marked angina improvement in multicenter study[6]

- 27% increase in time to onset of pain
- 30% increase in time to ST-segment depression

**RESULTS OF 57 PATIENTS EVALUATED IN A MULTICENTER STUDY[6]**

# CARDIZEM™ (diltiazem HCl) PRODUCED SIGNIFICANT DECREASE IN EFFORT ANGINA ATTACKS COMPARED WITH PLACEBO IN 63-PATIENT DIARY STUDY[7]

Cardizem therapy resulted in a mean reduction of 5.3 attacks per week during weeks 7 and 8, compared with a mean reduction with placebo of 2.0 attacks per week.



During weeks 9 and 10, Cardizem therapy resulted in a mean reduction of approximately 5.9 attacks per week compared with a mean reduction of 2.5 attacks per week with placebo.

## 41% TO 68% REDUCTION IN FREQUENCY OF PRINZMETAL'S VARIANT ANGINA ATTACKS WITH CARDIZEM™ (diltiazem HCl)[8]

Mean attack rate during 120-mg/day dosage period was reduced 41% from baseline period. In 240-mg/day phase, decrease with Cardizem was 68%. This shows a positive dose-related response.

**75% reduction in attack rate reported in 13-patient, cross-over, placebo-controlled study[1]**

**71% reduction in attack rate reported in 11-patient, cross-over, placebo-controlled study[9]**

cardizem™
(diltiazem HCl)
30 mg and 60 mg tablets

# LOW INCIDENCE OF SIDE EFFECTS WITH CARDIZEM™ (diltiazem HCl)

**In placebo-controlled trials conducted in the United States, the incidence of adverse reactions reported during Cardizem therapy was not greater than that reported during placebo therapy.**

Those adverse reactions reported most frequently with CARDIZEM™ (diltiazem HCl) have been:

- Nausea . . . . . 2.7%
- Swelling/edema . . . . . 2.4%
- Arrhythmia . . . . . 2.0%
- Headache . . . . . 2.0%
- Rash . . . . . 1.8%
- Fatigue . . . . . 1.1%

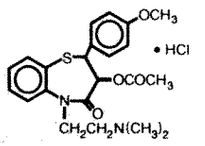
In many cases, the relationship to Cardizem has not been established.

Other reactions infrequently reported (<1.0%) during supervised trials were:

- Cardiovascular: Flushing, congestive heart failure, bradycardia, hypotension, syncope, pounding heart
- Central Nervous System: Drowsiness, dizziness, lightheadedness, nervousness, depression, weakness, insomnia, confusion, hallucinations
- Gastrointestinal: Vomiting, diarrhea, gastric upset, constipation, indigestion, pyrosis
- Dermatologic: Pruritus, petechiae, urticaria
- Other: Photosensitivity, nocturia, thirst, paresthesias, polyuria, osteoarticular pain

Of those adverse reactions reported, the most severe were:
A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of Cardizem.

Experience in 959 patients taking oral doses of Cardizem resulted in three cases (0.31%) of second-degree AV block and one case (0.10%) of third-degree AV block at doses of 240 to 360 mg daily.



In rare instances, mild to moderate transient elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK have been noted during Cardizem therapy. A single incident of markedly elevated liver enzymes associated with symptoms was reported in a patient taking 360 mg per day for four days. Drug was discontinued and enzymes normalized within 1 week.

# PROFESSIONAL USE INFORMATION

**cardizem™**
**(diltiazem HCl)**
30 mg and 60 mg tablets

## DESCRIPTION

CARDIZEM™ (diltiazem hydrochloride) is a calcium ion influx inhibitor (slow channel blocker or calcium antagonist). Chemically, diltiazem hydrochloride is 1,5-Benzothiazepin-4(5H)one,3-(acetyloxy)-5-[2-(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-, monohydrochloride,(+) -cis-. The chemical structure is:

Diltiazem hydrochloride is a white to off-white crystalline powder with a bitter taste. It is soluble in water, methanol, and chloroform. It has a molecular weight of 450.98. Each tablet of CARDIZEM contains either 30 mg or 60 mg diltiazem for oral administration.

## CLINICAL PHARMACOLOGY

The therapeutic benefits achieved with CARDIZEM are believed to be related to its ability to inhibit the influx of calcium ions during membrane depolarization of cardiac and vascular smooth muscle.

**Mechanism of Action.** Although precise mechanisms of its antianginal actions are still being delineated, CARDIZEM is believed to act in the following ways:

1. Angina Due to Coronary Artery Spasm: CARDIZEM has been shown to be a potent dilator of coronary arteries both epicardial and subendocardial. Spontaneous and ergonovine-induced coronary artery spasm are inhibited by CARDIZEM.
2. Exertional Angina: CARDIZEM has been shown to produce increases in exercise tolerance probably due to its ability to reduce myocardial oxygen demand. This is accomplished via reductions in heart rate and systemic blood pressure at submaximal and maximal exercise work loads.

In animal models, diltiazem interferes with the slow inward (depolarizing) current in excitable tissue. It causes excitation-contraction uncoupling in various myocardial tissues without changes in the configuration of the action potential. Diltiazem produces relaxation of coronary vascular smooth muscle and dilation of both large and small coronary arteries at drug levels which cause little or no negative inotropic effect. The resultant increases in coronary blood flow (epicardial and subendocardial) occur in ischemic and nonischemic models and are accompanied by dose-dependent decreases in systemic blood pressure and decreases in peripheral resistance.

**Hemodynamic and Electrophysiologic Effects.** Like other calcium antagonists, diltiazem decreases sinoatrial and atrioventricular conduction in isolated tissues and has a negative inotropic effect in isolated preparations. In the intact animal, prolongation of the AH interval can be seen at higher doses.

In man, diltiazem prevents spontaneous and ergonovine-provoked coronary artery spasm. It causes a decrease in peripheral vascular resistance and a modest fall in blood pressure and, in exercise tolerance studies in patients with ischemic heart disease, reduces the heart rate/blood pressure product for any given work load. Studies to date, primarily in patients with good ventricular function, have not revealed evidence of a negative inotropic effect; cardiac output, ejection fraction, and left ventricular end diastolic pressure have not been affected. There are as yet few data on the interaction of diltiazem and beta-blockers. Resting heart rate is usually unchanged or slightly reduced by diltiazem.

Intravenous diltiazem in doses of 20 mg prolongs AH conduction time and AV node functional and effective refractory periods approximately 20%. In a study involving single oral doses of 300 mg of CARDIZEM in six normal volunteers, the average maximum PR prolongation was 14% with no instances of greater than first-degree AV block. Diltiazem-associated prolongation of the AH interval is not more pronounced in patients with first-degree heart block. In patients with sick sinus syndrome, diltiazem significantly prolongs sinus cycle length (up to 50% in some cases).

Chronic oral administration of CARDIZEM in doses of up to 240 mg/day has resulted in small increases in PR interval, but has not usually produced abnormal prolongation. There were, however, three instances of second-degree AV block and one instance of third-degree AV block in a group of 959 chronically treated patients.

**Pharmacokinetics and Metabolism.** Diltiazem is absorbed from the tablet formulation to about 80% of a reference capsule and is subject to an extensive first-pass effect, giving an absolute bioavailability (compared to intravenous dosing) of about 40%. CARDIZEM undergoes extensive hepatic metabolism in which 2% to 4% of the unchanged drug appears in the urine. In vitro binding studies show CARDIZEM is 70% to 80% bound to plasma proteins. Competitive ligand binding studies have also shown CARDIZEM binding is not altered by therapeutic concentrations of digoxin, hydrochlorothiazide, phenylbutazone, propranolol, salicylic acid, or warfarin. Single oral doses of 30 to 120 mg of CARDIZEM result in detectable plasma levels within 30 to 60 minutes and peak plasma levels two to three hours after drug administration. The plasma elimination half-life following single or multiple drug administration is approximately 3.5 hours. Desacetyl diltiazem is also present in the plasma at levels of 10% to 20% of the parent drug and is 25% to 50% as potent as a coronary vasodilator as diltiazem. Therapeutic blood levels of CARDIZEM appear to be in the range of 50 to 200 ng/ml. There is a departure from dose-linearity when single doses above 60 mg are given; a 120-mg dose gave blood levels three times that of the 60-mg dose. There is no information about the effect of renal or hepatic impairment on excretion or metabolism of diltiazem.

## INDICATIONS AND USAGE

1. **Angina Pectoris Due to Coronary Artery Spasm.** CARDIZEM is indicated in the treatment of angina pectoris due to coronary artery spasm. CARDIZEM has been shown effective in the treatment of spontaneous chronic stable angina presenting as Prinzmetal's variant angina (resting angina with ST-segment elevation occurring during attacks).
2. **Chronic Stable Angina (Classic Effort-Associated Angina).** CARDIZEM is indicated in the management of chronic stable angina in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents. CARDIZEM has been effective in short-term controlled trials in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness is incomplete.

There are no controlled studies of the effectiveness of the concomitant use of diltiazem and beta-blockers or of the safety of this combination in patients with impaired ventricular function or conduction abnormalities.

## CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block, and (3) patients with hypotension (less than 90 mm Hg systolic).

## WARNINGS

1. **Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (4 of 959 patients for 0.42%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg diltiazem.
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.
4. **Acute Hepatic Injury.** There has been a single report in a patient receiving 120 mg of diltiazem t.i.d. of marked transaminase elevation (SGOT 4500, SGPT 2300) accompanied by hyperbilirubinemia (to 3 mg%), occurring after four days of treatment. The enzyme abnormalities resolved entirely, and enzymes were nearly normal a week after cessation of treatment. No rechallenge was carried out, but the patient had no evidence of viral hepatitis and received no other drugs but isosorbide dinitrate.

   No other similar liver injury has been reported in clinical trials, but marketing experience in Europe has resulted in a rechallenge-confirmed instance of hepatocellular injury. However, it should be noted that there have been further episodes of raised transaminases in the absence of diltiazem in this patient, so that the relationship to diltiazem of the abnormalities is not completely clear. Other instances of transaminase elevation have been reported in Europe, but their relationship to drug is uncertain.

## PRECAUTIONS

**General.** CARDIZEM is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any new drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

**Drug Interaction.** Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS.)

Uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities; the effect of diltiazem on serum digoxin levels has not been examined. The safety of the combination of CARDIZEM and beta-blockers or digitalis is currently being investigated in well-controlled studies.

**Carcinogenesis, Mutagenesis, Impairment of Fertility.** A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.

**Pregnancy.** Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

**Nursing Mothers.** It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when CARDIZEM is administered to a nursing woman if the drug's benefits are thought to outweigh its potential risks in this situation.

**Pediatric Use.** Safety and effectiveness in children have not been established.

## ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded. Experience with an added beta-blocker is also extremely limited.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

In addition, the following have been reported infrequently and represent occurrences which can be at least reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences, as well as their frequency of presentation, are nausea (2.7%), swelling/edema (2.4%), arrhythmia (2.0%), headache (2.0%), rash (1.8%), and fatigue (1.1%). In addition, the following events were reported infrequently (<1.0%). The order of presentation corresponds to the relative frequency of occurrence.

| | |
|---|---|
| Cardiovascular: | Flushing, congestive heart failure, bradycardia, hypotension, syncope, pounding heart. |
| Central Nervous System: | Drowsiness, dizziness, lightheadedness, nervousness, depression, weakness, insomnia, confusion, hallucinations. |
| Gastrointestinal: | Vomiting, diarrhea, gastric upset, constipation, indigestion, pyrosis. |
| Dermatologic: | Pruritus, petechiae, urticaria. |
| Other: | Photosensitivity, nocturia, thirst, paresthesias, polyuria, osteoarticular pain. |

The following additional experiences have been noted:

A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of CARDIZEM.

Experience in 959 patients taking oral doses of CARDIZEM resulted in three cases (0.31%) of second-degree AV block and one case (0.10%) of third-degree AV block at doses of 240 to 360 mg daily.

In rare instances, mild to moderate transient elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK have been noted during CARDIZEM therapy. A single incident of markedly elevated liver enzymes associated with symptoms was reported in a patient taking 360 mg per day for four days. Drug was discontinued and enzymes normalized within 1 week.

## OVERDOSAGE OR EXAGGERATED RESPONSE

Overdosage experiences with oral diltiazem have not been reported. Single oral doses of 300 mg of CARDIZEM have been well tolerated by healthy volunteers. In the event of overdosage or exaggerated response, appropriate supportive measures should be employed in addition to gastric lavage. The following measures may be considered:

| | |
|---|---|
| Bradycardia | Administer atropine (0.60 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously. |
| High-Degree AV Block | Treat as for bradycardia above. Fixed high-degree AV block should be treated with cardiac pacing. |
| Cardiac Failure | Administer inotropic agents (isoproterenol, dopamine, or dobutamine) and diuretics. |
| Hypotension | Vasopressors (eg, dopamine or levarterenol bitartrate). |

Actual treatment and dosage should depend on the severity of the clinical situation and the judgment and experience of the treating physician.

The oral $LD_{50}$'s in mice and rats range from 415 to 740 mg/kg and from 560 to 810 mg/kg, respectively. The intravenous $LD_{50}$'s in these species were 60 and 38 mg/kg, respectively. The oral $LD_{50}$ in dogs is considered to be in excess of 50 mg/kg, while lethality was seen in monkeys at 360 mg/kg. The toxic dose in man is not known, but blood levels in excess of 800 ng/ml have not been associated with toxicity.

## DOSAGE AND ADMINISTRATION

**Exertional Angina Pectoris Due to Atherosclerotic Coronary Artery Disease or Angina Pectoris at Rest Due to Coronary Artery Spasm.** Dosage must be adjusted to each patient's needs. Starting with 30 mg four times daily, before meals and at bedtime, dosage should be increased gradually to 240 mg (given in divided doses three or four times daily) at one- to two-day intervals until optimum response is obtained. The effectiveness and safety of dosages exceeding 240 mg per day are currently being investigated. There are no available data concerning dosage requirements in patients with impaired renal or hepatic function. If the drug must be used in such patients, titration should be carried out with particular caution.

**Concomitant Use With Other Antianginal Agents.**

1. **Sublingual NTG** may be taken as required to abort acute anginal attacks during CARDIZEM therapy.
2. **Prophylactic Nitrate Therapy** – CARDIZEM may be safely coadministered with short- and long-acting nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.
3. **Beta-blockers.** (See WARNINGS and PRECAUTIONS.)

## HOW SUPPLIED

CARDIZEM 30-mg tablets are supplied in bottles of 100 (NDC 0088-1771-47). Each green tablet is engraved with MARION on one side and 1771 engraved on the other. CARDIZEM 60-mg scored tablets are supplied in bottles of 100 (NDC 0088-1772-47). Each yellow tablet is engraved with MARION on one side and 1772 on the other.

# The ECG cartridge with 50 lives.

## DEL MAR AVIONICS

Conventional 24-hour Holter reel tapes have less than 9 lives. And cassettes are recommended only for single use.

But our advanced design, four-channel cartridge, when used with the Series 449 Electrocardiocorder® Systems, may be erased and re-used for up to 50 ambulatory recordings.

The reasons?

The cartridge has been specifically designed with extended tape life in mind. Combining the convenience of a cassette with the accuracy of a reel-to-reel design, the cartridge tape can be manipulated at today's high scanning speeds with exact precision. Moreover, precise data management can be attained without tape stretching or twisting, increasing tape life at least ten-fold.

Precise time coding, using a proprietary digital encoding process, ensures timing accuracy to within one second throughout the entire 24-hour recording. And the magnetic characteristics of the tape itself are matched exactly to the dynamic range of our analyzers. Total system compatibility gives you optimal fidelity.

And if that's not enough, one of the cartridge channels can be used to record ambulatory blood pressure, further extending your diagnostic capability.

For more details on the four-channel cartridge that gives you added life, superior fidelity and BP capability, contact Del Mar Avionics, 1601 Alton Avenue, Irvine, California 92714, Telephone (714) 549-1500, or call toll free at (800) 854-0481, (in California 800/432-8446), Telex: 68-5621.

# Frequency in Nonangioplasty Patients of Morphologic Findings Reported in Coronary Arteries Treated With Transluminal Angioplasty

JEFFREY M. ISNER, MD and ROBERTA V. FORTIN, BS

**The coronary arteries from 70 consecutive patients in whom percutaneous transluminal angioplasty (PTA) had *not* been performed during life were examined at necropsy for findings that have been previously described in patients or animals treated with PTA. In 33 (49%) of the 70 patients, 1 or more findings identical to those observed in necropsy studies of PTA-treated arteries were observed: "plaque fractures" in 31 (44%), "dissection clefts" in 26 (33%), and extensive medial thinning in 40 (57%). Observations in these 70 patients indicate that findings previously described in PTA-treated patients cannot necessarily be assumed to represent the results of PTA. The fact that improved vessel patency may be seen in the absence as well as the presence of such lesions precludes firm assurance that such lesions are the sole basis for successful angioplasty.**

Despite the fact that percutaneous transluminal angioplasty (PTA) has now been used successfully to treat peripheral, renal, and coronary arterial stenoses in thousands of patients, the mechanism by which PTA improves vascular patency remains an enigma. Dotter and Judkins[1] in their original description of the procedure as well as Grüntzig,[2] 12 years later, attributed the mechanism of PTA to redistribution and compression of the atheromatous intima. Subsequent investigators carried out a variety of pathologic studies to define the mechanism by which PTA improves vascular patency.[3–10] Most studies employed either human cadaver specimens subjected to PTA postmortem[3,5,8,9] or animals in which lesions had been experimentally induced[4,10]; few were performed in humans who had undergone PTA antemortem.[6,7] Most of these studies did not include comparison of the PTA-treated vessel with control, that is, non-PTA–treated, vessels. Accordingly, this study determines the frequency with which morphologic findings ascribed to PTA are present in histologic sections of coronary arteries excised at necropsy from patients who never were treated with PTA.

From the Departments of Pathology and Medicine (Cardiology), Tufts-New England Medical Center, Boston, Massachusetts. Manuscript received September 6, 1982; revised manuscript received October 27, 1982, accepted October 29, 1982.

Address for reprints: Jeffrey M. Isner, MD, Box 70, Tufts-New England Medical Center, 171 Harrison Avenue, Boston, Massachusetts 02111.

## Methods

The major extramural coronary arteries were excised intact from the hearts of 70 consecutive patients who had died and undergone necropsy examination. None had been treated with PTA. The coronary arteries were prepared for histologic examination as described elsewhere.[11] Briefly, each coronary artery was decalcified in a solution of 10% formic acid and formalin (Decalcifier I, Surgipath) if necessary, fixed overnight in 10% buffered formalin, and then cut transversely into 5 mm long segments. Representative segments were then dehydrated in graded alcohols, cleared with xylene, impregnated with and then embedded in paraffin, and finally cut into 4 $\mu$m thick sections. Sections stained with Verhoeff's elastic tissue stain as well as sections stained with hematoxylin and eosin were prepared from each 5 mm segment. Histologic sections prepared from the coronary arteries of each patient were reviewed by light microscopy for morphologic changes described previously in patients or animals treated with PTA.

## Results

**Plaque fractures:** Vertical or serpentine cracks in the atherosclerotic plaque, extending from the lumen into the plaque, have been interpreted as "fractures" resulting from PTA.[4,6,7,9,10] Plaque cracks extending from the lumen for variable lengths into the plaque and at times associated with an apparent secondary dissection cleft were observed in 31 (44%) of the 70 non-PTA–treated patients. Examples of these plaque cracks are illustrated in Figures 1 and 3a.

**Dissection clefts:** Apparent clefts within the atherosclerotic plaque or media, as well as cleft-like sepa-

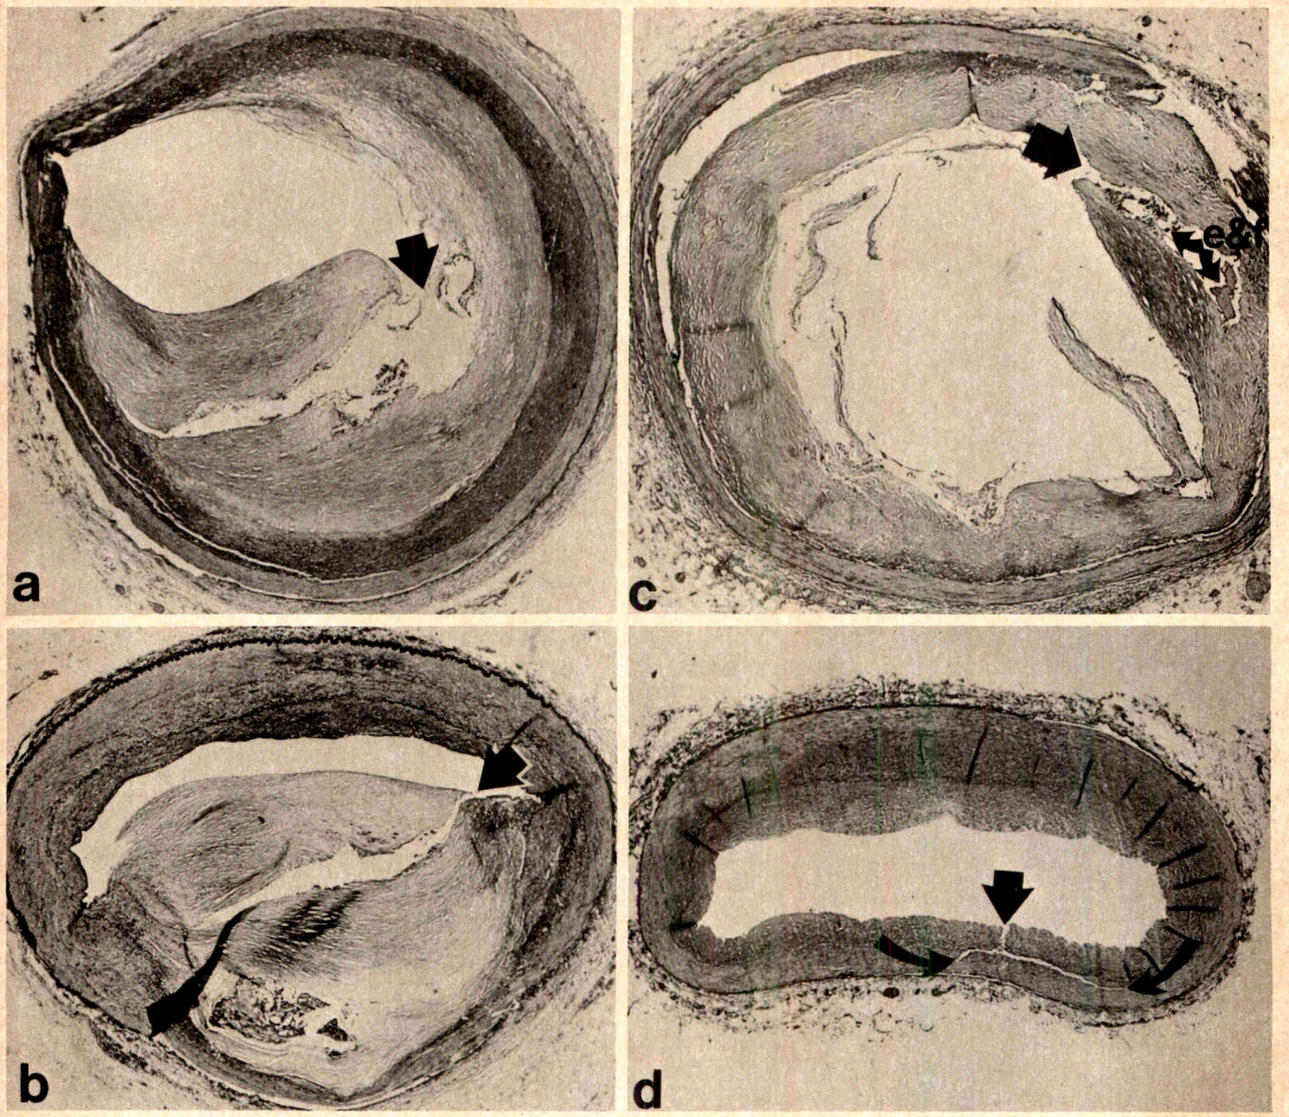

**FIGURE 1.** Photomicrographs of representative histologic sections of coronary arteries from nonangioplasty patients illustrating findings (**arrows**) similar to what have been called plaque fractures in angioplasty patients. In **d,** the vertical plaque fracture is continuous with a dissection cleft at the intima-media junction. In **c,** erythrocytes and fibrin (**e & f**) are present within the "fracture." (Elastic-tissue stain; all magnification ×5, reduced 6%).

rations at the junction of plaque and media were observed in sections from 26 (37%) of the patients in the present series. In 9 (13%) patients, these clefts were confined to the plaque itself, in 7 (10%) such clefts were limited to the media of the vessel, and in 10 (14%) the clefts involved the junction of plaque and media. Representative examples of such clefts are illustrated in Figures 1c and d, and 2.

**Stretching, thinning, or focal disruption of the media:** "Focal interruptions" or an absolute diminution in the smooth muscle content of tunica media component of the coronary arterial wall, or both, were observed in 40 (57%) of 70 control patients. In some patients near-obliteration of the media was seen in association with extensive atherosclerosis. These pathologic findings involving the media are illustrated in Figure 3.

## Discussion

That PTA is an effective means of improving vascular patency is no longer a matter for debate. Persistent amelioration of signs and symptoms of peripheral arterial insufficiency,[12] renal arterial stenosis,[13] and coronary arterial narrowing[14] have now been well documented. That PTA can be performed with low morbidity and mortality rates is attested to by the paucity of reported necropsy studies of patients treated with PTA. Partially as a result of such limited necropsy data, certainty regarding the efficacy of PTA has not been paralleled by an equal degree of certainty regarding the mechanism by which PTA reduces arterial narrowing.

Excepting 4 patients who died shortly after PTA and were studied at necropsy,[6,7] studies of the acute mor-

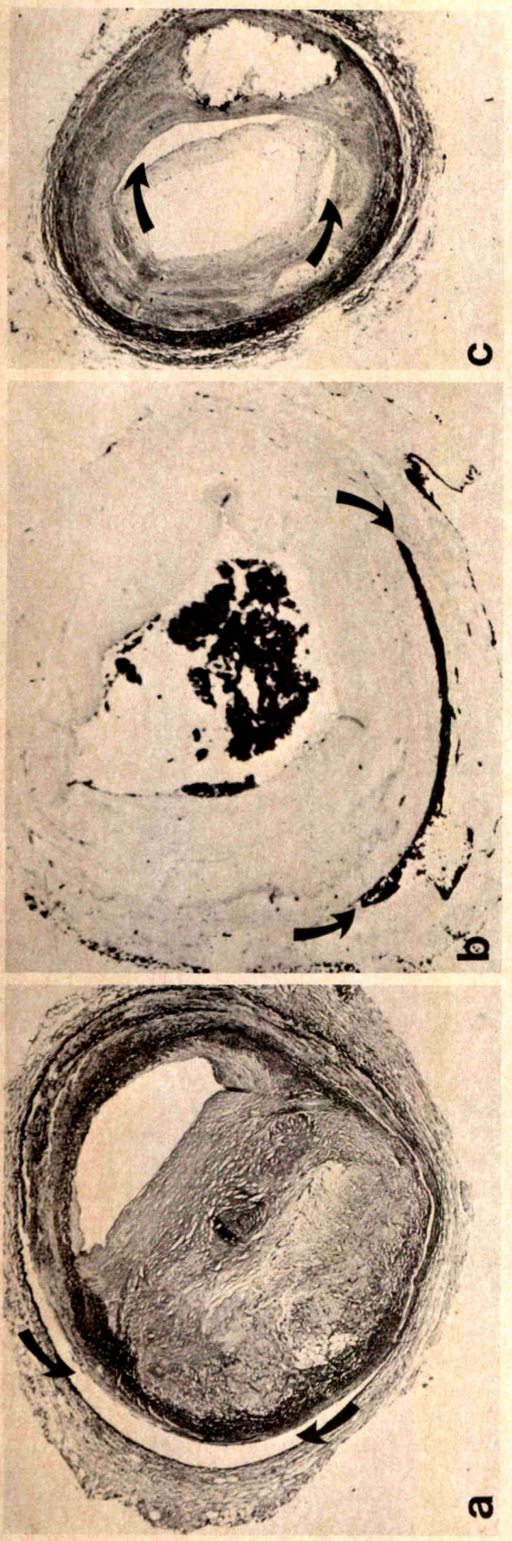

**FIGURE 2.** Photomicrographs of representative histologic sections of coronary arteries from nonangioplasty patients illustrating findings (**arrows**) similar to what have been called dissection clefts in angioplasty patients. **a,** cleft separates media from adventitia; **b,** barium sulfate injectate from a postmortem arteriogram within the cleft at the plaque-media junction; **c,** clefts are within plaque. (**a, c,** elastic-tissue stain; **b,** hematoxylin and eosin; all magnification X5, reduced 21%.)

phologic consequences of PTA have been limited to the effects of PTA on (1) the coronary arteries of cadaver hearts, and (2) artificially induced atherosclerotic lesions in the aorta and peripheral arteries of experimental animals. Major liabilities inherent in each of these methods have been acknowledged by the investigators themselves. The coronary arteries of cadaver specimens, for example, are "... more susceptible to damage than vessels in vivo ..." as a result of dehydration and the absence of normal luminal pressure distension; as a result, "... dilation catheters may ... [cause] dissection if forced through fixed stenotic segments."[4]

The use of experimental animal models has been limited by the nature of the atherosclerotic lesion in such models. The 2% cholesterol diet used to induce lesions in the aorta and peripheral arteries of the rabbit, for example, generally results in a lesion composed almost entirely of lipid-laden foam cells[4,10]; this is in marked contrast to the complicated atherosclerotic plaque seen in human coronary arteries that is composed primarily of collagen with a relatively small lipid content.[15] The morphologic changes induced by angioplasty of a foam-cell lesion cannot necessarily be extrapolated to the predominantly fibrous lesion of humans.[4]

Furthermore, there is a striking lack of unanimity among the findings reported by previous investigators. Although Castaneda-Zuniga[5] and Baughman[8] reported finding plaque fractures in segments of cadaver coronary arteries treated with PTA, Lee et al,[3] using the same model, found no plaque fractures among 21 lesions similarly treated. In a study of the rabbit diet-induced foam cell plaque treated with PTA, Block et al[4] found a dissection cleft in 1 and a plaque fracture in 2 segments of dilated iliac artery; 8 of 10 aortic stenoses that were successfully dilated, however, contained neither fractures nor clefts. Faxon et al[10] observed plaque fractures in 3 of 3 and dissection clefts in 1 of 3 successfully dilated rabbit peripheral arterial *foam cell* lesions; however, among 9 successfully dilated *complicated plaques* (analogous to human atherosclerotic lesions) induced by an indwelling catheter with or without dietary cholesterol supplementation, no plaque fractures and only 1 dissection cleft were observed. On occasion, an acute inflammatory response has been described in association with plaque fracture,[10] and in 2 reports of a dilated iliac artery, erythrocytes and fibrin were demonstrated within the plaque crack[6,9] (see Fig. 1c). Most reports,[4,5,7,8,10] however, have described a lone vertical or curvilinear split such as was found in sections from the present group of non-PTA control patients (Fig. 1a, b, and d).

In addition to the variability in findings reported from 1 laboratory to another, plaque fractures, dissection clefts, and medial thinning have not been consistently observed in all successfully dilated segments from an individual laboratory. Freudenberg[9] found plaque fractures and dissection clefts in some cadaver coronary arteries treated with PTA, but neither fractures nor clefts were observed in 6 of 17 and 12 of 17 dilated arteries, respectively. Likewise, Faxon[10] found dissection

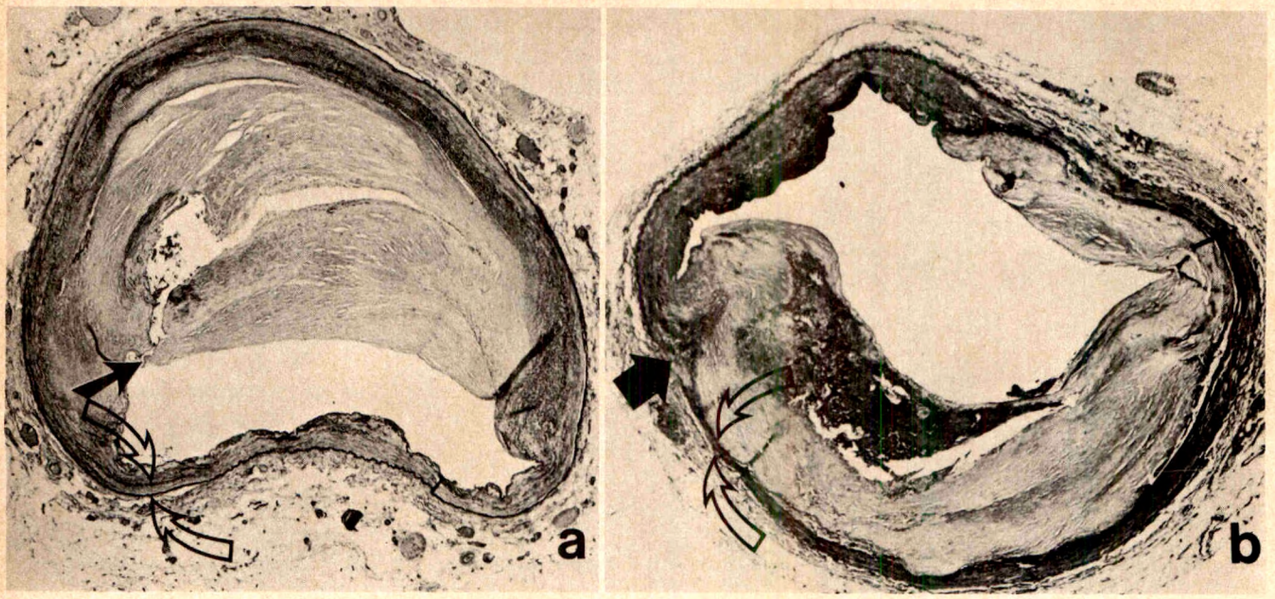

**FIGURE 3.** Photomicrographs of representative histologic sections of coronary arteries from nonangioplasty patients illustrating medial thinning (**a, b**) and interruption of the medial layer (**arrow** in **b**) of the coronary arterial wall. The media is defined as that portion of the coronary arterial wall between the internal and external elastic membranes (**white arrows**). (Elastic-tissue stain; magnification ×5, reduced 7%.)

clefts in only 2 of 12 successfully dilated rabbit arteries.

That findings similar to those described in PTA-treated patients were observed in the present group of non-PTA–treated control patients suggests that these findings cannot necessarily be invoked to explain the mechanism by which PTA improves vascular patency. Plaque fractures and dissection clefts observed in the present group of patients are most likely the result of artifact related to preparation of the coronary arteries for histologic examination. Dissection clefts may be seen in sections of coronary arteries prepared from mummies frozen 1,600 years before the advent of PTA.[16] Spurious dissection clefts also may be produced by postmortem injection of radiographic contrast media, particularly in a vessel with a high-grade proximal stenosis (Fig. 2b). On the other hand, the *lack* of a supporting medium (for example, postmortem injectate of barium sulfate) in the lumen of the coronary artery may result in artifactual fracture of the luminal surface of the atherosclerotic plaque when the artery is sectioned, particularly if the artery is sectioned before fixation. The extent of arterial calcific deposits also influences the likelihood of creating artifact in the preparation of coronary arteries for histologic examination. Although decalcification of coronary arteries is routine in most laboratories, including our own, incomplete decalcification may result in brittle arteries which tend to crack or develop circumferential dissociation of the layers of the arterial wall when the arteries are cut.[15] Interestingly, Baughman et al[8] found that the incidence of "intimal or medial disruption" in dilated cadaver coronary arteries was increased in those arteries that contained calcium compared with those that did not. Whether the morphologic changes in the calcified vessels were the result of PTA or the result of preparation, including cutting, for histologic examination remains speculative.

**FIGURE 4.** Photomicrograph of a section of the renal artery at the site of antemortem angioplasty. The histologic features of the atherosclerotic plaque and arterial wall are unremarkable. (Elastic-tissue stain; magnification ×5, reduced 13%.)

While the plaque fractures and dissection clefts seen in the present group of patients appear for the most part to represent artifactual findings, medial thinning (or medial disruption or medial interruption) is a finding *typical* of complicated atherosclerotic arterial segments.[11] The more extensive the plaque, that is, the greater the degree of cross-sectional area narrowing, the greater is the likelihood of the plaque eroding partially

or entirely through the media. Displacement of medial smooth muscle is a finding so frequently observed in non-PTA-treated coronary arteries that no special interpretation should be attached to its presence in PTA-treated segments.

As mentioned above, most previously published studies include a variable number of successfully dilated arterial segments in which no remarkable findings were observed on histologic examination. In fact, such a benign picture is common in patients who have died and been studied at necropsy late after angioplasty (Fig. 4).[17,18] The explanation for the paucity of remarkable findings in such patients has been that remodeling and healing have obliterated the unique pathologic features. This theory, however, is at odds with the observation that serial angiographic studies of patients treated with PTA tend to demonstrate *improvement* in vascular patency from the angiogram done initially postangioplasty to that performed several months later. If pathologic changes such as plaque fractures and dissection clefts are to be considered the basis for improved vascular patency after angioplasty, then it is difficult to resolve the paradox of late improvement in the angiographic appearance of the dilated vessel at a time when pathologic changes alleged to be responsible for the improvement are no longer observed.

The absence of unique pathologic findings in many PTA-treated animals and humans studied postmortem implies that successful arterial dilatation may occur by alternative mechanisms, such as transluminal dilatation of the vessel wall or the "compression" theory originally advanced by Dotter and Judkins[1] and later by Grüntzig.[2] Admittedly, the observations made in the present study do not provide direct evidence for either the dilatation or compression theories. Since neither compression nor dilatation (each of which implies a *serial* change) are phenomena that can be witnessed on a single histologic slide, other methodologies must be utilized to confirm or reject these theories. The compression and transmural dilatation theories, however, are attractive because each is compatible with the absence of unique histologic features. In this regard, each takes into account both (1) findings in the present study which suggest that pathologic findings previously described as unique consequences of PTA may be observed in the coronary arteries of patients who have not been treated with PTA, and (2) previous animal and human studies in which such unique pathologic features have not been observed despite successful dilatation.[3,10] The recent observation by Block et al[19] that the postangioplasty arterial effluent in the rabbit model contains no embolic debris might, in fact, be interpreted as evidence favoring either the transmural dilatation or compression theories. Plaque fractures, for example, would be more likely to result in release of plaque debris than would either plaque compression or transmural dilatation.

Finally, the fact that lesions resembling plaque fractures and dissection clefts have been observed to occur as the result of artifact does not exclude the possibility that such lesions may develop as a result of PTA. The fact that improved vessel patency may be seen in the absence as well as the presence of such lesions, however, precludes firm assurance that such lesions are the sole basis for a successful dilatation.

# Intravenous Nitroglycerin for the Treatment of Angina at Rest Unresponsive to Standard Nitrate Therapy

KERRY KAPLAN, MD, RICHARD DAVISON, MD, MICHELE PARKER, RN, JEAN PRZYBYLEK, RN, J. RUSSELL TEAGARDEN, RPh, and MICHAEL LESCH, MD

**Thirty-five patients who had angina at rest that was unresponsive to standard therapy comprised of oral or topical nitrates and beta-blocking drugs were treated with a continuous infusion of intravenous nitroglycerin (IVNTG). The infusion was started at 10 μg/min and increased by 10 μg/min increments every 5 minutes until an infusion rate of 50 μg/min was reached. After each episode of rest angina, the infusion was increased by 50 μg/min in the same stepwise manner. Data from a 24-hour baseline control period were compared with those from a 24-hour IVNTG endpoint period at which time the highest IVNTG infusion rate was administered. The average IVNTG infusion rate was 140 ± 15 μg/min. With IVNTG therapy, the number of episodes of angina at rest decreased from 3.5 ± 0.4 to 0.3 ± 0.1, sublingual nitroglycerin use decreased from 1.9 ± 0.3 to 0.4 ± 0.1 mg/day, and morphine sulfate administration decreased from 5.5 ± 1.3 to 0.4 ± 0.2 mg/day (all $p < 0.001$). When each patient's response on the endpoint day was analyzed, 25 were defined as complete (no rest angina), 8 as partial (>50% decrease in the number of episodes/day from control values), and 2 as nonresponders. No significant drug-induced adverse effects occurred.**

**IVNTG appears to be effective therapy for angina at rest refractory to standard oral and topical medications.**

Intravenous nitroglycerin (IVNTG) was recently approved by the Food and Drug Administration for treatment of angina pectoris; however, insufficient information is available concerning effective infusion rates, response rates, and complications. This study was designed to answer 2 questions about IVNTG therapy: Is it effective in controlling angina at rest in patients who have failed to respond to standard medical therapy? If it is, what is the range of effective infusion rates?

Angina at rest requires urgent therapy whether it is the first sign of ischemic heart disease, follows stable exertional angina, or occurs after an acute myocardial infarction.[1–4] Standard medical therapy with bed rest, oxygen, sedation, beta-adrenergic blocking agents, and oral or topical nitrates is effective in controlling angina at rest in most patients.[5] The role of beta-adrenergic blocking agents in the therapy of this condition is widely accepted,[5] but certain aspects remain controversial.[6] When angina at rest recurs despite standard medical therapy, calcium antagonists, intraaortic balloon counterpulsation, and emergency coronary artery bypass surgery have been advocated.[2,7–10]

Nitrates have been used for many years to treat myocardial ischemia because of their ability to decrease myocardial oxygen consumption and increase coronary artery blood flow.[11,12] Nitrates are available in sublingual, topical, oral, and intravenous preparations. IVNTG offers several possible advantages over other forms because of its ease of administration, rapid titration, and 100% bioavailability. Several reports suggest that IVNTG is effective in treating myocardial ischemia.[13–16]

## Methods

**Patient selection:** Patients with angina at rest unresponsive to standard medical therapy were entered into the protocol for IVNTG administration. Angina at rest was defined by the presence of typical chest pain associated with either reversible electrocardiographic changes (S-T elevation or depression ≥1 mm or symmetrical T-wave inversion in any

2 leads), or transient defects in a thallium myocardial scan obtained during pain. Standard medical therapy included bed rest in a coronary care unit with continuous cardiac rhythm monitoring, oxygen therapy, sedation, and at least 1 of the following nitrate regimens which are the usual doses recommended in the *Physicians' Desk Reference*[17]: (1) nitroglycerin ointment, 2 inches every 4 hours; (2) isosorbide dinitrate, 30 mg orally every 6 hours; (3) isosorbide dinitrate, 10 mg sublingually every 2 hours. The use of beta-adrenergic blocking agents was left to the discretion of the patient's attending physicians. In each instance, IVNTG was started only after angina at rest continued to occur despite progressively increasing topical and oral nitrate doses that exceeded maximal recommended doses. Twenty-four of the 35 patients had ≥3 episodes of angina at rest during the 24-hour period before initiation of IVNTG.

**Study design:** IVNTG supplied by American Critical Care Corporation was diluted with 5% dextrose in water to a concentration of 300 μg/ml. It was infused through polyvinyl chloride intravenous tubing; the infusion rate was controlled by an IMED volumetric infusion pump. The infusion was started at a rate of 10 μg/min; if no adverse effects occurred, it was increased every 5 minutes at 10 μg/min increments until an infusion rate of 50 μg/min was reached. This dose level was maintained until another episode of angina at rest occurred, at which time the infusion rate was increased in the same stepwise manner until a dose of 100 μg/min was achieved. Thus, after each anginal attack, the dose was increased by 50 μg/min. By titrating to therapeutic effect, each patient's highest infusion rate either represented the minimal effective therapeutic dose or the highest infusion rate received before IVNTG was considered a therapeutic failure. A therapeutic failure was identified by the need for the initiation of alternative antianginal therapy such as calcium-channel blocking agents, intraaortic balloon counterpulsation, and/or emergency coronary artery bypass surgery. During the study, no changes were made in the antianginal therapy other than modifications of the IVNTG infusion rates. Specifically, no changes were allowed in the dose of beta-blocking agents or oral or topical nitrates. Episodes of angina at rest were treated with sublingual nitroglycerin and, if unresponsive, with intravenous morphine sulfate. No fixed protocol was followed for discontinuing IVNTG. During the study the following information was collected daily: (1) number of episodes of angina at rest, (2) amount of morphine sulfate and sublingual nitroglycerin administered, (3) adverse effects of IVNTG, and (4) lowest blood pressure and highest and lowest pulse rates recorded at times other than during an ischemic episode.

**Data analysis:** Analysis was performed by comparing the 24-hour period immediately preceding the initiation of IVNTG—the baseline control period—with each subsequent 24-hour period during IVNTG administration. A 24-hour endpoint period was defined as the period during which the highest IVNTG infusion rate was given. This rate was either the minimal effective dose or the highest dose of IVNTG given before it was considered a therapeutic failure. The average number of episodes of rest angina, amount of sublingual nitroglycerin, and amount of intravenous morphine sulfate were compared for the baseline control period, each subsequent 24-hour period, and the endpoint period using a Student's *t* test of the difference. The incidence of rest angina was also compared for each day using analysis of variance. All numbers are reported as an average ± standard error of the mean.

In addition to analyzing the average response of the group, the response of each patient was considered in comparison with the control period. A complete response was defined as no episodes of rest angina occurring on the day under analysis; a partial response as >50% decrease in the number of episodes compared with the control period, and a nonresponse ≤50% decrease in anginal attacks compared with the control period.

## Results

**Patient population:** Fifty-three patients over an 18-month period met the inclusion criteria and began receiving IVNTG. Eighteen of these patients had changes in their antianginal therapy dictated by factors other than failure to control myocardial ischemia: In 8 patients propranolol dose was decreased because of bradycardia or congestive heart failure, whereas in 10 the nitrate or propranolol doses, or both, were changed simultaneously with the initiation of IVNTG. These 18 patients did not differ from the remaining 35 with regard to inclusion data, adverse effects, or outcome (myocardial infarction, death, intraaortic balloon counterpulsation, and/or coronary artery bypass grafting). However, because it was impossible to assess the relative contribution of the addition of IVNTG and the changes in other antianginal therapy on the improvement of rest angina, these patients were excluded from further analysis.

The remaining 35 patients included 22 men and 13 women with an average age of 63 years (range 36 to 81). Twenty of the 35 had recurrent angina at rest 1 to 7 days after an acute myocardial infarction. Comparison of the results for the 20 patients with postinfarction angina and the remaining 15 patients with unstable angina showed no significant difference in the groups. Therefore, all further data combine the results from these 2 subsets.

Twenty-two patients had had a previous myocardial infarction at least 2 weeks before beginning IVNTG therapy. Twenty-one of the 35 patients subsequently underwent cardiac catheterization; all had coronary artery disease. Four had single-vessel disease; 6 had 2-vessel and 11 had 3-vessel disease. Of the 35 patients, 34 had either a previous myocardial infarction or angiography-proven coronary artery disease.

The nitrate doses given to the study patients before starting the IVNTG were much higher than the minimum required by the protocol. Thirty-four patients were receiving nitroglycerin ointment in an average amount of 18 ± 0.8 inches/day, 27 patients were receiving oral isosorbide dinitrate at an average dose of 229 ± 31 mg/day, and 26 patients were receiving both forms of nitrates. Seventeen patients were receiving propranolol in an average dose of 202 ± 28 mg/day.

**IVNTG administration:** The average endpoint dose of IVNTG was 140 ± 15 μg/min (range 50 to 350), with an average length of infusion of 5.6 ± 0.8 days (range 2 to 25). The lowest mean arterial pressure and highest pulse rate did not change significantly from the baseline control day to the endpoint day. The average mean arterial pressure changed from 79 ± 9 to 77 ± 10 mm Hg ($p = 0.19$) and the heart rate from 84 ± 3 to 86 ± 3 beats/min ($p = 0.42$). In order to exclude the effect of beta blockade, the data on the 18 patients not receiving propranolol were analyzed separately and demonstrated no significant changes in heart rate or blood pressure.

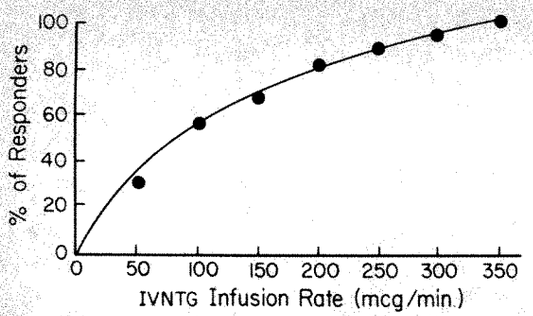

**FIGURE 1.** Percentage of complete or partial responders for each infusion rate of IVNTG, showing the IVNTG dose on the endpoint day for the 33 patients who had a >50% decrease in anginal episodes on the endpoint day compared with the control day.

**TABLE I Clinical Response to IVNTG: Control Day Versus Endpoint Day***

| | Control Day | Endpoint Day |
|---|---|---|
| Episodes of rest angina | 3.5 ± 0.4 | 0.3 ± 0.1† |
| Sublingual nitroglycerin (mg/day) | 1.9 ± 0.3 | 0.4 ± 0.1† |
| Morphine sulfate (mg/day) | 5.5 ± 1.3 | 0.4 ± 0.2† |

* Mean ± standard error of the mean.
† $p < 0.001$ for comparison of control and endpoint days.

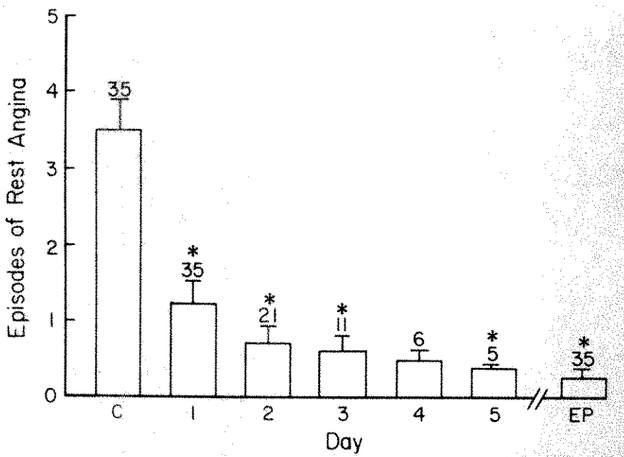

**FIGURE 2.** Number of episodes of rest angina for baseline control day (C) and each day with IVNTG up to the endpoint day (EP). The average number of episodes of rest angina for the control day and each day of IVNTG is shown. Patients were removed from this analysis after reaching their endpoint day because at that time they either had no further rest angina or were considered a therapeutic failure and started receiving an alternate form of therapy. The **numbers above the bars** represent the number of patients left for analysis on each day. **Asterisks** indicate $p < 0.05$ compared with control day.

No association was demonstrated between the maximal dose of IVNTG and age, sex, weight, extent of coronary artery disease, history of previous myocardial infarction, previous administration of beta-blocking agents, or number of episodes of rest angina on the control day. Figure 1 shows the percentage of complete or partial responders with each infusion rate of IVNTG. Of the patients who responded to IVNTG, over half were controlled at an infusion rate of ≤100 μg/min and over two thirds at ≤200 μg/min.

**Clinical response:** The number of episodes of rest angina, amount of sublingual nitroglycerin, and amount of morphine sulfate were significantly decreased when the control and endpoint periods were compared (Table I). Episodes of rest angina decreased from 3.5 ± 0.4 to 0.3 ± 0.1/day ($p < 0.001$), sublingual nitroglycerin use decreased from 1.9 ± 0.3 to 0.4 ± 0.1 mg/day ($p < 0.001$), and morphine sulfate administration decreased from 5.5 ± 1.3 to 0.4 ± 0.2 mg/day ($p < 0.001$).

To show that this benefit is not an artifact that results from arbitrarily selecting a particular day and labeling it the therapeutic endpoint, a day-by-day analysis was done of the average number of episodes of rest angina. Patients were removed from this analysis after reaching their endpoint day because at this time they either had no further rest angina or were considered a therapeutic failure and an alternate form of therapy was begun (Fig. 2). The number of episodes of rest angina clearly decreased for each time period in comparison with the control day. When each patient's response on the endpoint day was analyzed, 25 were complete responders, 8 were partial responders, and 2 were nonresponders.

The average number of days from the start of IVNTG to attaining the maximal dose was 2.7 ± 0.6. Fourteen patients received their maximal IVNTG dose on the first day, 10 on the second, and 5 on the third day of nitroglycerin administration.

No correlation was found between therapeutic response (assessed by degree of reduction in pain from the control day to the endpoint day) and age, sex, extent of coronary artery disease, initial mean arterial pressure or change in mean arterial pressure during therapy. In addition there was no significant difference in the therapeutic response of patients with and without recent or remote myocardial infarction, or those who were or were not receiving propranolol.

**Adverse effects:** An adverse effect was defined as an event that prompted a decrease in the rate or discontinuation of the IVNTG infusion. Fifteen patients had a headache which either required no treatment or responded to standard analgesics. In 1 patient, severe headache necessitated a decrease in the IVNTG dose. In no instance was an adjustment of the infusion rate dictated by the development of hypotension, bradycardia, or tachycardia.

**Outcome:** Of the 35 patients, 23 were eventually weaned from IVNTG: 14 without a change in their standard medical therapy compared with the control period, 5 with an increase in nitrates, 2 with an increase in propranolol, and 2 with an increase in both nitrates and propranolol.

Two patients receiving IVNTG because of recurrent rest angina after a recent myocardial infarction had extension of their infarct, developed cardiogenic shock, and died. Ten patients continued receiving IVNTG until coronary artery bypass was performed; they received IVNTG for an average of 8 days. Three of these had a recent myocardial infarction and were operated

on an average of 13 days after their infarction. There were 2 perioperative deaths: 1 in a patient with combined coronary and carotid artery revascularization who suffered a cerebrovascular accident, and another after a combined coronary artery bypass and insertion of an aortic valve prosthesis that was complicated by cardiogenic shock.

## Discussion

Several previous reports suggest that intravenous nitrates are effective in treating refractory angina pectoris.[13–16] Dauwe[13] reported on 14 patients with unstable rest angina refractory to conventional medical therapy. All 14 patients had a decrease in the incidence of chest pain during treatment with an average of 47 μg/min of IVNTG. Distante[14] used intravenous isosorbide dinitrate in a double-blind crossover trial of 12 patients with myocardial ischemia at rest. They had a significant decrease in the number of episodes of ischemia between the placebo and treatment periods. Mikolich[15] reported retrospective results in 75 patients with chest pain treated with IVNTG. Pain relief was obtained in 40 of 45 patients with unstable angina and 22 of 30 patients with chest pain after myocardial infarction. They did not describe the concurrent medical therapy their patients were receiving or whether that therapy remained constant during the IVNTG infusion. This study also differed from ours in using a much lower mean maximal infusion rate (54 μg/min) of a nonindustrially prepared solution of IVNTG. In a review article on IVNTG, Hill[16] states that he administered IVNTG to 20 patients with unstable angina refractory to maximal therapy and that all patients responded; however, no details are provided.

Nitrates may be effective in treating myocardial ischemia because they decrease myocardial oxygen consumption and increase myocardial blood flow.[11] Their primary pharmacologic action is the relaxation of vascular smooth muscle, having greater effect on venous than arterial vessels. By dilating peripheral veins and increasing venous capacitance, venous return to the heart is decreased. This reduction in preload results in decreased left ventricular wall tension and myocardial oxygen consumption.[18–20] Nitrates act as vasodilators on native and collateral coronary arteries[21–23]; however, it is uncertain whether the blood flow to ischemic myocardial tissue is actually increased.[24–26] Because angina at rest has been shown to be secondary to transient decreases in myocardial blood flow,[27–29] it is possible that IVNTG acts in this situation to combat coronary artery spasm.[20]

We have shown that the use of IVNTG is associated with the suppression of angina at rest in patients who have failed to respond to standard medical therapy; however, it is well-known that unstable angina has a tendency to spontaneous remission. The only way to address this problem would have been to use a double-blind, placebo-controlled crossover format, but we felt that the clinical status of our patients was too tenuous to include a placebo phase. Nevertheless, we believe that the results demonstrate a therapeutic effect for 2 reasons. First, patients were not aware of the infusion rate they were receiving, yet there was a correlation between the IVNTG dose and the clinical response. Second, there were 3 instances of recurrence of rest angina during temporary accidental interruption of the IVNTG infusion that the patients were not aware of. After the infusion was reinstituted, angina did not recur.

Another limitation of the study is that IVNTG was infused through polyvinyl chloride tubing. It is known that nitroglycerin is adsorbed by this type of tubing and, therefore, the exact amount reaching the patient is unknown. When using polyvinyl chloride tubing, the concentration of IVNTG reaching the patient also depends on variables such as length of intravenous tubing, infusion flow rate, duration of infusion, and initial concentration of the solution.[30] When IVNTG is infused through polyethylene tubing—which is now commercially available—insignificant amounts are lost. The doses used in this study were administered using polyvinyl chloride tubing and cannot be applied when a more efficient delivery system is used. Unfortunately, the polyethylene system was not available when this study was initiated.

The mechanism whereby the addition of IVNTG was successful in controlling rest angina that had not responded to high doses of oral and topical nitrates is not entirely clear. One would expect that the response would be dependent on total nitrate levels regardless of the method of administration, and it appears that similar levels are obtained with topical and intravenous nitroglycerin.[31] Unfortunately, we were not able to measure nitrate blood levels so we cannot correlate the nitrate concentration with therapeutic response. The superior results with IVNTG could be due to the stability of nitrate blood levels which avoids the fluctuations seen with standard therapy. Alternatively, the ability to more rapidly attain a new level could account for the improved efficacy.

Although IVNTG is a known arterial vasodilator, its use in our patients was not associated with a significant hypotensive effect. This may be due to the fact that our patients were already receiving large amounts of nitrates before IVNTG was initiated. It is also possible that by decreasing afterload, cardiac output was increased sufficiently to maintain blood pressure.

We have shown that IVNTG can be given safely without hemodynamic monitoring and that infusion rates of 50 to 350 μg/min are effective in controlling myocardial ischemia previously unresponsive to oral and topical nitrates.

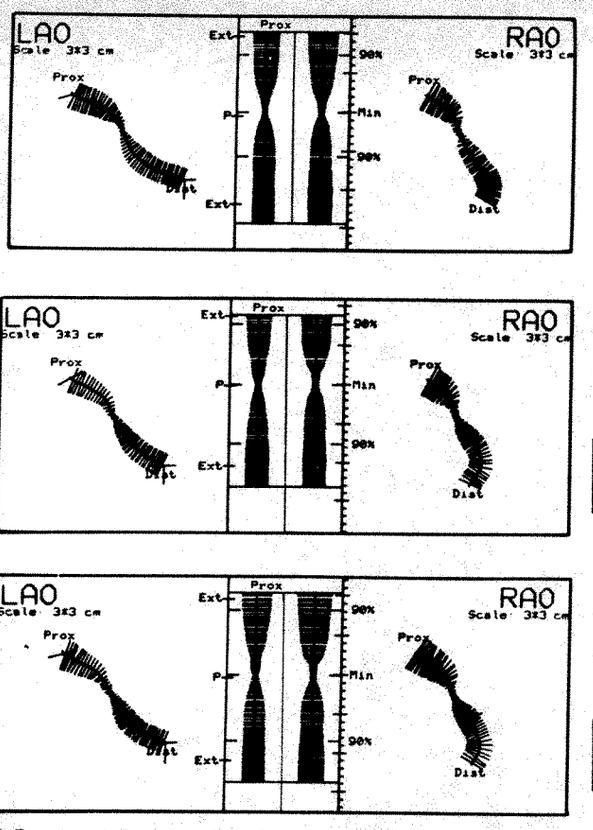
# Effects of Verapamil on Coronary Hemodynamic Function And Vasomobility Relative to Its Mechanism Of Antianginal Action

CHRISTOPHER Y. C. CHEW, MD, B. GREGORY BROWN, MD, PhD, BRAMAH N. SINGH, MD, DPhil, MAYLENE M. WONG, MD, CINDY PIERCE, BS, and ROBERT PETERSEN, PhD

**The effect of intravenous verapamil on systemic and coronary hemodynamic function was studied at cardiac catheterization in 12 patients with coronary artery disease. Verapamil was administered as a 2-minute bolus (0.145 mg/kg) followed by an infusion (0.005 mg/kg/min). Cardiac output and coronary sinus blood flow were measured by thermodilution techniques. Caliber of the large coronary arteries and of diseased segments was determined from the coronary angiogram using a computer-assisted method. Verapamil reduced mean arterial pressure 14% ($p < 0.001$), systemic vascular resistance 21% ($p < 0.01$), and stroke work index 16% ($p < 0.001$). Coronary vascular resistance decreased 24% ($p < 0.01$) with a small increase in coronary sinus blood flow (+13%, difference not significant [NS]). Myocardial oxygen consumption determined in 5 patients showed no significant change with verapamil. Luminal area in 39 coronary lesions was measured in the "normal" portion of the diseased segment and at its maximal constriction, and an estimate of flow resistance in the stenosis was computed. Overall, 50% of "normal" and of diseased coronary segments dilated significantly with verapamil. Stenosis dilation resulted in an average 14% reduction ($p < 0.01$) in estimated flow resistance. In 8 patients, the luminal changes ($n = 27$) induced by sublingual nitroglycerin were compared with those induced by verapamil. Nitroglycerin induced a significantly greater increase in coronary caliber in both normal and diseased segments; estimated stenosis flow resistance decreased 28% with nitroglycerin compared with 14% with verapamil ($p < 0.01$).**



**Thus, verapamil moderately dilates the systemic and coronary small vessel resistance bed without apparently increasing myocardial metabolic demand. Furthermore, verapamil mildly dilates large coronary conductance vessels in both "normal" and diseased segments, although significantly less than does nitroglycerin.**

Slow-channel inhibitors are being used increasingly in the management of various myocardial ischemic syndromes.[1–3] In contrast to beta-adrenergic antagonists, these compounds have been shown experimentally to dilate coronary arteries,[4,5] and thus their antianginal effects are of potential value in exertional as well as in vasospastic ischemic syndromes. However, relatively little data are available on coronary hemodynamic function and vasomobility in patients with coronary artery disease. From gross angiographic appearances, Mignault[6] concluded that intravenously administered verapamil did not alter the caliber of normal and atherosclerotic coronary vessels, whereas Luebs et al,[7] using myocardial clearance of rubidium as an index of coronary blood flow, found that intravenous verapamil increased coronary blood flow in patients without coronary artery disease whereas no such effect was observed in patients with coronary artery disease. More recently, however, Simonsen[8] found that intravenous verapamil produced a small but significant reduction in coronary vascular resistance in patients with coronary heart disease.

The purpose of our study, therefore, was to determine the effects of intravenously administered verapamil, a prototype of the slow-channel inhibitors, on systemic

and coronary hemodynamic functions and on coronary artery caliber with particular reference to changes in large vessel cross-sectional area and stenosis flow resistance as measured by quantitative coronary angiography.

## Methods

Twelve male patients undergoing diagnostic cardiac catheterization for the evaluation of coronary artery disease were studied. The mean age of the group was 53 years (range 48 to 69). Two had 1-vessel coronary disease, 7 had 2-vessel disease, and 3 had 3-vessel disease. Their ventricular ejection fractions ranged from 22 to 70 (mean 50.5). All patients and the design of the protocol were reviewed and approved by the Human Subjects Committee of the Wadsworth Veterans Administration Hospital. All patients had sinus rhythm with no evidence of atrioventricular heart block. Patients who were receiving a chronic beta-adrenoreceptor blocking drug were studied 48 hours after its discontinuation. All chronic nitrate therapy was discontinued 10 to 12 hours before angiography.

**Hemodynamic measurements:** Systemic hemodynamic measurements were obtained through percutaneous cannulation of both femoral artery and vein. Right heart pressures and cardiac output were obtained with a triple lumen thermodilution catheter connected to an output computer (Santa Barbara model 1700). In 9 patients, a 7Fr catheter (Wilton Webster Laboratories, Altadena, California) was placed in the mid-coronary sinus through the left basilic vein, and coronary sinus blood flow (CSBF) was measured by the method of Ganz et al.[9] Repeated contrast injection was used to document the positional stability of the coronary sinus catheter. Heart rate was monitored in lead II of the electrocardiogram.

Systemic vascular resistance (SVR) (dynes s $cm^{-5}$) was calculated as SVR = MAP/Co, where MAP = mean arterial pressure. Stroke work index (SWI in g-m/$m^2$) was calculated as SWI = (MAP − PCWP) × SVI × 1.36 × $10^{-3}$, where PCWP = pulmonary capillary wedge pressure in mm Hg and SVI = stroke volume index in ml/$m^2$. Coronary vascular resistance (CVR) was calculated as the ratio of MAP to CSBF (CVR = MAP/CSBF). Myocardial oxygen consumption ($MVO_2$) was determined in 5 patients as the product of CSBF and arterial-coronary venous oxygen difference: $MVO_2$ = CSBF × (AO − Cs) $O_2$.

**Quantitative coronary angiographic analysis:** Computer-assisted analysis of coronary arterial segments was performed by a technique recently described[10,11] and validated in several laboratories.[12–14] The method is briefly described here.

High-quality coronary cineangiograms were obtained in the conventional fashion using the Judkins technique in multiple projections. For each left anterior oblique (LAO) projection, a corresponding perpendicular right anterior oblique (RAO) projection was obtained. For quantitative analysis, cineangiographic frames were selected from the perpendicular pair of projections that showed the lesion most clearly. Three frames were selected, usually in diastole, from each of the 2 views. The frames were projected at about 5-fold magnification onto a large surface marked off in X,Y coordinates. The outline of the magnified, projected lesion image was traced from the "normal" proximal to the "normal" distal portion

of the diseased arterial segment. The scaling factor was calculated from a traced section of the catheter tip of known dimensions. The traced images were digitized and transmitted to a PDP 11/45 computer which was programmed to reduce the lesion image to true scale by compensating for pincushion distortion, x-ray beam divergence, and magnification. An example of a computer printout of a typical processed lesion is shown in Figure 1. The true scale images from the 2 perpendicular views are then matched along their center lines and the combination of data from the perpendicular projections provides a 3-dimensional characterization of the diseased coronary arterial segment. From these data the computer calculates the vessel diameter and cross-sectional area in the "normal" proximal and distal portion and at the point of the greatest narrowing of the diseased segment. Percent diameter and area stenosis were calculated according to the formula described by Brown et al[10] and estimates of stenosis flow resistance at a hypothetical flow of 1.0 ml/s are calculated using published formulas.[11] This method is accurate to within 0.08 mm for measurements of known dimensions and has a variability of 0.1 mm (standard deviation) on repeated estimates for minimal luminal diameter and ±3% for percent stenosis estimates.[11–13] The angiographic sequence was carefully concealed from those making the lesion measurements using a blinding protocol described elsewhere.[15]

**Protocol:** The sequence of data acquisition was as follows: 10 minutes were allowed to elapse after diagnostic left ventriculography and coronary angiography. Control hemodynamic and coronary sinus blood flow measurements were then obtained over a 3-minute period. Verapamil hydrochloride (0.145 mg/kg) was given intravenously as a loading dose over 2 minutes and a constant infusion (0.005 mg/kg/min) begun at the end of the loading period and continued for approximately 20 minutes. Hemodynamic variables were recorded continuously for the first 5 minutes, after which steady state conditions were achieved. A further measurement of these variables was made at the 10th minute after which a second coronary angiographic study with identical projections as the control study was performed. At least 15 minutes after discontinuation of the verapamil infusion, with return of the hemodynamic variables to within 10% of the initial control values, 0.4 mg of sublingual nitroglycerin was administered in 8 patients while aortic pressure and heart rate were monitored. Coronary angiograms were repeated in the selected views approximately 30 seconds after the aortic systolic pressure nadir (within 4 to 5 minutes after nitroglycerin administration).

**Statistical analysis:** Observations made before and after verapamil and nitroglycerin administration were compared for significance or differences using 2-tailed Student's *t* test for paired data. Differences were considered not significant if the probability of the null hypothesis was >0.05. The data are presented as mean values ±1 standard deviation.

## Results

**Verapamil dose:** For the entire series of patients studied, the mean total dose of verapamil was 19 ± 4 mg and the duration of infusion averaged 20 ± 5 minutes. We previously showed that the regimen of verapamil administration used in this study produced steady-state plasma drug levels with stable hemodynamic variables by the fifth minute of drug administration which was maintained during drug infusion.[16]

**Systemic and coronary hemodynamics:** Mean hemodynamic data for all patients are presented in Table I. Verapamil decreased mean arterial pressure 14% ($p < 0.001$), systemic vascular resistance 21% ($p < 0.01$), and coronary vascular resistance 24% ($p < 0.01$). There was a significant increase of 5 mm Hg (31%; $p < 0.001$) in the value of mean pulmonary capillary wedge pressure and mean pulmonary arterial pressure of 4 mm Hg (+17%; $p < 0.01$), but the changes in heart rate, cardiac index, stroke volume index, or pulmonary vascular resistance were not significant. Verapamil *increased* coronary sinus blood flow from 96 ± 32 to 108 ± 35 ml/min, but this change did not reach statistical significance. In 5 patients, $MVO_2$ remained unchanged by verapamil despite significant reduction in the heart rate × systolic blood pressure product. In these 5 patients, mean values for coronary vascular resistance and coronary sinus flow did not differ significantly from those of the other patients in whom $MVO_2$ could not be determined for technical reasons.

**Effects of verapamil on coronary caliber:** A total of 39 coronary arterial segments with various degrees of luminal obstruction of the left anterior descending or circumflex coronary arteries were analyzed by quantitative coronary angiography. This method allows for accurate quantitation of very small changes in coronary caliber which are not usually appreciated by subjective visual interpretation.

The effects of verapamil on coronary caliber and predicted stenosis flow resistance are summarized in Figures 2 and 3. Each point on the plot in each figure represents the value from a single lesion. In "normal"

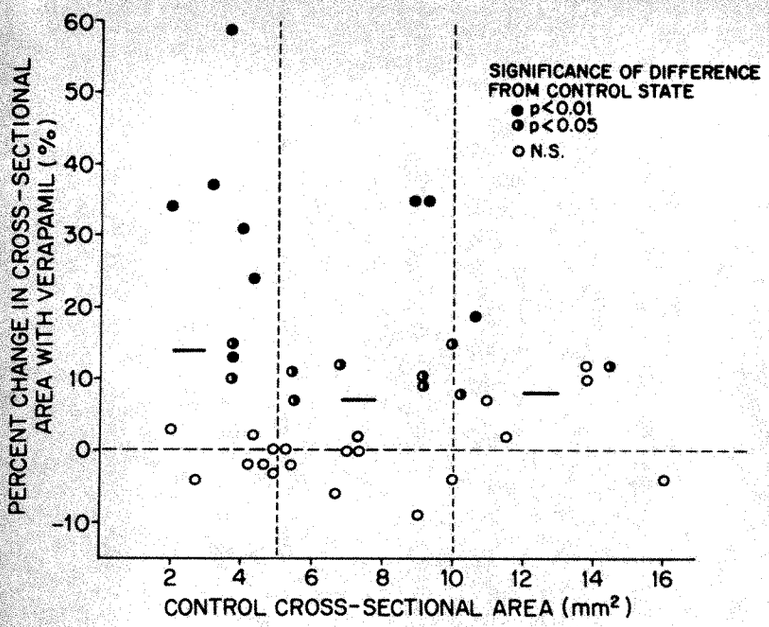

**FIGURE 2.** Individual changes in cross-sectional area in "normal" coronary segments after intravenous verapamil. Each point represents data from a single lesion and is averaged from 6 estimates of coronary calibers. Partly or totally "closed" circles show a statistically significant change by the paired *t* test of the 6 estimates in each of the pre- and postverapamil angiographic images. The overall data indicate the vasodilatory propensity of verapamil at the site of coronary stenosis.

areas, verapamil increased cross-sectional area in 19 of 39 lesions (49%) analyzed (Fig. 2). Smaller vessels (<5 $mm^2$ cross-sectional area) tended to be more vasoreactive with a mean increase of 14% compared with medium-sized vessels (5 to 10 $mm^2$) and larger vessels (> 10 $mm^2$) which dilated by a mean of 7 and 8%, respectively. However, this difference between small and medium to large arteries did not attain statistical significance. In stenosed segments, verapamil induced a comparable increase in cross-sectional area in both "mild" and significant (>50% diameter stenosis) lesions with a resultant decrease in estimated stenosis flow resistance (Fig. 3). However, not all stenosed lesions dilated with verapamil. Nineteen of 38 lesions (50%) showed no significant change in caliber in the diseased segment.

**Comparative effects of verapamil and nitroglycerin on coronary vasomobility:** In 27 diseased segments (average 38% stenosis, range 8 to 82%) in 8 patients, changes in coronary caliber after verapamil and after sublingual nitroglycerin were compared directly. The mean data are summarized in Figures 4 and 5. In "normal" segments, verapamil and nitroglycerin increased cross-sectional area by 7 and 22%, respectively ($p < 0.01$), whereas in the stenosed areas the changes were 13 and 28% ($p < 0.01$), respectively. Nitroglycerin decreased stenosis flow resistance 28%, twice that induced by verapamil (14%, $p < 0.01$).

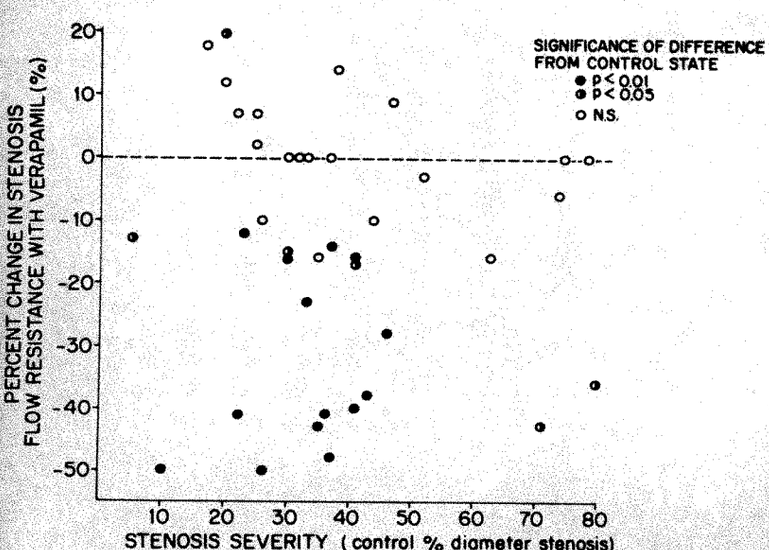

**FIGURE 3.** Individual changes in estimated stenosis flow resistance after verapamil. Each point represents a single lesion. Points falling below the zero line indicate stenosis dilation. Points that are partly or totally darkened show statistically significant change by paired *t* test of the 6 estimates in each of the pre- and postverapamil angiographic images. Verapamil reduced stenosis flow resistance significantly.

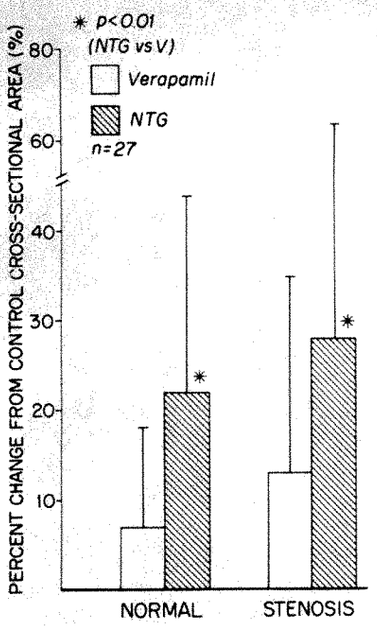

**FIGURE 4.** Comparative effects on luminal cross-sectional areas after verapamil (V) and nitroglycerin (NTG) with both "normal" and stenosed segments of coronary arteries. The data are means and standard deviations. Both drugs increase cross-sectional areas in normal as well as in narrowed segments of the coronary arteries; nitroglycerin is more potent.

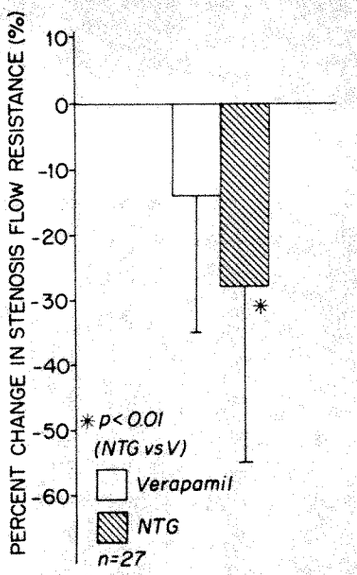

**FIGURE 5.** Comparative changes in estimated stenosis flow resistance after verapamil (V) and nitroglycerin (NTG). The effects were tested in the same lesions sequentially and data were acquired at doses of the drugs that were equipotent with respect to reduction in systolic arterial pressure. The data are means ± standard deviations; nitroglycerin had a more significant effect in reducing stenosis flow resistance.

## Discussion

The present findings demonstrate that verapamil is frequently but inconsistently a mild dilator of epicardial coronary arteries, producing dilation not only of their "normal" but also of their narrowed segments, with a resulting reduction in estimated stenosis flow resistance. These results contradict the generally held belief that atherosclerotic lesions in man do not have the propensity to dilate under the action of pharmacologic intervention. Total coronary vascular resistance also decreased after verapamil with a tendency for coronary sinus blood flow to increase. Because the coronary sinus flow did not decrease, as occurs with dipyridamole,[22] our observations suggest that verapamil dilates both conductance as well as resistance components of the coronary arteries. The findings agree with recent experimental work[17] using in vitro strips of canine coronary arteries in which verapamil was found to block calcium-dependent action potentials in both the large and the small coronary vessels.

Our data on coronary hemodynamics, however, differ somewhat from those recently reported by Ferlinz and Turbow.[18] These investigators found that in patients with coronary artery disease, verapamil (0.1 mg/kg bolus followed by infusion of 0.005 mg/kg per minute) *decreased* CSBF 12% with no significant effect on coronary vascular resistance, whereas myocardial oxygen consumption was reduced 18%. In our study, coronary vascular resistance invariably *decreased* after verapamil, and this decrease was maintained during the entire period of drug infusion. Absolute coronary sinus blood flow increased, although it reached statistical significance only at the third minute of drug administration when plasma verapamil concentration was at its peak.[16] In an earlier study, Simonsen[8] found that in patients with coronary disease, intravenous verapamil decreased coronary arteriolar resistance 13% compared with 24% in our study. However, in this study by Simonsen, verapamil was given as a single bolus injection (0.15 mg/kg) without a subsequent continuous infusion and the test measurements were made 15 minutes later. We previously showed[16] that many characteristic hemodynamic responses to single-bolus injection of verapamil are largely dissipated in 10 minutes after intravenous drug administration. Therefore, it is likely that in Simonsen's study, hemodynamic variables were measured at a time when changes were minimal. This possibility is further supported by the fact that the changes in systemic hemodynamics were much smaller than those observed in our study. The alteration in systemic hemodynamic variables noted in the present study were comparable to those previously reported by us[16,20] and found by others.[19]

Fifty percent of the lesions analyzed showed no significant change in coronary cross-sectional area with verapamil. Failure of these segments to dilate may be a reflection of the decrease in distending pressure with verapamil, possibly mediated by reflex vasoconstriction.[21] However, we were unable to find any correlation between the directional changes in coronary caliber with the degree of reduction in aortic pressure or systemic vascular resistance. A second explanation for variation in vasomobility response may reflect the greater degrees of ongoing adrenergic or calcium-mediated vasomotor tone in some patients at the time of cardiac catheter-

ization. We recently showed that verapamil is able to block adrenergically mediated coronary constriction.[22] A third explanation for variability in the vasodilatory response to verapamil may relate to the histologic aspects of the coronary stenosis. In an eccentric lesion in which the remaining lumen is circumscribed by a relatively normal segment of arterial wall, the potential for vasomobility would be greater than that in a concentric lesion, the lumen of which is surrounded entirely by more rigid components of the atherosclerotic plaque.[23]

Our data show that the degree of large vessel coronary dilatation induced by verapamil is relatively mild and perhaps only appreciated in our study by a computer-assisted method for analysis of changes in coronary caliber. This finding may explain the previous findings of Mignault,[6] who, using gross angiographic appearances, reported that intravenous verapamil altered the caliber of neither normal nor atherosclerotic coronary vessels.

The observed coronary caliber changes induced by verapamil appeared to be relatively minor compared with those after nitroglycerin, although a dose-response relation was not examined. However, these changes with verapamil are of greater magnitude than those induced by dipyridamole, which produces only a slight nonsignificant dilation of normal and diseased coronary segments.[24] Using a similar technique of computer-assisted analysis of 85 coronary lesions from 57 patients with ischemic heart disease, Brown et al,[15] in our laboratory, recently showed that nitroglycerin dilated normal segments of coronary arteries by an average of 18% in cross-sectional area, whereas estimated stenosis flow resistance decreased 25% in moderately severe lesions and 38% in severe lesions. However, these changes, albeit from a larger data base, are of comparable magnitude to those found in our study. Thus, in the resting state, nitroglycerin is 2 to 3 times more potent a vasodilator of epicardial conductance vessels than verapamil. Relatively mild coronary vasodilator effects using a similar, but not identical, computer-assisted technique were recently described for nifepidine.[25] However, the observations with verapamil pertain only to the coronary vessel in the basal state and do not negate the obvious clinical efficacy of verapamil and other calcium antagonists in vasospastic angina[26–29] where the degree of vasodilation could be greater. Furthermore, evidence is accumulating that a major role for calcium antagonists lies in the *prevention* of coronary artery spasm associated with Prinzmetal's angina.[30,31] Nifepidine was recently shown to exert a selective antivasoconstrictor effect in the coronary vasculature by preventing abnormal hemodynamic coronary changes due to the cold pressor test.[32] In human studies using quantitative coronary angiography, intravenous verapamil inhibited both sympathetic and ergonovine-induced coronary vasoconstriction in diseased human coronary arteries.[22]

**Clinical implications:** Although data from intravenous studies cannot always be extrapolated directly to the clinical contexts in which calcium antagonists are being used to alleviate myocardial ischemia, our data permit some inferences. Verapamil reduces coronary vascular resistance while producing an increase, albeit small, in lumen cross-sectional area of both diseased and "normal" coronary vessels. These findings, in addition to the recent observation that verapamil reverses both sympathetically mediated as well as ergonovine-induced coronary vasoconstriction,[22] provide the physiologic basis for the drug's salutary effects in Prinzmetal's and other vasospastic ischemic syndromes. In chronic stable angina, the mechanism of the beneficial action is less clear and unlike that of beta-blocking agents, not explainable solely on the basis of changes in the gross indexes of myocardial oxygen consumption.[33] Our data suggest that stenosis dilatation as a contributing mechanism cannot be discounted.

# Nifedipine in Chronic Stable Angina: A Double-Blind Placebo-Controlled Crossover Trial

LON G. SHERMAN, MD and CHANG-SENG LIANG, MD, PhD

**Thirty patients with chronic stable angina pectoris were randomized in a double-blind prospective placebo-controlled crossover trial to assess the efficacy of nifedipine (30 to 60 mg/day orally) in controlling symptoms and objective signs of myocardial ischemia using a symptom-limited treadmill exercise test. Adverse effects that occurred during both nifedipine and placebo treatment were minor and generally well tolerated. Twenty-three patients were analyzed from the crossover phase of the study. Nifedipine significantly reduced the frequency of angina by 55% and nitroglycerin consumption by 59%, and increased exercise time by 34%. These changes were significantly greater than those in the placebo group. Hemodynamic evaluation during exercise revealed a significant reduction in systolic and diastolic blood pressures in the nifedipine group at the onset of angina and at maximal exercise without significant differences in heart rate responses in the nifedipine and placebo groups. The pressure-rate product during submaximal exercise was significantly smaller in the nifedipine group than in the placebo group, but did not differ significantly in the 2 groups at the onset of angina or on maximal exercise. Furthermore, S-T segment depressions that occurred during exercise at the same pressure-rate products were smaller in the nifedipine period than in the placebo period. Thus, it appears that the antianginal effects of nifedipine are caused by a reduced myocardial oxygen demand for a specific work load and possibly by an increased blood supply to ischemic myocardium.**

Beta-receptor blocking agents and nitrates are presently the mainstays of treatment for symptomatic coronary artery disease. Nifedipine is a relatively new agent. It does not cause bronchospasm or myocardial depression, both of which are major adverse effects of beta-receptor blockers and limit their use in certain clinical situations. Nifedipine and nitrates, albeit similar in mechanisms of action, differ greatly in that nifedipine has little effect on preload.[1]

Despite enthusiastic acceptance of nifedipine by clinicians, there has been no completed long-term placebo-controlled crossover study to date. Preliminary double-blind studies including some multicenter trials using nifedipine in patients with angina pectoris have demonstrated promising results.[2–7] The present study is a randomized, prospective, double-blind, placebo-controlled crossover trial from a single center. Its purpose was to assess the efficacy of the nifedipine in reducing both subjective and objective signs of myocardial ischemia in symptomatic patients with chronic stable angina pectoris.

## Methods

Thirty patients were included in the study. All had a history of angina pectoris characterized by chest pain, chest pressure, or distress, usually brought on by exertion or emotional stress, and relieved by nitroglycerin, rest, or removal of emotional stress. These symptoms had been stable without acute myocardial infarction for at least 6 months. All patients had at least 5 episodes/week of angina pectoris or had <5 episodes of angina/week but exhibited >0.2 mV of horizontal or downsloped S-T segment depression during exercise. Coronary artery disease was confirmed by at least 1 of the following: (1) coronary angiography showing ≥70% diameter narrowing of ≥1 major coronary arteries, (2) documentation of a prior transmural myocardial infarction, (3) demonstration of typical angina pectoris during exercise stress testing associated with ischemic electrocardiographic changes. Two patients with stable angina who had undergone aortocoronary bypass surgery 3 and 10 years earlier were included. Informed consent was obtained from all patients. All patients were withdrawn from concomitant therapy with long-acting ni-

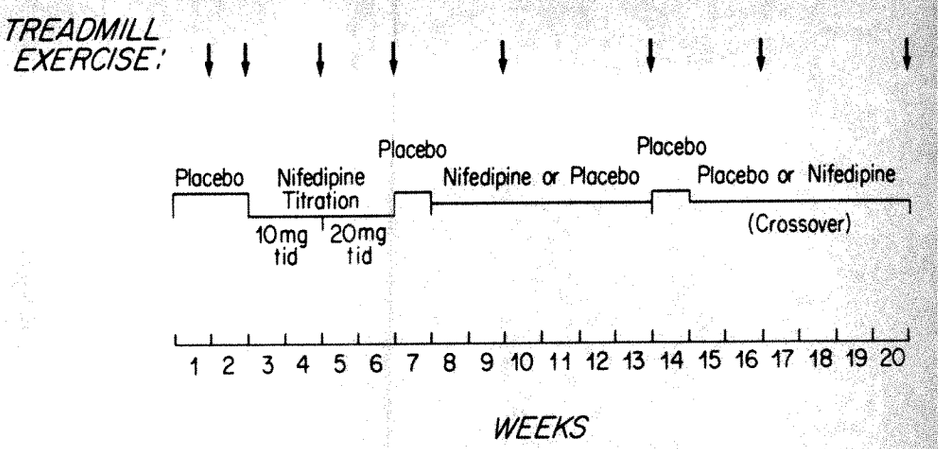

**FIGURE 1.** The weeks during which subjects received either placebo or nifedipine. During the titration phase (weeks 3 to 6), the optimal dose of nifedipine was established which was later given during the double-blind phase of the study (weeks 8 to 13 or weeks 15 to 20). Patients were crossed over from nifedipine to placebo or placebo to nifedipine during the second leg of the double-blind phase (weeks 15 to 20) after a single-blind placebo week. Exercise treadmill tests were performed at specific times denoted by **arrows**.

trates or beta-receptor blocking agents at least 1 week before entering the study. Two patients who had received quinidine, 1 procainamide, and 2 disopyramide for ventricular arrhythmias before the study continued receiving the maintenance therapy. Sixteen patients continued receiving maintenance doses of thiazide diuretics (n = 13) and furosemide (n = 3), and appropriate doses of potassium supplements to prevent hypokalemia. Three of the patients taking diuretics also received maintenance doses of alpha-methyldopa for control of hypertension. Seven patients continued receiving digoxin therapy. None of the patients included had uncontrolled congestive heart failure, forms of heart disease considered to result from causes other than atherosclerotic cornary disease, unstable cardiac arrhythmias, cerebral vascular insufficiency, uncontrolled hypertension, serious hepatic, renal, and hematopoietic diseases, or concomitant disorders with symptoms that could be confused with angina.

The study design consisted of 3 phases (Fig. 1). Initially, all patients underwent a baseline phase during which no long-term antianginal medications were used. During this time, placebo was taken in a single-blind manner. Thereafter, there was a 4-week single-blind titration phase during which nifedipine was administered orally at either 10 or 20 mg 3 times a day to determine the optimal dosage for each patient. This was followed by a 14-week randomized double-blind crossover phase consisting of two 6-week drug periods with 1-week placebo washout periods before each 6-week drug period. The placebo and nifedipine capsules were identical in appearance.

Treadmill exercise testing (12 leads) was done using a modified Balke's procotol,[8] in which patients were exercised on a treadmill with stages of 3 minutes each, initially at 2.0 mph with a 3% grade followed by an increase in speed to 3.3 mph and a 6% grade. The treadmill speed was held constant thereafter with incremental increases of grade by 3% during all subsequent stages. During exercise, times were recorded at the onset of angina and maximal exercise tolerance which was defined by angina pain of moderately severe intensity (primary endpoint). In addition, exercise tests were terminated if any of the following were observed: severe shortness of breath, a significant decrease in systolic blood pressure, or severe fatigue. None of the patients developed significant ventricular arrhythmia during exercise that necessitated termination of the study. Measurements of heart rate, arterial blood pressure by an arm cuff sphygmomanometer, and S-T segment depression were taken every minute during exercise. Systolic arterial pressure and heart rate were multiplied to yield the pressure-rate product. The work performed at each minute of exercise was derived using approximate total body oxygen consumption[8] and expressed in METs. One MET is the energy expenditure at rest, equivalent to approximately 3.5 ml of oxygen/kg body weight/min. The total work performance achieved at the onset of angina and maximal exercise was computed by summing the work performed at each minute of exercise until the specified times. All exercise tests were done 2 hours after intake of nifedipine or placebo, and at least 3 hours after meals. No patient took nitroglycerin within 6 hours before treadmill exercise. Exercise testing was done at the end of weeks 1 and 2. Patients were allowed to continue in the study if exercise times in the 2 baseline testings were discordant by <15%.

At the start of the third week, nifedipine was given single-blinded at a dosage of 10 mg every 8 hours for 2 weeks (weeks 3 and 4) and increased to 20 mg every 8 hours, if tolerated for the next 2 weeks (weeks 5 and 6). Exercise testing was repeated at the end of weeks 4 and 6. The optimal nifedipine dosage was determined by the highest dose tolerated without signs or symptoms related to significant blood pressure reduction, deterioration of myocardial function, or laboratory evidence suggesting adverse effects upon renal, hepatic, or hematopoietic systems.

All patients received placebo during the seventh week. From weeks 8 through 13, patients were given their optimal dose of nifedipine or placebo in a randomized, double-blind manner followed by a week of placebo. Thereafter, from weeks 15 through 20, patients were crossed-over double-blinded to nifedipine or placebo. Patients who had increasing frequency of chest pain during the initial leg of the crossover period could be entered early into the next leg. Exercise tests were done at the end of the second week and the last week of each leg during the double-blind period.

In addition to exercise testing, patients kept a diary of all anginal attacks as well as total nitroglycerin tablets taken during each phase. All patients were periodically examined and tested for observed or laboratory evidence of adverse effects.

Results are expressed as mean ± standard error. The percentage of difference from baseline values during the single-blind titration phase and double-blind crossover phase were compared using the Student's $t$ test for paired comparisons. Because the exercise time was reproducible with a coefficient of variation of 7.7% for the 2 treadmill testings during each leg of the double-blind crossover period, the 2 exercise measurements for each leg were averaged. The crossover periods were assessed using analysis of variance for repeated measures with a crossover design.[9] The S-T segment responses for

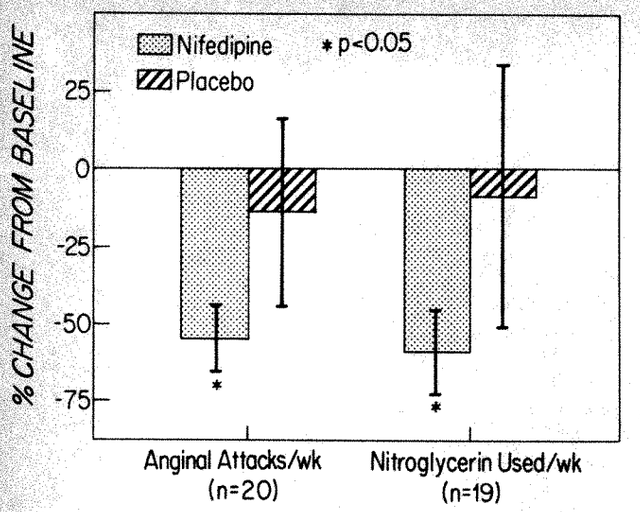

**FIGURE 2.** Changes in frequency of angina and nitroglycerin consumption from baseline by nifedipine and placebo during the double-blind crossover phase. Values are mean ± standard error. **Asterisks** indicate values that differ from placebo at $p < 0.05$, as determined by Student's *t* test for paired comparisons.

specific pressure-rate products were determined from regression analyses for each patient. The values were then averaged for both treatment groups and compared using Student's *t* tests. The incidence of adverse effects in the 2 treatment groups was compared using a chi-square test. Values are considered statistically significant if $p < 0.05$.

## Results

Thirty patients, 19 men and 11 women aged 43 to 70 years, were randomized to the nifedipine-placebo crossover study. No patient had serious cardiovascular complications, prolonged bed rest, or hospitalization. Seven patients, however, were excluded from the crossover statistical analyses. Three were excluded because of early termination during the titration phase due to headache, loss in follow-up, and uneasiness in participating in the research protocol, respectively. Two patients were prematurely crossed-over because of increasing frequency of chest pain during the initial (placebo) leg of the double-blind phase. These patients subsequently improved during the second leg of the study when they received nifedipine. One patient was dropped from the final (placebo) leg of the double-blind crossover phase because of increasing chest pain. One patient was excluded from analysis because of incomplete data collection. When data were not available from some patients, the number of subjects analyzed are indicated in parentheses.

**Anginal episodes and nitroglycerin consumption:** Nifedipine significantly decreased the frequency of anginal attacks during the low-dose (30 mg/day) and high-dose (60 mg/day) titration phases. Anginal attacks significantly decreased from 4.4 ± 0.7 before treatment to 2.8 ± 0.5/week during the lower dosage (n = 25), and from 5.0 ± 0.8 to 2.7 ± 0.5/week with the higher dose (n = 19). Six patients had severe headaches and could not tolerate the higher dosage. Nitroglycerin use also was

| | Placebo | Nifedipine |
|---|---|---|
| Time (seconds) | | |
| Onset of angina | 274 ± 21 | 319 ± 25* |
| Maximal exercise | 440 ± 43 | 490 ± 48* |
| Work performance achieved (METs) | | |
| Onset of angina | 17.5 ± 2.3 | 22.3 ± 2.8* |
| Maximal exercise | 38.2 ± 6.6 | 45.3 ± 7.4* |
| S-T segment depression (mV) | | |
| Onset of angina | 0.11 ± 0.02 | 0.09 ± 0.02 |
| Maximal exercise | 0.18 ± 0.02 | 0.14 ± 0.02* |

Values are mean ± standard error. N = 17 for data obtained at the onset of angina and n = 23 for maximal exercise.
* Values that differ from the placebo at $p < 0.05$.

significantly decreased from the baseline (5.1 ± 1.2 tablets/week) to 3.5 ± 0.7 tablets/week during the low-dose titration phase and from 6.2 ± 1.3 to 2.7 ± 0.7 tablets/week during the high-dose phase. In addition, nifedipine but not placebo reduced anginal frequency and nitroglycerin use during the crossover period (Fig. 2).

**Exercise time, work performance, and ischemic S-T segment response:** During the titration phase, patients had angina after 229 ± 29 seconds of exercise before receiving nifedipine, but remained free of angina until 276 ± 36 seconds into exercise while taking the low-dose nifedipine (n = 23). The maximal duration of

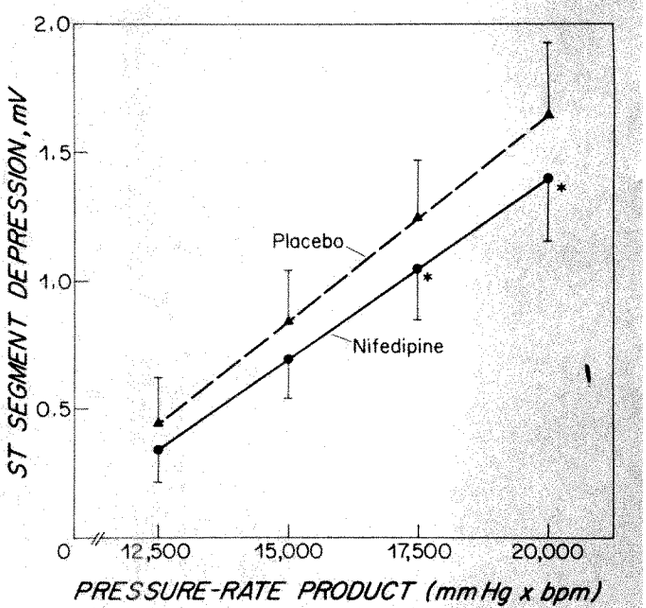

**FIGURE 3.** Comparisons of ischemic S-T segment depressions at specific pressure-rate products in the double-blind nifedipine and placebo periods (n = 17). The values of S-T segment depressions were calculated for each patient by interpolation from the regression lines that correlated S-T segment depressions and pressure-rate products during exercise. **Bars** indicate standard errors. **Asterisks** show values that differ significantly from the corresponding values during the placebo period at $p < 0.05$, as determined by Student's *t* test for paired comparisons.

exercise increased from 368 ± 35 to 434 ± 39 seconds (n = 28). The time to onset of angina and maximal exercise also increased in patients receiving the high-dose nifedipine. Unlike the baseline exercise testing during which all patients stopped exercise because of moderately severe chest pain, 6 patients did not have chest pain and stopped exercise because of fatigue or severe shortness of breath. Of the remaining 17 patients, the time to onset of angina increased from 206 ± 16 to 290 ± 22 seconds. The maximal duration of exercise for all patients increased from 369 ± 37 to 489 ± 55 seconds.

The increase in exercise tolerance was reflected in total work performance achieved at the onset of angina which increased significantly from 14 ± 3 to 19 ± 5 METs during the low-dose nifedipine period (n = 23) and from 11 ± 1 to 19 ± 2 METs with the high dose (n = 17). Total work performance achieved at maximal exercise also increased significantly from baseline during the low-dose nifedipine (29 ± 4 to 37 ± 5 METs) and high-dose nifedipine (29 ± 5 to 46 ± 9 METs).

The amount of S-T segment depression at the onset of angina was not significantly reduced by either the low- or the high-dose nifedipine. At maximal exercise, however, S-T segment depression was significantly reduced by nifedipine, decreasing from 0.18 ± 0.01 at baseline to 0.15 ± 0.02 mV with the low-dose nifedipine, and from 0.17 ± 0.01 to 0.12 ± 0.02 mV with the high dose.

During the crossover period, the time to the onset of angina and the maximal duration of exercise were significantly greater during the nifedipine period (Table I). Similarly, significantly greater work performance was achieved at the onset of angina and at maximal exercise during the nifedipine period than with placebo. The S-T segment depression at the onset of angina did not differ significantly in the nifedipine and placebo periods. However, a significant reduction in S-T segment depression was found at maximal exercise during nifedipine treatment compared with placebo. Furthermore, Figure 3 shows that nifedipine was associated with a reduction in the magnitude of S-T segment depression during exercise-induced increases in pressure-rate products. At pressure-rate products ≥17,500 mm Hg·beats/min, the amount of S-T segment depression was significantly reduced by nifedipine compared with placebo.

**TABLE II Exercise Hemodynamic Values in the Double-Blind Crossover Periods**

| | Placebo | Nifedipine |
|---|---|---|
| Onset of angina | | |
| Heart rate (beats/min) | 122 ± 4 | 123 ± 3 |
| Systolic pressure (mm Hg) | 159 ± 5 | 154 ± 4* |
| Diastolic pressure (mm Hg) | 87 ± 3 | 82 ± 4* |
| Pressure-rate product (mm Hg·beats/min × $10^{-3}$) | 19.5 ± 0.9 | 18.8 ± 0.6 |
| Maximal exercise | | |
| Heart rate (beats/min) | 133 ± 4 | 133 ± 4 |
| Systolic pressure (mm Hg) | 167 ± 6 | 157 ± 5* |
| Diastolic pressure (mm Hg) | 88 ± 4 | 80 ± 3* |
| Pressure-rate product (mm Hg·beats/min × $10^{-3}$) | 22.4 ± 1.2 | 20.9 ± 0.9 |

Values are mean ± standard error; n = 17.
* Values that differ from the placebo at $p < 0.05$.

**Hemodynamics during exercise:** The data reported in Table II include 17 patients whose exercise response was associated with typical anginal pain during both legs of the crossover period. The resting heart rate during the nifedipine phase (79 ± 3 beats/min) was slightly higher than during the placebo phase (75 ± 3 beats/min, n = 23, p = 0.044), but the heart rate response to exercise did not differ in the 2 phases. The lack of differences was noted both at the onset of angina and at maximal exercise. In contrast, the systolic and diastolic blood pressures during exercise were signifi-

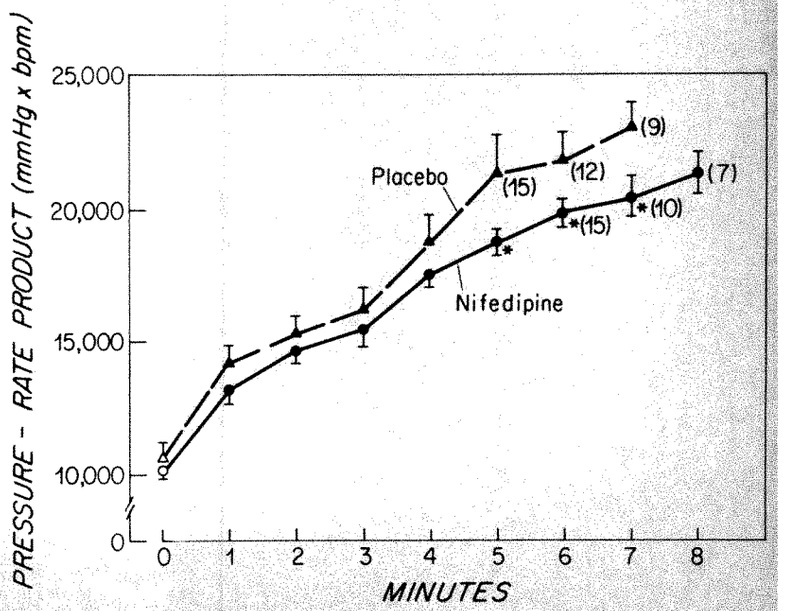

**FIGURE 4.** Temporal changes in pressure-rate product during exercise in double-blind nifedipine and placebo periods. N = 17 unless otherwise indicated in parentheses. **Bars** show standard errors. **Asterisks** indicate values that differ significantly from the corresponding values in the placebo period at $p < 0.05$, as determined by Student's *t* test for paired comparisons.

**TABLE III Incidence of Adverse Effects**

| Adverse Effect | Nifedipine | Placebo |
|---|---|---|
| Headache | 4 | 0* |
| Lack of energy | 4 | 3 |
| Gastrointestinal symptoms | 4 | 1 |
| Dizziness | 2 | 2 |
| Flushing | 1 | 0 |
| Paresthesia | 1 | 1 |
| Palpitations | 1 | 0 |
| Rash | 1 | 0 |
| Restlessness | 0 | 1 |

Total of 30 patients in each treatment group.
* Value that differs significantly from the nifedipine at $p < 0.05$, as determined by chi-square test.

cantly lower with nifedipine than with placebo both at the onset of angina and at maximal exercise.

Figure 4 shows that the pressure-rate product increased progressively as exercise duration lengthened, and that the increase in pressure-rate products beyond 4 minutes of exercise was significantly smaller in patients receiving nifedipine compared with placebo. The pressure-rate products at the onset of angina and maximal exercise, however, did not differ significantly in the nifedipine and placebo groups (Table II).

When the 6 patients who did not experience angina during crossover periods were included in the analysis, similar significant decreases were noted in the systolic and diastolic pressures during nifedipine treatment compared with placebo. Likewise, the maximal exercise pressure-rate product during nifedipine treatment (22,045 ± 1,128 mm Hg·beats/min) was not significantly different from placebo (23,196 ± 1,224 mm Hg·beats/min).

**Adverse effects:** Adverse effects observed in the study were minor and were well tolerated by the patients (Table III). They were present in 16 of the 30 patients studied, 6 of whom were receiving placebo when the adverse effects occurred. No untoward effects were reflected by laboratory data. The most common adverse effects were headaches, lack of energy, and various gastrointestinal symptoms including nausea or vomiting, diarrhea, and flatulence. Lack of energy was the most common complaint of patients receiving placebo. Dizziness was equally common during nifedipine and placebo treatment. Headaches, flushing, palpitation, and a rash were evident only during nifedipine usage and, with the exception of headaches, were uncommon. Only headaches were statistically more common during the nifedipine use compared with placebo. The causal relation between the observed adverse effects and nifedipine usage, however, was not established. No patient had peripheral edema during the study period.

## Discussion

The present study demonstrates that nifedipine improves both symptoms and objective signs of myocardial ischemia in patients with angina pectoris. Nifedipine decreased frequency of anginal episodes and nitroglycerin usage. This is further supported by our findings that unstable angina occurred in 3 patients while receiving placebo. In addition, exercise time until the onset of angina and maximal tolerated exercise was prolonged during nifedipine use compared with placebo. The ischemic S-T segment depression at given pressure-rate products during moderate to maximal tolerated exercise was reduced by nifedipine compared with placebo. Some minor adverse effects occurred during both the nifedipine and placebo treatment, but were generally well tolerated. Headache was the only symptom that occurred more frequently during nifedipine than placebo.

The improvement in patients with ischemic heart disease who were receiving nifedipine is likely related to a favorable shift in the balance between myocardial oxygen supply and demand. Angina pectoris is thought to be inducible when a mismatch develops between myocardial oxygen supply and demand for oxygen during aerobic cardiac metabolism.[10] Our results show that nifedipine, in comparison with placebo, causes a significant decrease in systolic and diastolic arterial pressure due to its vasodilatory effect upon the systemic circulation, without differences in heart rate during exercise. This decrease in systolic blood pressure was reflected in a lower pressure-rate product during exercise when patients were taking nifedipine. Since the pressure-rate product is known to correlate closely with myocardial oxygen consumption during exercise in patients with ischemic heart disease,[11,12] a reduction in the product would imply less myocardial oxygen consumption due to a reduction in oxygen demand. Thus, it appears likely that the blunted response of the systolic blood pressure during exercise is responsible, at least in part, for the longer exertional period that lapses before the pressure-rate product anginal threshold is reached. Since angina occurs reproducibly at specific pressure-rate products for a given patient, the pressure-rate products are similar with nifedipine and placebo at the onset of angina.[13]

Alternatively, nifedipine may favorably affect myocardial oxygen supply by enhancement of coronary flow to ischemic regions. Nifedipine is known to be a direct coronary vasodilator.[14,15] It has also been shown to produce sustained increases in collateral flow during ischemia in animal studies,[16,17] and may induce protective collateralization during chronic ischemia.[18] Recently, it has been shown that in patients with coronary artery disease, nifedipine increases regional myocardial blood flow supplied by vessels with significant coronary obstruction.[19] However, these studies were done with patients in the resting nonischemic states, and most patients were maintained with propranolol. Similarly, during experimental myocardial ischemia, intracoronary nifedipine resulted in increased coronary blood flow at moderate reductions in coronary perfusion pressure.[20] Our finding that nifedipine was associated with a reduction in the ischemic S-T segment depression at given pressure-rate products during moderate to maximal exertion compared with placebo is consistent with increased myocardial oxygen supply. Thus, it appears that nifedipine may also ameliorate the

myocardial oxygen supply-demand ratio by increasing blood flow to hypoperfused myocardium.

*In summary*, our study supports the view that nifedipine may act by reducing myocardial oxygen demand for a given work load through its vasodilator effects upon the peripheral circulation and, in addition, may enhance myocardial oxygen supply by direct coronary vasodilation or increased collateral flow. These hemodynamic changes during exercise are converse to the changes seen in anginal patients exercised during beta-receptor blockade in which a reduction in the pressure-rate product is predominantly attributed to a slowing of heart rate with some contribution due to a diminution in systolic pressure.[21-25] The mechanism by which nifedipine benefits the signs and symptoms of angina pectoris will require invasive hemodynamic studies for validation.

# Effect of Intravenous and Intracoronary Nifedipine on Coronary Blood Flow and Myocardial Oxygen Consumption

PETER SCHANZENBÄCHER, MD, GERHART LIEBAU, MD, PETER DEEG, MD, and KURT KOCHSIEK, MD

**The effect of intravenous and intracoronary nifedipine on coronary sinus blood flow, coronary vascular resistance, and myocardial oxygen consumption was studied in 20 patients with coronary artery disease. An intravenous infusion of 1.0 mg nifedipine resulted in a decrease in mean aortic pressure, an increase in heart rate and coronary blood flow, and no significant change in myocardial oxygen consumption. In contrast, the intracoronary injection of 0.1 mg nifedipine led to a moderate reduction in mean aortic pressure, no change in heart rate, an increase in coronary blood flow, and a significant reduction in myocardial oxygen consumption. During rapid atrial pacing before and approximately 6 minutes after the intracoronary nifedipine injection, coronary blood flow and myocardial oxygen consumption reached identical levels. Thus, only intracoronary injection of nifedipine increases coronary flow in the presence of reduced myocardial oxygen consumption. After intravenous administration, reflex tachycardia counteracts the direct myocardial effect of nifedipine and the potential oxygen-saving effect of afterload reduction. There is no evidence of a prolonged oxygen-sparing effect after cessation of the immediate effects.**

Nifedipine is increasingly being used in the treatment of angina pectoris.[1-4] Based on experimental studies, nifedipine is believed to inhibit calcium ion influx across muscle cell membranes.[5] In vascular smooth muscle, this results in relaxation with subsequent vasodilation. In cardiac muscle, there is less contraction and a negative inotropic effect.[5,6] The following mechanisms might therefore contribute to the antianginal properties of nifedipine: (1) a reduction in myocardial oxygen consumption by a direct myocardial effect, (2) a decreased myocardial oxygen demand due to afterload reduction resulting from the dilation of peripheral resistance vessels, and (3) an increased coronary blood flow with a subsequent improved oxygen supply due to coronary vasodilation. These effects have never been verified in the intact resting heart in man. We therefore studied the effect of intravenous and intracoronary nifedipine on coronary sinus blood flow, coronary vascular resistance, and myocardial oxygen consumption in patients with chronic stable angina due to coronary artery disease.

A prolonged anti-ischemic activity of nifedipine during stress was recently reported in the absence of altered hemodynamic function. These data suggested a reduction in myocardial oxygen requirements without a change in the usual indexes of myocardial energy demand.[7] In order to evaluate this hypothesis, coronary sinus blood flow and myocardial oxygen consumption were measured during rapid atrial pacing before and after intracoronary nifedipine administration.

## Methods

**Patients:** The study was performed on 20 patients, 19 men and 1 woman, undergoing routine cardiac catheterization for chronic stable angina. Coronary artery disease was defined as >60% diameter reduction of 1 or more major coronary arteries. Patient data are summarized in Table I.

**Protocol:** Drug treatment was withheld for 48 hours before study. Cardiac catheterization was performed with the patient in the fasting state without premedication. Right- and left-sided heart catheterization, single-plane ventriculography, and selective coronary angiography in multiple projections were performed by way of the femoral route. A preshaped coronary sinus catheter with 2 thermistors and bipolar pacing

electrodes (type CCS- 7U-90B, Wilton Webster Laboratories, Altadena, California) was inserted from the right antecubital vein and placed in the coronary sinus so that the external thermistor was about 2 to 3 cm inside the coronary sinus. Catheter positions were frequently documented on videotape throughout the study. Changes in catheter position could therefore be ruled out. There was at least a 15-minute interval between the last injection of contrast medium for diagnostic coronary angiography and coronary sinus flow measurements.

The effect of intravenous nifedipine was studied on the first 10 patients. Coronary sinus blood flow and myocardial oxygen consumption were determined at rest. One mg of nifedipine in a 10 ml solution was continuously infused within 2 minutes.

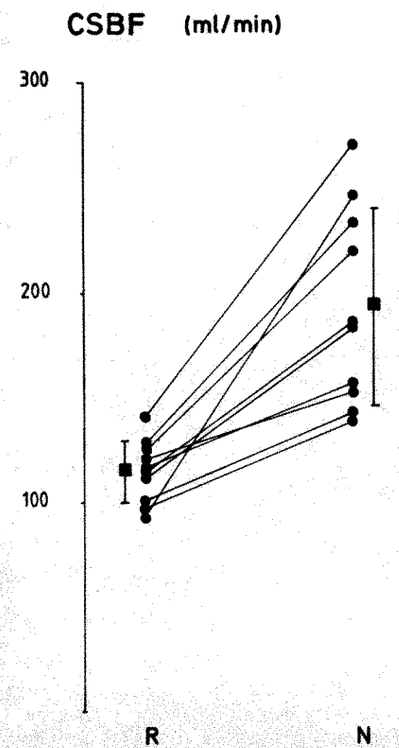

**FIGURE 2.** Coronary sinus blood flow (CSBF) before (R) and 1 minute after the intracoronary injection of 0.1 mg nifedipine (N). Each patient's individual response is shown.

Coronary sinus flow and the corresponding oxygen saturations were measured immediately after the infusion and after 4, 6, and 12 minutes. Heart rate and aortic pressure were continuously monitored.

The second group of 10 patients received intracoronary nifedipine. Coronary sinus flow and myocardial oxygen consumption were again determined at rest. The patients were then paced beyond the angina pectoris threshold or until a frequency-dependent atrioventricular block appeared. The mean pacing rate was 118 ± 6 beats/min. Right atrial pressure did not change during pacing. Coronary sinus reflux could therefore be excluded.[8] After determining coronary sinus flow and myocardial oxygen consumption, there was a brief recovery period for the heart rate to return to basal levels. Thereafter, 0.1 mg nifedipine was injected into the left coronary artery within 10 seconds and coronary sinus flow and myocardial oxygen consumption were measured after 1, 3, and 5 minutes. Patients were then paced with their individual preinjection pacing rates and coronary sinus flow and myocardial oxygen consumption measurements repeated.

**Calculations:** Coronary sinus blood flow was measured by the constant infusion thermodilution technique.[9] Arterial and coronary sinus blood samples were simultaneously drawn for the determination of oxygen saturation and content. Oxygen saturation was measured using an AO-Oximeter (American Optical, Bedford, Massachusetts). The coronary arteriovenous oxygen difference ($AVO_2$) was calculated as follows: $AVO_2 = (SAO_2 - SCSO_2) \times 1.34 \times Hb$, where $SAO_2$ = arterial oxygen saturation, $SCSO_2$ = coronary sinus blood oxygen saturation, 1.34 = oxygen carrying capacity of hemoglobin, and Hb = hemoglobin concentration. Myocardial oxygen consumption was calculated as the product of coronary sinus blood flow and the coronary arteriovenous oxygen difference. Coronary vascular resistance was derived from the ratio of mean aortic pressure to coronary sinus blood flow.

## Results

**Intravenous nifedipine:** Coronary sinus blood flow increased from 131 ± 53 to 186 ± 69 ml/min after completing the infusion of 1.0 mg nifedipine ($p < 0.001$). Coronary vascular resistance decreased from 0.96 ± 0.40 to 0.54 ± 0.19 mm Hg/ml/min ($p < 0.001$). Mean aortic pressure decreased from 107 ± 10 to 89 ± 10 mm Hg ($p < 0.001$) and the heart rate increased from 74 ± 12 to 88 ± 14 beats/min ($p < 0.001$). Six minutes after initiation of the infusion, coronary sinus blood flow, coronary vascular resistance, and heart rate had returned to preinfusion values. Mean aortic pressure remained low for 12 minutes ($p < 0.05$). Myocardial oxygen con-

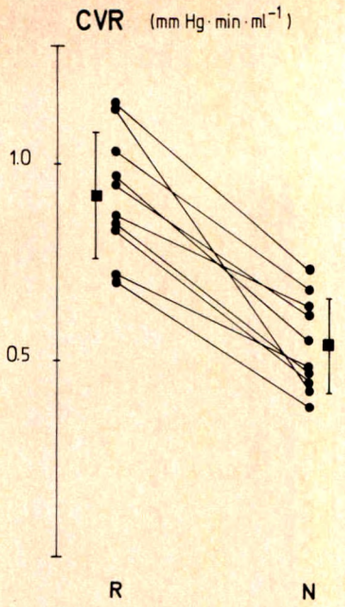

**FIGURE 3.** Coronary vascular resistance (CVR) before (R) and 1 minute after the intracoronary injection of 0.1 mg of nifedipine (N).

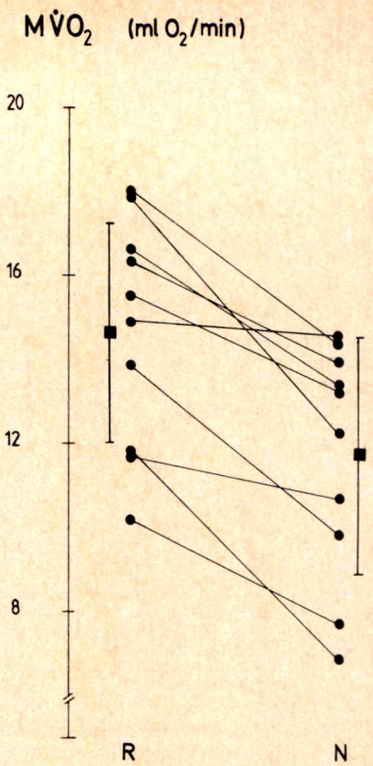

**FIGURE 4.** Myocardial oxygen consumption ($MVO_2$) before (R) and 1 minute after the intracoronary injection of 0.1 mg of nifedipine (N).

sumption decreased slightly from 17.1 ± 6.7 to 16.5 ± 6.3 ml $O_2$/min ($p < 0.3$). There were no significant changes in the rate-pressure product. Mean values are shown in Table II. There was a linear correlation between myocardial oxygen consumption and the rate-pressure product ($r = 0.73$, Fig. 1).

**Intracoronary nifedipine:** One minute after the intracoronary injection of 0.1 mg nifedipine, coronary sinus blood flow increased from 115 ± 15 to 193 ± 47 ml/min ($p < 0.001$) and coronary vascular resistance decreased from 0.92 ± 0.16 to 0.54 ± 0.12 mm Hg/ml/min ($p < 0.001$). A reduction in coronary vascular resistance with a subsequent increase in flow occurred in all patients studied (Fig. 2 and 3).

Intracoronary injection led to a significant reduction in myocardial oxygen consumption (from a mean of 14.6 ± 2.6 to 11.7 ± 2.8 ml $O_2$/min, $p < 0.05$, Fig. 4). This was accompanied by a decrease in mean aortic pressure from 107 ± 5 to 99 ± 3 mm Hg ($p < 0.01$). There were no significant changes in heart rate (72 ± 9 versus 74 ± 12 beats/min). In 6 of 10 patients, coronary sinus blood flow and myocardial oxygen consumption had returned to resting values 3 minutes after the intracoronary injection. After 5 minutes, coronary flow (113 ± 18 ml/min) and myocardial oxygen consumption (14.9 ± 3.1 ml $O_2$/min) stabilized at preinjection levels. Mean aortic pressure was not significantly different from control values after 3 (108 ± 6 mm Hg) and 5 minutes (108 ± 13 mm Hg).

**Atrial pacing:** During rapid atrial pacing (mean rate 118 ± 6 beats/min), coronary sinus blood flow and myocardial oxygen consumption increased to 172 ± 62 ml/min and 19.8 ± 5.0 ml $O_2$/min, respectively. Similar coronary sinus flow (177 ± 69 ml/min) and myocardial oxygen consumption values (20.6 ± 7.3 ml $O_2$/min) were obtained when the patients were paced at their individual preinjection pacing rates approximately 6 minutes after the intracoronary nifedipine administration (Fig. 5 and 6). There were no differences in the mean aortic pressure during the 2 pacing periods (108 ± 6 versus 109 ± 7 mm Hg).

## Discussion

**Coronary effects of nifedipine:** Intracoronary and intravenous nifedipine resulted in a marked increase in coronary flow. The increase in blood flow was more pronounced after the intracoronary injection of 0.1 mg nifedipine than after the intravenous infusion of 1.0 mg (a mean of 70 versus 44%). Both intravenous and intracoronary nifedipine reduced coronary vascular resistance to almost the same level. Differences in flow are due to different coronary perfusion pressures. Intravenous nifedipine produced a marked and sustained decrease in mean aortic pressure, while intracoronary nifedipine only resulted in moderate and transient pressure changes. Since only changes in the entire left ventricular outflow can be detected by the thermodilution technique,[10] our data do not permit an analysis of regional perfusion patterns or a correlation between individual responses to nifedipine and the severity and distribution of coronary arterial stenoses.

The changes in coronary vascular resistance observed in this study represent the combined effect of nifedipine on large epicardial conductance vessels and small intramural resistance vessels. In the presence of eccentric stenosis, resistance in the extramural conductance vessels may be a combination of the luminal narrowing

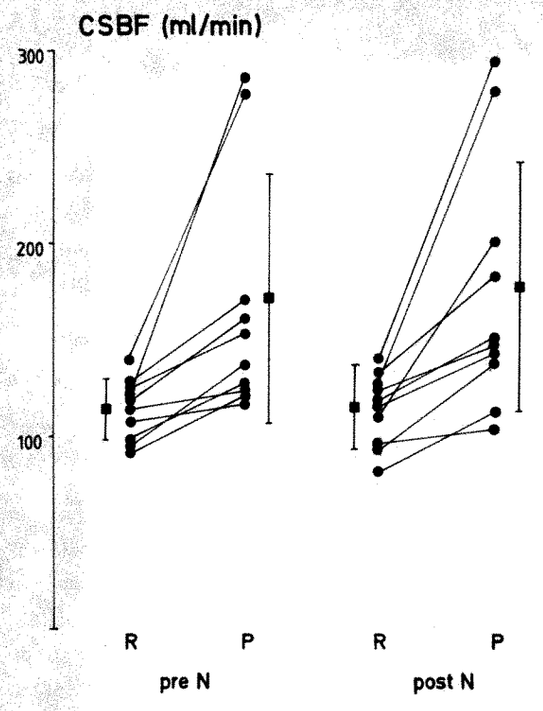

**FIGURE 5.** Coronary sinus blood flow (CSBF) at rest (R) and during rapid atrial pacing (P) before (pre N) and about 6 minutes after the intracoronary injection of 0.1 mg nifedipine (post N). Individual pacing rates were identical during the 2 pacing periods.

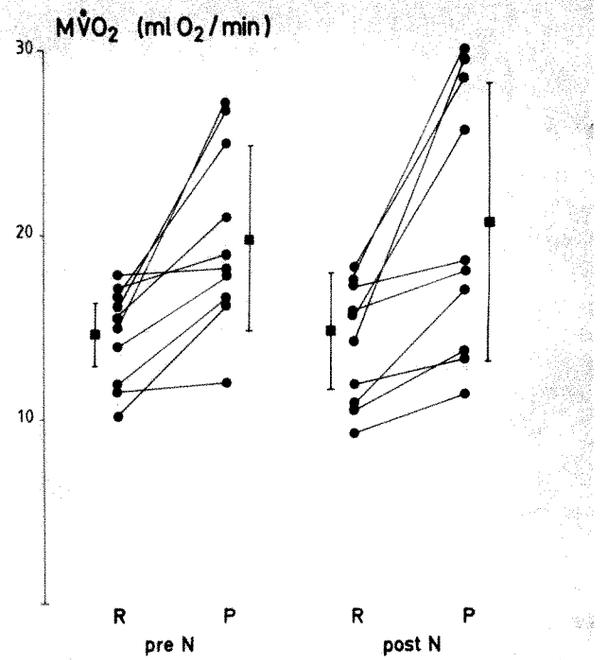

**FIGURE 6.** Myocardial oxygen consumption ($M\dot{V}O_2$) at rest (R) and during rapid atrial pacing (P) before (pre N) and about 6 minutes after the intracoronary injection of 0.1 mg of nifedipine (post N).

caused by the fixed lesion and the degree of coronary artery constriction in the normal arterial wall opposite the organic lesion. Recent data indicate that the degree of stenosis can be influenced pharmacologically.[11] This effect might contribute to the increase in poststenotic coronary blood flow after nifedipine administration.[12] Coronary flow returned to basal levels within about 5 minutes after intracoronary nifedipine administration. However, prolonged dilation of large epicardial coronary arteries after the intracoronary injection of 0.1 mg nifedipine has been documented by angiography.[13] This implies that nifedipine predominantly results in a sustained relaxation of the epicardial conductance vessels, while intramural arterioles are only transiently dilated.

**Nifedipine and myocardial oxygen consumption:** There were no significant changes in myocardial oxygen consumption after the intravenous infusion of 1 mg of nifedipine. The rate-pressure product, generally accepted as a reliable predictor of myocardial energy requirements,[14] also did not change significantly. There was a linear correlation between myocardial oxygen consumption and the double product. The potential oxygen-saving effect of nifedipine due to an afterload reduction was therefore counteracted by a reflex tachycardia.

This mechanism is potentially dangerous in patients with severely stenosed coronary arteries. A detrimental effect of high doses of nifedipine on regional myocardial perfusion has been observed in animals with subtotally occluded coronary arteries.[15] This is explained by a decrease in diastolic perfusion pressure, a shortening of the diastolic perfusion time, and an exhaustion of the poststenotic coronary vascular reserve at basal levels.

In contrast to this, the intracoronary injection of 0.1 mg nifedipine resulted in a significant reduction of myocardial oxygen consumption. Since intravenous injection of the same dose did not induce any hemodynamic changes,[7] the decrease in myocardial oxygen consumption results from a direct negative inotropic effect of nifedipine, which is unmasked by the absence of indirect peripheral effects. A higher local concentration of nifedipine might also be important. In accordance with this, selective intrabypass injections in patients with successful aortocoronary bypass grafting revealed a delay in shortening in regional wall motion in areas directly supplied by the injected bypass, while contraction in normally perfused areas remained unchanged.[16]

**Nifedipine and stress:** A significant reduction in exercise-induced S-T segment depression has been reported in patients with severe coronary artery disease after intracoronary infusion of 0.1 mg nifedipine.[7] Earlier studies on different calcium-channel blockers during pacing-induced angina also revealed antianginal activity without altered hemodynamic function.[17] These findings suggested a reduced myocardial oxygen consumption without changes in the usual indexes of myocardial oxygen demand. Myocardial oxygen consumption was not assessed directly in these studies.

Our data contradict this hypothesis. Both coronary sinus blood flow and myocardial oxygen consumption reached identical levels during atrial pacing before and

6 minutes after intracoronary injection. There was no evidence of a metabolically mediated, sustained oxygen-saving effect of nifedipine after the cessation of its immediate effects.

**Implications:** The intracoronary administration of nifedipine will be increasingly used during routine coronary angiography and reperfusion of acute myocardial infarction. It permits us to distinguish an organic lesion from a functional one and to determine to what extent a functional component contributes to the significance of a critical lesion.[13] It enables us to rule out coronary arterial spasm as the cause of acute myocardial ischemia.[4] Intracoronary nifedipine provides antiischemic action by decreasing myocardial oxygen consumption while increasing coronary flow. After systemic administration, nifedipine has comparable effects on coronary vascular resistance. However, a reduction in myocardial oxygen consumption can only be expected when an increase in heart rate does not take place.

**Acknowledgment:** We thank Bayer Pharmaceutical Company, West Germany, for supplying us with nifedipine solution. Sincere appreciation is also extended to Annemarie Bosse, Thea Dinauer, and Susanne Oschmann for technical assistance. Secretarial assistance was provided by Carmen Kneyer and Claudia Dietrich.

# Electrocardiographic Criteria for the Diagnosis of Combined Inferior Myocardial Infarction and Left Anterior Hemiblock

ROBERT A. WARNER, MD, NORMA E. HILL, RN, SAKTI MOOKHERJEE, MD, and HAROLD SMULYAN, MD

**New electrocardiographic (ECG) criteria for diagnosing the combination of inferior myocardial infarction and left anterior hemiblock are proposed. The proposed criteria are based upon the relations between portions of the vectorcardiographic QRS loop in the frontal plane and the corresponding portions of the QRS complexes recorded by the limb leads. The application of the proposed criteria requires that the tracings be obtained with 3-channel ECG machines. The proposed criteria for the diagnosis of inferior myocardial infarction and left anterior hemiblock are as follows: (1) leads aVR and aVL both end in R waves, with the peak of the terminal R wave in lead aVR occurring later than the peak of the terminal R wave in lead aVL, and (2) a Q wave of any magnitude is present in lead II. The performance of the proposed criteria was superior to that of 10 combinations of traditional ECG criteria for inferior myocardial infarction and left anterior hemiblock.**

The diagnosis of the combination of inferior myocardial infarction and left anterior hemiblock is difficult when traditional methods of electrocardiographic (ECG) analysis are used. However, several groups of investigators have shown the vectorcardiogram to be more reliable than the electrocardiogram for this purpose.[1–6] This is because each of the 2 abnormalities is associated with a characteristically different contour of the vectorcardiographic (VCG) QRS loop in the frontal plane. Whereas both inferior myocardial infarction and left anterior hemiblock produce deviations of portions of the loop superiorly, the former results specifically in clockwise rotation of the initial forces.[7–10] Since the latter causes counterclockwise rotation of the loop, the combination of the 2 abnormalities is manifested by clockwise rotation of the initial portion, followed by counterclockwise rotation of the terminal portion of the QRS loop in the frontal plane.[1–6]

In the present study, new electrocardiographic criteria for diagnosing inferior myocardial infarction and left anterior hemiblock are described. The proposed criteria are based upon the relations between the limb leads of the scalar electrocardiogram and the VCG loop in the frontal plane and permit important features of the contour of the VCG loop to be inferred from the electrocardiogram. Applying the proposed criteria requires that the tracings be obtained using 3-channel ECG machines. These machines, which have been widely used for several years, permit analysis of the temporal relations among corresponding portions of simultaneously recorded QRS complexes.

## Methods

### Selection of Patients

Two groups of patients were selected to evaluate the performance of the proposed criteria for inferior myocardial infarction and left anterior hemiblock. The patients in Group I were selected on the basis of angiographic and VCG evidence

From the Veterans Administration Medical Center and Upstate Medical Center, Syracuse, New York. Manuscript received March 30, 1982; revised manuscript received November 3, 1982, accepted November 5, 1982.

Address for reprints: Robert A. Warner, MD, Cardiology Section, Veterans Administration Medical Center, Irving Avenue and University Place, Syracuse, New York 13210.

of inferior myocardial infarction or left anterior hemiblock, or both. The patients in Group II were selected on the basis of serial ECG changes that were obtained under clinical circumstances in which the development of, respectively, inferior myocardial infarction alone, left anterior hemiblock alone, and inferior myocardial infarction and left anterior hemiblock was likely.

**Group I:** A total of 163 male patients, aged 26 to 82 years (mean 61), who had undergone both vectorcardiography and cardiac catheterization at the Syracuse Veterans Administration Medical Center between April 17, 1978 and March 1, 1982 were included in this group. Of these, 30 patients (Subgroup IA) had angiographic and VCG evidence of inferior myocardial infarction and VCG evidence of left anterior hemiblock. The 133 patients in Subgroup IB had either angiographic and VCG evidence of inferior myocardial infarction without left anterior hemiblock (29 patients), angiographic and VCG evidence of left anterior hemiblock without inferior myocardial infarction (53 patients), or angiographic and VCG evidence of the absence of both inferior myocardial infarction and left anterior hemiblock (51 patients).

The angiographic evidence of inferior myocardial infarction consisted of a ≥75% obstruction of the dominant coronary artery and either asyneresis, akinesia, or dyskinesia of the inferior wall of the left ventricle. The VCG criteria for inferior myocardial infarction that were used were those of Starr et al.[7] These VCG criteria were chosen because they were shown in a recent report to have the highest overall accuracy for diagnosing inferior myocardial infarction of 3 sets of criteria tested.[9] The VCG criteria used for diagnosing left anterior hemiblock were those of Benchimol et al.[11] Although all of the patients in Group 1 also had scalar electrocardiograms obtained, the patients were assigned to either Subgroup IA or IB only on the basis of their angiographic and VCG findings.

**Group II:** In order to confirm the high degrees of sensitivity and specificity exhibited by the proposed criteria when the data from Group I were analyzed (see later), serial electrocardiograms from an additional group of 185 patients (136 men and 49 women, aged 28 to 84 years) were studied. The patients in Group II had been patients at 1 of the following hospitals in Syracuse, New York between July 1, 1975 and March 1, 1982: the Veterans Administration Medical Center, the State University Hospital, or the Crouse-Irving Memorial Hospital.

*Subgroup IIA:* This subgroup consisted of 35 patients with acute anterior myocardial infarction manifested by a typical clinical history, elevation of cardiac enzymes, and the development of S-T segment elevation and Q waves in ECG leads $V_1$ through $V_4$, but without concomitant S-T segment elevation or Q waves in leads II, III, or aVF. During the evolution of the ECG changes of anterior infarction, each patient developed leftward deviation of the frontal plane QRS axis which was not initially present. In each patient, atrioventricular block also occurred in the course of the evolution of the infarction. The QRS complexes analyzed were those of supraventricular beats recorded after leftward deviation of the axis had occurred, but before they had become longer than 100 ms in duration. Therefore, artificially paced complexes, idioventricular complexes, and complexes showing right or left bundle branch block were excluded.

*Subgroup IIB:* This subgroup consisted of 133 patients with acute inferior myocardial infarction manifested by a typical history, elevation of cardiac enzymes, and the development of S-T segment elevation and Q waves in ECG leads II, II, and aVF, but without the concomitant appearance of S-T segment elevation or Q waves in leads $V_1$, $V_2$, $V_3$, or $V_4$. In the tracings obtained before the changes of inferior myocardial infarction, none of the patients had QRS complexes in leads aVR and aVL that both ended in R waves. The electrocardiograms analyzed were those of each patient that showed the greatest degree of leftward deviation of the frontal plane QRS axis that developed in the evolution of the changes of inferior myocardial infarction.

*Subgroup IIC:* This subgroup consisted of 17 patients who met the same criteria for selection as those of Subgroup IIB, except for the following: in the tracings obtained before the changes of inferior myocardial infarction, each of the patients of Subgroup IIC had QRS complexes in leads aVR and aVL that both ended in R waves, with the peak of the terminal R wave in lead aVL preceding the peak of the terminal R wave in lead aVR.

## Collection of Data

The vectorcardiograms were recorded using the Frank lead system and an Instruments for Cardiac Research model 1001 vectorcardiograph. The electrocardiograms were recorded using 12 standard leads and either a Marquette MAC 1-T or Hewlett-Packard model 1517-A electrocardiograph at a paper speed of 25 mm/s. These machines use 3 channels and simultaneously record leads I, II, and III; then leads aVR, aVL, and aVF; then leads $V_1$, $V_2$, and $V_3$; and finally leads $V_4$, $V_5$, and $V_6$. All recordings were made at a paper speed of 25 mm/s. In order to be certain that all 3 channels were operating simultaneously, the relative times of onset of the 1.0 mV standardization marks were inspected. If the times of onset of the standardization marks were not identical, a correction for the discrepancy was made when the QRS complexes were analyzed. For example, if the standardization mark in channel 2 began 10 ms before the marks in channels 1 and 3, the QRS complexes in leads II and aVL were considered to have actually begun 10 ms later than they appeared on the tracing.

## Rationale for the Proposed Criteria

The relations between the VCG QRS loop in the frontal plane and the scalar electrocardiogram in a typical patient with inferior myocardial infarction and left anterior hemiblock are shown in Figure 1. The figure shows that important features of the contour of the VCG loop can be inferred by analyzing the simultaneously-recorded pairs of ECG leads. On the basis of the illustrated relations, new ECG criteria for diagnosing inferior myocardial infarction and left anterior hemiblock are proposed; these are listed in Table I.

## Comparison of Electrocardiographic Criteria

In order to provide a comprehensive basis for evaluating the proposed criteria, the electrocardiograms were also interpreted according to 5 sets of traditional criteria for diagnosing inferior myocardial infarction and 2 sets of traditional criteria for diagnosing left anterior hemiblock. The comparison criteria for inferior myocardial infarction that were chosen are as follows: (1) Q waves of at least 30 ms duration in leads II, III, and aVF (2, 3, aVF criterion)[7]; (2) Q wave of at least 30 ms duration in lead aVF without regard to leads II and III (aVF criterion)[7]; (3) the criteria of Myers et al[12]; (4) the criteria of Walsh et al[13]; and (5) the criteria of the New York Heart Association.[14]

The comparison criteria for diagnosing left anterior hemiblock were as follows: (1) frontal plane QRS axis between −30° and −90° < −30° criterion; and (2) frontal plane QRS axis between −45° and −90° < −45° criterion.

Because the electrocardiograms were interpreted according to each of 5 sets of comparison criteria for inferior myocardial infarction in addition to each of 2 comparison criteria for left anterior hemiblock, a total of 10 combinations of comparison criteria were used.

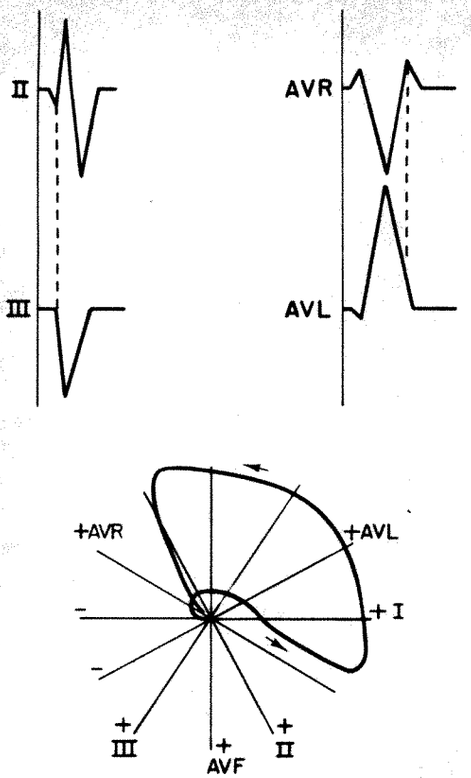

**FIGURE 1.** Diagram of a VCG QRS loop in the frontal plane of a tracing that reveals the combination of inferior infarction and left anterior hemiblock, with the hexaxial reference figure superimposed upon it. The **arrows** show that the initial portion of the loop is clockwise and the terminal portion is counterclockwise. The initial portion of the loop is maximally represented on the negative half of the axis of lead II before it is maximally represented on the negative half of the axis of lead III. Therefore, the nadir of the Q wave in lead II occurs before the nadir of the Q wave lead III. If the initial clockwise portion of the VCG loop were to travel inferiorly and to the right for a short time before going superior to the E point (thus still meeting the VCG criteria for inferior infarction of Starr et al), lead III would begin with a small R wave rather than with a Q wave. In the latter case, the peak of the initial R wave in lead III would precede the nadir of the Q wave in lead II. The terminal portion of the loop is maximally represented on the positive half of the axis of lead aVL before it is maximally represented on the positive half of the axis of lead aVR. Therefore, the peak of the R wave in lead aVL occurs before the peak of the R wave in lead aVR.

## Analysis of Data

The relative odds, that is, the odds of being a case among patients who have positive results relative to the odds among those who have negative results, were chosen to measure the diagnostic capabilities of the proposed and comparison ECG criteria. The measurement of relative odds incorporates both the sensitivity and specificity of a test and is not affected by the prevalence of cases in the population being evaluated. It is defined by the following formula: Relative odds = [(sensitivity) (specificity)]/[(1 − sensitivity) (1 − specificity)]. When the sensitivity and/or specificity = 1, the denominator of the expression is assigned a value of 1.

In addition, for patients with discordant predictions by the proposed versus traditional criteria, the hypothesis of no difference in performance was evaluated by the sign test corrected for continuity.[15] In order to control the type I error for multiple tests, two-tailed p values <0.01 were taken to indicate statistical significance at the joint 5% level.

**TABLE I Proposed Electrocardiographic Criteria for the Diagnosis of the Combination of Inferior Myocardial Infarction and Left Anterior Hemiblock**

1. Leads aVR and aVL both end in R waves, with the peak of the terminal R wave in lead aVR occurring later than the peak of the terminal R wave in lead aVL

AND

2. A Q wave of any magnitude is present in lead II

## Results

The performances of the proposed and all the combinations of comparison criteria in Groups I and II are summarized in Table II. As Table II shows, the proposed criteria were positive in all patients in Subgroups IA and IIC and were negative in all patients in Subgroups IB, IIA, and IIB. The comparison criteria that exhibited the best diagnostic performances (as indicated by having the highest values of relative odds) were the inferior myocardial infarction criteria of Walsh et al combined with the left anterior hemiblock criteria of $< -30°$ and $< -45°$, respectively. Therefore, it was these 2 combinations of criteria that were chosen for a more detailed comparison with the proposed criteria using the sign test corrected for continuity. The superiority of the proposed criteria over the Walsh et al $< -30°$ and the Walsh et al $< -45°$ criteria is significant at the $p < 0.005$ level in each case.

In all of the patients with left anterior hemiblock with or without inferior myocardial infarction, leads aVR and aVL ended in R waves and the peak of the R wave in lead aVL preceded the peak of the R wave in lead aVR. In all the patients with left anterior hemiblock alone, the QRS complexes in both leads II and III began with R waves. Only when inferior myocardial infarction was also present did any patient with left anterior hemiblock have a Q wave in lead II. Of the total of 162 patients with inferior myocardial infarction alone, 161 (99%) had Q waves in both leads II and III and, in each instance, the nadir of the Q wave in lead II preceded the nadir of the Q wave in lead III. Of the total of 47 patients with inferior myocardial infarction and left anterior hemiblock, 33 (70%) also had Q waves in both leads II and III with the nadir of the Q wave in lead II preceding the nadir of the Q wave in lead III. Of the remaining patient with inferior myocardial infarction alone and the remaining 14 patients with inferior myocardial infarction and left anterior hemiblock, the Q waves in lead II were associated with small initial R waves in lead III, with the peak of the latter preceding the nadir of the former. Thus, using the method of analysis shown in Figure 1, we could infer from the electrocardiogram that in all patients with inferior myocardial infarction either alone or in combination with left anterior hemiblock, the initial forces of ventricular depolarization were clockwise and predominantly superior. Similarly, we could infer that in all patients with left anterior hemiblock alone or in

combination with inferior myocardial infarction, the terminal forces of ventricular depolarization were counterclockwise and superior.

## Discussion

One reason that it is difficult to diagnose inferior myocardial infarction and left anterior hemiblock using traditional methods of ECG analysis is that both abnormalities can result in deviation of the frontal plane QRS axis to the left. Another reason is that the presence of left anterior hemiblock commonly modifies the ECG manifestations of inferior myocardial infarction.[1,5,6] This is because left anterior hemiblock tends to direct the initial forces of ventricular depolarization inferiorly by way of the intact posterior fascicle.[5,6,16] Therefore, unless the inferior myocardial infarction happens to involve that portion of the left ventricular myocardium which is activated early by the posterior fascicle, the hemiblock reduces the propensity of the infarction to produce Q waves in the inferior leads. Our data support the contention that left anterior hemiblock tends to obscure some of the traditional manifestations of inferior myocardial infarction. Whereas 30% of our patients with inferior myocardial infarction and left anterior hemiblock did not have a Q wave in lead III, only 1% with inferior myocardial infarction alone failed to have a Q wave in that lead.

Several groups of investigators have described the importance of the respective contours of the initial and terminal portions of the VCG QRS loop in the frontal plane for diagnosing inferior myocardial infarction and left anterior hemiblock.[1–6] The data from the patients in Group I indicate that our method of analyzing the electrocardiogram permits us to infer the VCG findings that are important for making this diagnosis. The data from Group II confirm the high degrees of sensitivity and specificity of our criteria. Serial electrocardiograms obtained during the evolution of isolated acute anterior myocardial infarction that show the development of left axis deviation and subsequently of atrioventricular block (Subgroup IIA) make it likely that the left axis deviation is due to left anterior hemiblock. Conversely, patients with isolated inferior myocardial infarction (Subgroup IIB) would not be expected to have left anterior hemiblock during the evolution of acute infarction. All the patients in Subgroup IIA and none of the patients in Subgroup IIB developed terminal R waves in both leads aVR and aVL with the peak of the R wave in aVL preceding the peak of the R wave in lead aVR. We therefore used this set of findings in leads aVR and aVL as a marker of left anterior hemiblock. In a recent study of left anterior hemiblock unassociated with inferior myocardial infarction, our group used data from the same patients who comprise Subgroups IIA and IIB of the present study in addition to other data to show that the above marker of left anterior hemiblock was not also produced by other conditions reported to lead to false-positive diagnoses of left anterior hemiblock, namely isolated inferior myocardial infarction, left ventricular enlargement, alteration of the position of the heart within the thorax, or pulmonary emphysema.[17]

Hurd et al,[9] in a comparison of VCG and traditional ECG criteria for inferior myocardial infarction, demonstrated the diagnostic importance of the "contour information" provided by the vectorcardiogram.[9] The findings of the present study show that this "contour information" can also be obtained from the electrocardiogram. Our group has used similar principles of analysis to develop new ECG criteria for diagnosing inferior myocardial infarction in the absence of left anterior hemiblock.[18]

We evaluated the performance of the proposed criteria for inferior myocardial infarction and left anterior hemiblock using electrocardiograms that were recorded at standard paper speed and without comparing the electrocardiograms with tracings obtained previously from the same patients. The proposed ECG criteria duplicate the performance of the vectorcardiogram for detecting inferior myocardial infarction and left anterior hemiblock and therefore permit this diagnosis to be made reliably even when the vectorcardiogram is not readily available.

# THE LEADER
# in Balloon Flow-Directed Pacing

ELECATH®

## The widest selection and most widely used Balloon Flow-Directed Catheters for all your *temporary pacing* needs.

## ELECATH® BALECTRODE®

- The *only* major manufacturer of Balloon Flow-Directed pacing kits to offer non-corroding *platinum* electrodes to assure optimal physiological response, and to prevent the migration effect seen in stainless steel electrodes.
- Balloon Flow-Directed assures easy, accurate placement for rapid and complete capture.
- Two French sizes are available: 3 French (KBE 1) and 5 French (KBE 2) for various patient physiological requirements.
- Complete, convenient, sterile kit, consisting of an introducer, shielded EKG adapter, and vented syringe for exact, accurate balloon inflation.

**You can rely on your ELECATH representative to provide specialized service and recommendations on the complete ELECATH Family of pacing products.**

**SLOW-K®**
potassium chloride **slow-release tablets**

*Brief Summary of Prescribing Information*

**DESCRIPTION**
Slow-K is a sugar-coated (not enteric-coated) tablet containing 600 mg potassium chloride (equivalent to 8 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

**INDICATIONS**
**BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.**
1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy; and certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

**CONTRAINDICATIONS**
Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).
Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to an enlarged left atrium.
All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

**WARNINGS**
**Hyperkalemia:** In patients with impaired mechanisms for excreting potassium the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic.
The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.
**Interaction with Potassium-Sparing Diuretics:** Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.
**Gastrointestinal lesions:** Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Slow-K is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains approximately one per 100,000 patient-years. Slow-K should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.
**Metabolic acidosis:** Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

**PRECAUTIONS**
The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

**ADVERSE REACTIONS**
The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.
One of the most severe adverse effects is hyperkalemia (see Contraindications, Warnings and Overdosage). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

**DOSAGE AND ADMINISTRATION**
The usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires the loss of 200 or more mEq of potassium from the total body store. Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for the prevention of hypokalemia to 40-100 mEq per day or more for the treatment of potassium depletion.
**Note:** Slow-K slow-release tablets must be swallowed whole and never crushed or chewed.

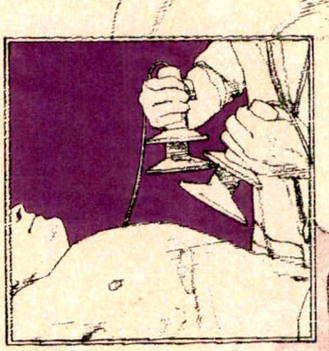
In the CCU, after conversion of VF...

# Bretylol® (bretylium tosylate)

## Follow-up therapy helps maintain stabilization

During the two or three days **after** conversion of ventricular fibrillation, the patient may still be electrically unstable. During this critical high risk period, **another** episode of VF may occur, completely unheralded.

### Good reasons to keep the VF patient on Bretylol follow-up therapy!



1. Bretylol raises the VF threshold almost three times control, protecting the heart from fibrillation.[1]*
   **No other agent has this dramatic effect.**
2. Bretylol also suppresses reentry, a major cause of VF by helping to equalize the electrophysiological differences between injured and normal ventricular tissue.[2]*
   **No other agent can do this.**

### And, Bretylol offers added benefit in treating the acute episode, too.

Bretylol, a first-line agent in the acute control of VF, should be used in the very first stages of VF, as soon as cardiopulmonary resuscitation and countershock have been attempted. Bretylol not only raises the fibrillation threshold...it reduces the energy required for defibrillation.[3,4]* Another critical difference in the Bretylol mechanism of action.

That's why it makes sense to use Bretylol to maintain stabilization in the CCU, as well as in the first few minutes of acute VF episodes.

There are no contraindications to the use of Bretylol in VF. Hypotension and postural hypotension have been the most frequently reported adverse reactions. Consult brief summary of prescribing information on the following page.

For further information, please contact the Medical Services Department, American Critical Care, a division of American Hospital Supply Corporation, 1600 Waukegan Road, McGaw Park, IL 60085, Phone 312/473-3000.

**Bretylol...adds a different and unique dimension in control of ventricular fibrillation**

**American Critical Care**

# Bretylol®
## (bretylium tosylate)

**Brief summary of prescribing information**

**INDICATIONS**—BRETYLOL is indicated in the prophylaxis and therapy of ventricular fibrillation.

BRETYLOL is also indicated in the treatment of life-threatening ventricular arrhythmias, such as ventricular tachycardia, that have failed to respond to adequate doses of a first-line antiarrhythmic agent, such as lidocaine.

Use of BRETYLOL should be limited to intensive care units, coronary care units or other facilities where equipment and personnel for constant monitoring of cardiac arrythmias and blood pressure are available.

Following injection of BRETYLOL there may be a delay of 20 minutes to 2 hours in the onset of antiarrhythmic action, although it appears to act within minutes in ventricular fibrillation. The delay in effect appears to be longer after intramuscular than after intravenous injection.

**CONTRAINDICATIONS**—There are no contraindications to use in treatment of ventricular fibrillation or life-threatening refractory ventricular arrhythmias.

**WARNINGS—1. Hypotension:** Administration of BRETYLOL regularly results in postural hypotension, subjectively recognized by dizziness, lightheadedness, vertigo or faintness. Some degree of hypotension is present in about 50% of patients while they are supine. Hypotension may occur at doses lower than those needed to suppress arrhythmias.

> Patients should be kept in the supine position until tolerance to the hypotensive effect of BRETYLOL develops. Tolerance occurs unpredictably but may be present after several days.

Hypotension with supine systolic pressure greater than 75 mm Hg need not be treated unless there are associated symptoms. If supine systolic pressure falls below 75 mm Hg, an infusion of dopamine or norepinephrine may be used to raise blood pressure. When catecholamines are administered, a dilute solution should be employed and blood pressure monitored closely because the pressor effects of the catecholamines are enhanced by BRETYLOL. Volume expansion with blood or plasma and correction of dehydration should be carried out where appropriate.

**2. Transient Hypertension and Increased Frequency of Arrhythmias:** Due to the initial release of norepinephrine from adrenergic postganglionic nerve terminals by BRETYLOL, transient hypertension or increased frequency of premature ventricular contractions and other arrhythmias may occur in some patients.

**3. Caution During Use with Digitalis Glycosides:** The initial release of norepinephrine caused by BRETYLOL may aggravate digitalis toxicity. When a life-threatening cardiac arrhythmia occurs in a digitalized patient, BRETYLOL should be used only if the etiology of the arrhythmia does not appear to be digitalis toxicity and other antiarrhythmic drugs are not effective. Simultaneous initiation of therapy with digitalis glycosides and BRETYLOL (bretylium tosylate) should be avoided.

**4. Patients with Fixed Cardiac Output:** In patients with fixed cardiac output (i.e., severe aortic stenosis or severe pulmonary hypertension) BRETYLOL should be avoided since severe hypotension may result from a fall in peripheral resistance without a compensatory increase in cardiac output. If survival is threatened by the arrhythmia, BRETYLOL may be used but vasoconstrictive catecholamines should be given promptly if severe hypotension occurs.

**USE IN PREGNANCY**—The safety of BRETYLOL in human pregnancy has not been established. However, as the drug is intended for use only in life-threatening situations, it may be used in pregnant women when its benefits outweigh the potential risk to the fetus.

**USE IN CHILDREN**—The safety and efficacy of this drug in children has not been established. BRETYLOL has been administered to a limited number of pediatric patients, but such use has been inadequate to define fully proper dosage and limitations for use.

**PRECAUTIONS—1. Dilution for Intravenous Use:** BRETYLOL should be diluted (one part BRETYLOL with four parts of Dextrose Injection, USP or Sodium Chloride Injection, USP) prior to intravenous use. Rapid intravenous administration may cause severe nausea and vomiting. Therefore, the diluted solution should be infused over a period greater than 8 minutes. In treating existing ventricular fibrillation BRETYLOL should be given as rapidly as possible and may be given without dilution.

**2. Use of Various Sites for Intramuscular Injection:** When injected intramuscularly, not more than 5 ml should be given in a site, and injection sites should be varied since repeated intramuscular injection into the same site may cause atrophy and necrosis of muscle tissue, fibrosis, vascular degeneration and inflammatory changes.

**3. Reduce Dosage in Impaired Renal Function:** Since BRETYLOL is excreted principally via the kidney, the dosage interval should be increased in patients with impaired renal function.

**ADVERSE REACTIONS**—Hypotension and postural hypotension have been the most frequently reported adverse reactions (see Warnings section). Nausea and vomiting occurred in about three percent of patients, primarily when BRETYLOL was administered rapidly by the intravenous route (see Precautions section). Vertigo, dizziness, light-headedness and syncope, which sometimes accompanied postural hypotension, were reported in about 7 patients in 1000.

Bradycardia, increased frequency of premature ventricular contractions, transitory hypertension, initial increase in arrhythmias (see Warnings section), precipitation of anginal attacks, and sensation of substernal pressure have also been reported in a small number of patients, i.e., approximately 1-2 patients in 1000.

Renal dysfunction, diarrhea, abdominal pain, hiccups, erythematous macular rash, flushing, hyperthermia, confusion, paranoid psychosis, emotional lability, lethargy, generalized tenderness, anxiety, shortness of breath, diaphoresis, nasal stuffiness and mild conjunctivitis, have been reported in about 1 patient in 1000. The relationship of BRETYLOL administration to these reactions has not been clearly established.

**HOW SUPPLIED**—NDC 0094-0012-10: 10 ml ampul containing 500 mg bretylium tosylate in Water for Injection, USP pH adjusted, when necessary, with dilute hydrochloric acid or sodium hydroxide. Sterile, non-pyrogenic.

**The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.**

# Cardiac Bioprostheses

**Proceedings of the Second International Symposium**
**Rome, Italy, May 17-19, 1982**

**edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD**
**ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00**

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

## Who are the editors?

**Lawrence H. Cohn, MD,** is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982*.

**Vincenzo Gallucci, MD,** is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

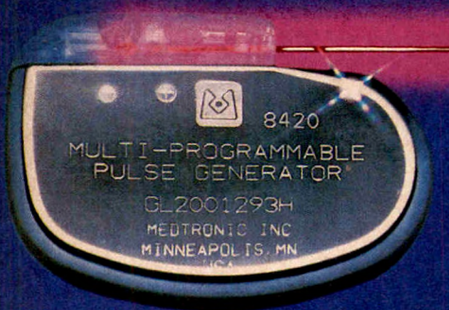
# SPECTR

## THE WORLD'S MOST PRESCRIBED PACEMAKER

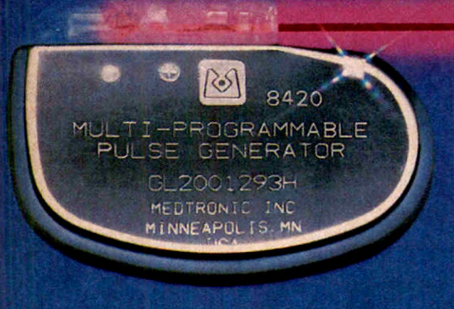
### THRESHOLD MARGIN TEST.



**Insure adequate threshold safety margins—even over the telephone**

A 66 year old female patient on vacation calls your office long distance for a routine pacer check. Are the pacing pulses sufficient to stimulate her heart? Here's how the unique Spectrax SXT™ **threshold margin test** helps you. Your patient simply positions the magnet she carries over her pacemaker and the Spectrax SXT automatically performs the test. Energy in the 3rd of 3 pulses emitted at 100 **ppm** is reduced 25% with no loss of capture, indicating an adequate safety margin. Long distance diagnosis is complete and your patient enjoys peace of mind.

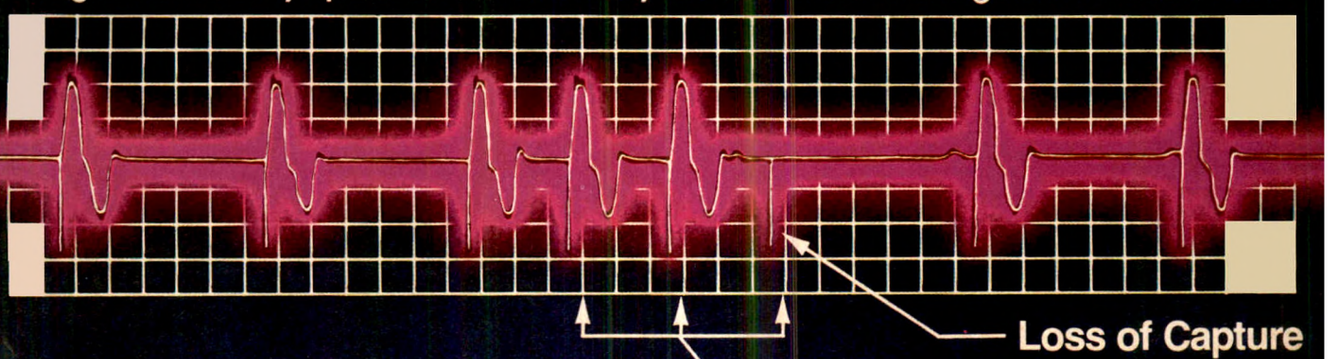
### AUTOMATIC THRESHOLD MEASUREMENT.



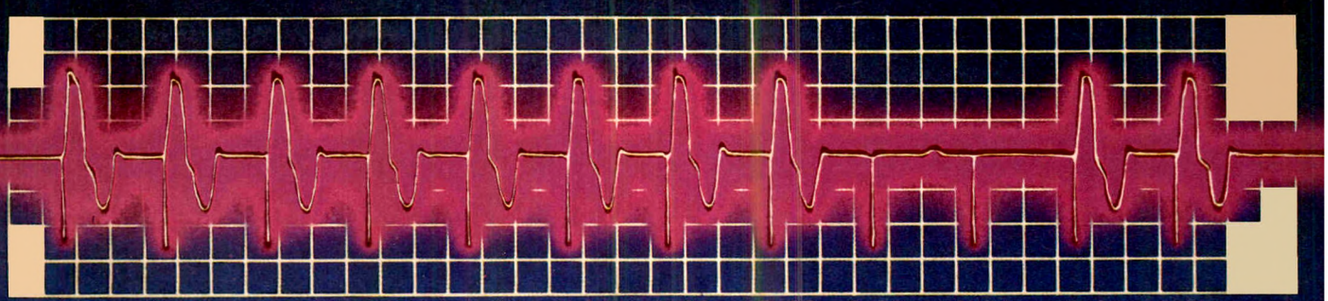
**Determine pacing energy levels—fast.**

You suspect loss of capture in a 62 year old male referral patient. What energy levels are needed for effective pacing stimulation of his heart? The exclusive **threshold measurement** built into his Spectrax SXT™ pacemaker gives you the answers fast. With the advanced Medtronic® CENSYS™ programmer, **automatic threshold measurement** is a simple pushbutton procedure. Reducing pulse width to the point of capture/loss tells you within 0.1 **ms** your patient's threshold. Restore original pulse width with no reprogramming needed and adjust to guarantee capture. Simple, convenient and electronically precise. That's Spectrax SXT's **automatic threshold measurement** feature.

### PULSE GENERATOR BATTERY DEPLETION WARNING.



**(EOL). 3 distinct warnings signal elective replacement.**



Your 70 year old female patient has rushed to your office in alarm. During her routine pulse self-check test, she determined that her pacemaker had dropped 10% in rate. The implanted unit is a Spectrax SXT though, and you are able to reassure her. This rate change is simply a safeguard warning signalling elective replacement. Pulse width on the Spectrax SXT automatically increases to compensate for the gradual decline in battery voltage. She is in no danger of pacemaker battery failure or loss of capture. This fact is easily and visibly confirmed with Spectrax SXT's noteworthy telemetry which prints out battery status on command. In this case the print out has changed from **"Battery OK"** to **Elec. Replace Time!** Seeing is believing. You and your patient have several months in which to make her surgery decision. You can confidently relieve her anxiety.

## DISCOVER THE REMARKABLE CLINICAL BENEFITS OF SPECTRAX SXT FOR YOURSELF

(Turn this page over for more information)

**Medtronic**

## Medtronic Implantable Pulse Generators and Leads

### Intended Uses

Ventricular pacing using an implantable ventricular pulse generator is for long-term therapeutic control of heart rate in patients with impulse formation or conduction disorders leading to bradyarrhythmias, tachyarrhythmias and heart block (see product labeling for detailed list of intended uses). An atrial pulse generator is for long-term therapeutic control of heart rate in patients with impulse formation disorders but with intact, functioning A-V conduction systems. Cardiac pacing using an implantable A-V sequential pulse generator is for long-term therapeutic control of heart rate in patients where restoration of A-V synchrony is indicated to improve cardiac output or to protect against arrhythmias related to sequence of cardiac impulse propagation.

### Contraindications

There are no known contraindications to the use of pacing as a therapeutic modality for the control of heart rate in patients with normal conduction systems. In certain patients with anomalies of the conduction system (WPW syndrome and related conditions), patients may be benefited or harmed by cardiac pacing. Therefore, electrophysiologic studies are required prior to therapeutic application of pacing. In addition, the patient's age and medical condition may dictate the particular pacing system and implantation procedure used by the physician.

### Warnings

Diathermy should not be used on patients with pacemakers because of possible heat damage to electronic components. Electrosurgical units should never be used in the vicinity of unipolar pulse generators or bipolar pulse generators implanted in the unipolar mode because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead. Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. See the specific precautions and warnings in the technical manuals included with the pulse generator.

### Precautions

The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also, that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

### Side Effects

Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

# How thorough and unbiased is your drug reference?

If it's not MODERN DRUG ENCYCLOPEDIA, you can't be sure.

## MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 16th Edition

**Arthur J. Lewis,** MD, Executive Editor
**Gertrude Dittus Gonzales,** R.Ph., B.S. Pharm., Executive Editor
**Charles L. Winek,** Ph.D., Contributing Editor

The all new 16th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

**Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:**

- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a-z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension.
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

**The 1,000 page main section** arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

**Three a-z indexes provide** instant access to all the material found in the main section as follows:

- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to read information on prescription drugs.

**Yorke Medical Books**
Box C-757, Brooklyn, New York 11205 AJCC3

Please send me a copy of the all-new 16th Edition of MODERN DRUG ENCYCLOPEDIA. If this new edition is the best drug information reference for practitioners available, I will remit $49.00 plus shipping. Otherwise, I will return it within 30 days and owe nothing.
☐ I am enclosing $49.00 now as full payment.

# The angina onslaught

# The angina shield:
# CORGARD®
# (nadolol tablets)

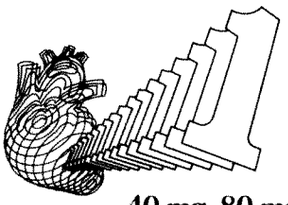
SQUIBB®

# Reliable 24-hour-a-day protection...

Physical exertion, emotional strain, and the unexpected crises of daily life — these can unleash an anginal attack at any time. So it's important to be certain that your patients are protected continuously. Unlike other beta-blockers, Corgard provides this protection around the clock with a once-daily dose — reducing the anginal attack rate, increasing work capacity, and decreasing the dependence on nitroglycerin.

# with convenient once-a-day dosage

A single daily dose of Corgard controls angina all day, every day. And since Corgard is associated with a low incidence of side effects,* your patients can lead more comfortable lives. An added convenience of Corgard is that it can be taken at any time of day, regardless of meals, because its absorption is not affected by food.



*For a full discussion of CONTRAINDICATIONS, PRECAUTIONS, ADVERSE REACTIONS, and WARNINGS, including avoidance of abrupt withdrawal, please see brief summary on next page.

# CORGARD® (nadolol tablets)

## The only once-a-day beta-blocker for both angina pectoris and hypertension

*Please see next page for brief summary.*

# The only once-a-day beta-blocker for both angina pectoris and hypertension

# CORGARD® (nadolol tablets)

**40 mg, 80 mg, 120 mg, and 160 mg scored tablets available in a variety of bottle sizes and in Convenience Packages of 40 mg and 80 mg tablets**

**CORGARD® TABLETS**
**Nadolol Tablets**

**DESCRIPTION:** Corgard (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

**CONTRAINDICATIONS:** Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

**WARNINGS: Cardiac Failure** — Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

**Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal** — Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

**Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)** — PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

**Major Surgery** — Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

**Diabetes and Hypoglycemia** — Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

**Thyrotoxicosis** — Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

**PRECAUTIONS: Impaired Hepatic or Renal Function** — Use nadolol with caution in presence of either of these conditions (see DOSAGE AND ADMINISTRATION section of package insert).

**Information for Patients** — Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign or symptom of impending failure.

**Drug Interactions** — Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. When treating patients with nadolol plus a catecholamine-depleting agent, carefully observe for evidence of hypotension and/or excessive bradycardia which may produce vertigo, syncope, or postural hypotension.

**Carcinogenesis, Mutagenesis, Impairment of Fertility** — In 1 to 2 years' oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

**Pregnancy** — In animal reproduction studies with nadolol, evidence of embryo- and fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times greater (on a mg/kg basis) than maximum indicated human dose; no teratogenic potential was seen in any of these species. There are no well-controlled studies in pregnant women; therefore, use nadolol in pregnant women only if potential benefit justifies potential risk to the fetus.

**Nursing Mothers** — It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when nadolol is administered to a nursing woman. Animal studies showed that nadolol is found in the milk of lactating rats.

**Pediatric Use** — Safety and effectiveness in children have not been established.

**ADVERSE REACTIONS:** Most adverse effects have been mild and transient and have rarely required nadolol withdrawal.

**Cardiovascular** — Bradycardia with heart rates of less than 60 beats per minute occurs commonly, and heart rates below 40 beats per minute and/or symptomatic bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral vascular insufficiency, usually of the Raynaud type, have occurred in approximately 2 of 100 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have each occurred in about 1 of 100 patients. Single instances of first degree and third degree heart block have been reported; intensification of AV block is a known effect of beta-blockers (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS). **Central Nervous System** — Dizziness or fatigue reported in approximately 2 of 100 patients; paresthesias, sedation, and change in behavior reported in approximately 6 of 1000 patients. **Respiratory** — Bronchospasm reported in approximately 1 of 1000 patients (see CONTRAINDICATIONS and WARNINGS). **Gastrointestinal** — Nausea, diarrhea, abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating, and flatulence each reported in 1 to 5 of 1000 patients. **Miscellaneous** — Each of the following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, eyes, or skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; cough; nasal stuffiness; sweating; tinnitus; blurred vision. Although relationship to drug usage is not clear, sleep disturbances have been reported. The oculomucocutaneous syndrome associated with practolol has not been reported with nadolol.

**Potential Adverse Effects:** Although other adverse effects reported with other beta-adrenergic blocking agents have not been reported with nadolol, they should be considered potential adverse effects of nadolol. **Central Nervous System** — reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place; short-term memory loss, emotional lability with slightly clouded sensorium; decreased performance on neuropsychometrics. **Gastrointestinal** — mesenteric arterial thrombosis; ischemic colitis. **Hematologic** — agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura. **Allergic** — fever combined with aching and sore throat; laryngospasm; respiratory distress. **Miscellaneous** — reversible alopecia; Peyronie's disease; erythematous rash.

**OVERDOSAGE:** Nadolol can be removed from the general circulation by hemodialysis. In addition to gastric lavage, employ the following measures as appropriate. In determining duration of corrective therapy, take note of long duration of effect of nadolol.

**Excessive Bradycardia** — Administer atropine (0.25 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.

**Cardiac Failure** — Administer a digitalis glycoside and diuretic. It has been reported that glucagon may also be useful in this situation.

**Hypotension** — Administer vasopressors, e.g., epinephrine or levarterenol. (There is evidence that epinephrine may be the drug of choice.)

**Bronchospasm** — Administer a $beta_2$-stimulating agent and/or a theophylline derivative.

**DOSAGE:** For all patients, DOSAGE MUST BE INDIVIDUALIZED.

For **angina pectoris,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments at 3 to 7 day intervals until optimum clinical response or pronounced slowing of the heart rate; usual maintenance dose is 80 to 240 mg q.d. (most patients respond to 160 mg or less daily). If treatment is to be discontinued, reduce dosage gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments until optimum blood pressure reduction is achieved; usual maintenance dose is 80 to 320 mg q.d. (rarely, doses up to 640 mg may be needed).

Patients with renal failure require adjustment in dosing interval; see package insert for dosage in these patients.

For full prescribing information, consult package insert.

**HOW SUPPLIED:** In scored tablets containing 40, 80, 120, or 160 mg nadolol per tablet in bottles of 100 and 1000 tablets and in Unimatic® unit-dose packs of 100 tablets. The 40 mg and 80 mg tablets are also available in convenience packages containing 4 blister cards of 7 tablets each.

# Improved Electrocardiographic Criteria for the Diagnosis of Left Anterior Hemiblock

ROBERT A. WARNER, MD, NORMA E. HILL, RN, SAKTI MOOKHERJEE, MD and HAROLD SMULYAN, MD

**New electrocardiographic (ECG) criteria for the diagnosis of left anterior hemiblock are proposed. The proposed criteria are based upon the relation between portions of the vectorcardiographic (VCG) QRS loop in the frontal plane and the corresponding portions of the ECG QRS complexes recorded by the limb leads. The application of the proposed criteria requires that the tracings be obtained with 3-channel ECG machines so that the temporal relation between the QRS complexes in simultaneously recorded limb leads can be inspected. This type of analysis of the electrocardiogram permits prediction of features of the VCG QRS loop that are important for the diagnosis of left anterior hemiblock. The proposed ECG criteria for the diagnosis of left anterior hemiblock are (1) the QRS complexes in leads aVR and aVL each end in an R wave (terminal R wave), and (2) the peak of the terminal R wave in lead aVR occurs later than the peak of the terminal R wave in lead aVL. The sensitivity and specificity of the proposed criteria were empirically evaluated using series of electrocardiograms obtained under clinical circumstances during which the occurrence of left anterior hemiblock was, respectively, likely and unlikely. The performance of the proposed criteria was statistically superior to that of 2 sets of frontal plane QRS axis criteria.**

The electrocardiographic (ECG) diagnosis of left anterior hemiblock has depended largely upon the identification of marked left axis deviation in the frontal plane. Because various investigators disagree as to the magnitude of the axis deviation required for the diagnosis and because other conditions can also result in left axis deviation, the ECG diagnosis of left anterior hemiblock is often uncertain.[1–18] The vectorcardiogram (VCG) has been found useful in the diagnosis of left anterior hemiblock because the frontal plane QRS loop exhibits a characteristic pattern of counterclockwise rotation with superior deviation of the mid and terminal forces.[2,5,7,8,10,11,13,14,16,17,19–23]

In the present study, we describe a new method for diagnosing left anterior hemiblock using the scalar electrocardiogram. Because this method is based upon the relations between the limb leads of the electrocardiogram and the VCG loop in the frontal plane, it more closely approximates the accuracy of the vectorcardiogram in diagnosing left anterior hemiblock than does examination of the frontal plane QRS axis alone. An important feature of the present method is the examination of the temporal relations between corresponding portions of the QRS complexes in a pair of simultaneously recorded limb leads. Therefore, the application of the method requires that the tracings be obtained using 3-channel ECG machines. These machines, which simultaneously record leads I, II, and III and then leads aVR, aVL, and aVF, have been in widespread clinical use for several years.

## Methods

**Selection of patients:** The principal group of patients selected for study consisted of patients who had serial ECG findings elicited during clinical circumstances that permitted us to assess empirically the sensitivity and specificity of our ECG criteria for left anterior hemiblock.

A total of 168 patients (122 men and 46 women) aged 28 to 84 years (mean 55) comprised the study group. They had been patients at 1 of the following hospitals in Syracuse, New York between July 1, 1975 and January 1, 1982: the Veterans Administration Medical Center, the State University Hospital, or the Crouse-Irving Memorial Hospital.

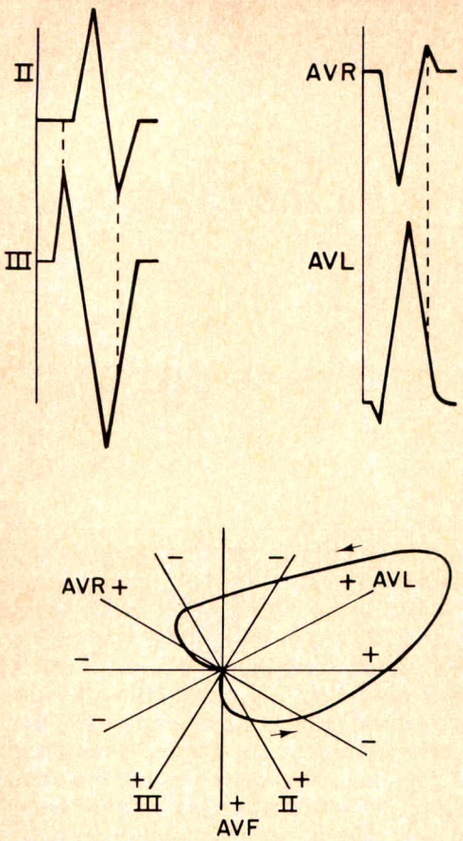

**FIGURE 1.** Diagram of a VCG QRS loop in the frontal plane of a tracing that shows left anterior hemiblock. The hexaxial reference figure is superimposed upon the loop. The **arrows** show that the loop is inscribed in a counterclockwise direction. Above the loop are diagrams of the QRS complexes recorded by 2 pairs of scalar leads—II and III and aVR and aVL—that correspond to the loop. The complexes in each of the 2 pairs were recorded simultaneously by a 3-channel ECG machine. The initial portion of the loop is maximally represented on the positive half of the axis of lead III before it is maximally represented on the positive half of the axis of lead II. Therefore, the peak of the R wave in lead III occurs before the peak of the R wave in lead II. The terminal portion of the loop is maximally represented on the negative half of the axis of lead III before it is maximally represented on the negative half of the axis of lead II and maximally represented on the positive half of the axis of lead aVL before it is maximally represented on the positive half of the axis of lead aVR. Therefore, the nadir of the S wave in lead III occurs before the nadir of the S wave in lead II and the peak of the R wave in lead aVL occurs before the peak of the R wave in lead aVR.

*Group A:* This group consisted of 35 patients with isolated acute anterior myocardial infarction consisting of a typical history, elevation of cardiac enzymes, and the development of S-T segment elevation and Q waves in ECG leads $V_1$ through $V_4$, but without the concomitant appearance of S-T segment elevation or Q waves in ECG leads II, III, or aVF. During the evolution of the ECG changes of anterior infarction, each patient had leftward deviation of the frontal plane QRS axis that was not present initially. In each patient, third-degree or Mobitz type II second-degree atrioventricular block subsequently occurred in the course of the evolution of the infarction. The QRS complexes that were analyzed in this group were those of supraventricular beats that were recorded after leftward deviation of the axis in the frontal plane had occurred, but before they had become >100 ms in duration. Therefore, artifically paced complexes, idioventricular complexes, and complexes showing right or left bundle branch block were excluded. In 8 (23%) of the patients in Group A, the preinfarction electrocardiograms showed left ventricular enlargement by the criteria of Romhilt and Estes.[24] In each of the patients in Group A, left ventricular enlargement was present on ECG findings obtained before as well as after infarction had occurred.

**TABLE I Proposed ECG Criteria for the Diagnosis of Left Anterior Hemiblock**

1. The QRS complexes in leads aVR and aVL each end in an R wave (terminal R wave)

AND

2. The peak of the terminal R wave in lead aVR occurs later than the peak of the terminal R wave in lead aVL

*Group B:* This group consisted of 133 patients with isolated acute inferior myocardial infarction manifested by a typical history, elevation of cardiac enzymes, and the development of S-T segment elevation and Q waves in ECG leads II, III, and aVF, but without the concomitant appearance of S-T segment elevation or Q waves in leads $V_1$, $V_2$, $V_3$, or $V_4$. The ECG findings that were analyzed were those of each patient's series that showed the greatest degree of leftward deviation of the frontal plane QRS axis that developed in the evolution of the changes of inferior infarction. In 14 (11%) of the ECG results that were analyzed in Group B, the Romhilt and Estes criteria for left ventricular enlargement were met.

Because the leftward deviation of the frontal plane QRS axis that occurred in Group A is likely to have been due to the development of left anterior hemiblock, the ECG findings analyzed in this group are designated as cases of left anterior hemiblock. Conversely, because left anterior hemiblock is unlikely to have developed in the patients in Group B, the ECG results analyzed in this group are designated as noncases of left anterior hemiblock. Therefore, the ECG findings of Group A were used to assess the sensitivity, and those of Group B the specificity, of the criteria for left anterior hemiblock.

*Confirmatory series:* In order to further evaluate the specificity exhibited by the proposed criteria, an additional series of patients was studied. These patients were selected to show whether a noncardiac condition that might produce superior deviation of the QRS axis in the frontal plane would result in false-positive diagnoses of left anterior hemiblock by the proposed criteria. The confirmatory series consisted of 43 patients who had electrocardiograms obtained during the third trimester of pregnancy and again 4 to 6 weeks postpartum. At the time that the first of the pairs of electrocardiograms was taken, the mean week of gestation of the patients was 33 (range 27 to 36) and the mean abdominal girth of the patients was 99.5 cm (range 80 to 124). In order to maximize the degree of superior displacement of the diaphragm, and therefore of the heart overlying it, the electrocardiograms obtained during pregnancy were recorded during full expiration. The tracings obtained during the postpartum period were recorded during normal respiration.

**Collection of data:** The ECG findings were obtained in each patient using 12 standard leads and either a Marquette MAC 1-T or Hewlett-Packard model 1517-A electrocardiograph. These machines use 3 channels and simultaneously record leads I, II, and III, then leads aVR, aVL, and aVF, then leads $V_1$, $V_2$, and $V_3$, and finally leads $V_4$, $V_5$, and $V_6$. All recordings were made at a paper speed of 25 mm/s. In order to

be certain that all 3 channels were operating simultaneously, the relative times of onset of the 1.0 mV standardization marks were inspected. In most cases, the standardization marks were inscribed simultaneously. However, when the times of onset of the standardization marks were not identical, a correction for the discrepancy was made in the analysis of the QRS complexes. For example, if the standardization mark in channel 2 began 10 ms before the marks in channels 1 and 3, the QRS complexes in leads II and aVL were considered to have actually begun 10 ms later than they appeared on the tracing.

**Rationale for the proposed criteria:** The vectorcardiographic features of left anterior hemiblock have been described by Benchimol et al.[13] The relations between the VCG QRS loop in the frontal plane and the scalar ECG findings in patients with left anterior hemiblock are illustrated in Figure 1. As the figure shows, important features of the contour of the VCG loop can be inferred by analyzing simultaneously recorded pairs of ECG leads. On the basis of the illustrated relations, new ECG criteria for the diagnosis of left anterior hemiblock are proposed and are listed in Table I.

**Comparison ECG criteria:** In order to provide a basis by which to evaluate the performance of our proposed criteria, the ECG results of all the patients were also interpreted with respect to the following 2 sets of comparison criteria for the diagnosis of left anterior hemiblock: (1) frontal plane QRS axis between −30° and −90° (<−30° criterion), and (2) frontal plane QRS axis between −45° and −90° (<−45° criterion).

**Analysis of data:** For patients with discordant predictions by the proposed versus each set of comparison ECG criteria, the hypothesis of no difference in performance was evaluated by Fisher's exact test.[25] This is a rigorous test of comparative performance which is not affected by the level of case prevalence. In order to control the type I error for multiple tests, 2-tailed p values <0.01 were taken to indicate statistical significance at the joint 5% level.

## Results

In Group A, the proposed criteria were met in all the patients after anterior infarction had occurred and in none of the patients before infarction had occurred. In Group B, the proposed criteria were met in none of the patients either before or after inferior infarction occurred. The distribution of the values of the frontal plane QRS axes is shown in Table II. The performances of the proposed and comparison ECG criteria for the diagnosis of left anterior hemiblock are summarized in Table III. The superiority of the proposed over the <−30° and the <−45° criteria is significant at the p <0.001 level in each case.

Of the 8 patients in Group A and the 14 patients in Group B who met the ECG criteria for left ventricular enlargement, only those in Group A met the proposed criteria for left anterior hemiblock, and these only after anterior infarction had occurred.

*Confirmatory series:* In none of the 43 patients in this series did either the proposed or the comparison criteria become positive with pregnancy.

## Discussion

The traditional ECG criteria for the diagnosis of left anterior hemiblock require that some degree of left axis deviation be present. In diagnosing left anterior hemiblock, some investigators have demanded that the frontal plane QRS axis be −45° or less.[9,10,12,13] Others have advocated the less stringent criterion of an axis of ≤−30° for the diagnosis.[1,4,5,7,8,11,16] Still others have recognized that left anterior hemiblock may be present even though the QRS axis is less negative than −30° in the frontal plane.[2,3,6] However, since conditions other than left anterior hemiblock, such as inferior myocardial infarction, left ventricular enlargement, pulmonary emphysema, Wolff-Parkinson-White syndrome, hyperkalemia, and an altered position of the heart within the thorax, also have been reported to result in left axis deviation, relatively liberal axis criteria for diagnosing left anterior hemiblock are likely to be less specific.[7,10,11,14,15,17,18] Because of these considerations, Rosenbaum et al[10] described the choice of a particular value of the frontal plane QRS axis to identify patients with left anterior hemiblock as "arbitrary."

Various groups have emphasized the importance of the characteristic contour of the VCG QRS loop in the frontal plane for diagnosing left anterior hemiblock.[2,5,7,8,10,11,13,14,16,17,19–23] Several types of studies have confirmed that the features of the VCG findings described in the present report indicate that left anterior hemiblock is present. Vectorcardiographic loops similar to those upon which we based the rationale for

**TABLE III Performances* of the Criteria for the Diagnosis of Left Anterior Hemiblock**

| B (noncases) | 133 | 100 | 92 | 95 |

* The tabulated percentages are the sensitivities and specificities of the cases and noncases, respectively.

our proposed electrocardiographic criteria have been observed after angiography of the left coronary artery,[14,23] after surgical interruption of the anterior fascicle in both experimental animals,[14,26] and humans,[7,14,19] during spontaneously occurring intermittent conduction disturbances,[2,5,7,14,19] and in conduction disturbances caused by inducing premature atrial contractions.[27]

When the proposed criteria are positive, it indicates not only that the terminal forces of the ventricular depolarization are deviated superiorly, but also that they are inscribed in a counterclockwise direction. This makes the proposed criteria especially useful for distinguishing left anterior hemiblock from inferior myocardial infarction, since the latter produces superior deviation and clockwise rotation of the initial forces in the frontal plane.[28] In this regard, the authors have recently described improved ECG criteria for the diagnosis of inferior myocardial infarction which use a method of ECG analysis similar to that employed in the present investigation.[29]

The clinical context in which the ECG findings of the patients in Group A developed leftward deviation of the frontal plane QRS axis (isolated acute anterior infarction and subsequent atrioventricular block) makes it highly probable that this change in axis can be attributed to the occurrence of left anterior hemiblock. Therefore, the patients in this subgroup were used to evaluate the sensitivities of the proposed and comparison criteria. The development of high degree atrioventricular block in the patients in Group A illustrates that the proposed electrocardiographic criteria can accurately identify left anterior hemiblock that is functionally significant.

Conversely, the clinical circumstances during which the ECG changes of the patients in Group B were recorded (acute inferior without concomitant anterior infarction) make it unlikely that left anterior hemiblock occurred in this group. Because, as noted above, clinical entities other than inferior infarction have also been reported to produce false-positive evidence of left anterior hemiblock, the specificity of the proposed criteria was evaluated in additional ways. First, the presence of abdominal distension associated with the third trimester of pregnancy failed to produce false-positive evidence of left anterior hemiblock, even though the tracings were obtained in full expiration to maximize the superior displacement of the left hemidiaphragm and the heart overlying it. Second, of 22 patients with ECG evidence of left ventricular enlargement, the proposed criteria for left anterior hemiblock became positive only in the patients in Group A, and only after anterior infarction had occurred. Third, although no patients with Wolff-Parkinson-White Syndrome were included in our study, it is unlikely that this disorder would affect the terminal portions of leads aVR and aVL. This is because, in patients in sinus rhythm, conduction over accessory pathways alters the morphology of only the initial portion of the QRS complex. Finally, the ECG findings of patients with hyperkalemia sufficiently severe to influence the appearance of the QRS complexes can be identified by the characteristic alterations of P and T waves associated with this disorder.[17]

The present study shows that ECG criteria based on features of the VCG QRS loop in left anterior hemiblock diagnose this abnormality more reliably than do traditional frontal plane QRS axis criteria. Therefore, the accuracy with which left anterior hemiblock is diagnosed may be increased without resorting to the less widely available, costly, and time-consuming vectorcardiogram.

# Effects of Provocation on Transcardiac Thromboxane in Patients With Coronary Artery Disease

PAUL D. HIRSH, MD, BRIAN G. FIRTH, MD, DPhil, WILLIAM B. CAMPBELL, PhD, GREGORY J. DEHMER, MD, JAMES T. WILLERSON, MD, and L. DAVID HILLIS, MD

**Thromboxane $A_2$ exerts powerful effects on vascular smooth muscle tone and platelet aggregability. Previous studies have demonstrated increases in transcardiac thromboxane $B_2$ (a stable thromboxane $A_2$ metabolite) in patients with unstable angina and recent chest pain. To determine whether these increases in transcardiac thromboxane $B_2$ are unique to the unstable anginal syndrome or are merely a consequence of ongoing myocardial ischemia, simultaneous ascending aortic and coronary sinus blood samples were obtained for quantitation of thromboxane $B_2$ in 52 patients with a history of chest pain. Provocation was performed with (1) rapid cardiac pacing in 23 patients, (2) cold pressor stress in 19 patients, and (3) sustained isometric exertion in 10 patients. Of the 52 patients, only 5 had a substantial (>3-fold) increase in coronary sinus thromboxane $B_2$ in response to provocation: 1 had unstable angina and chest pain during the previous 48 hours and 4 had a myocardial infarction within the previous 6 weeks. Similarly, only 7 had a >3-fold increase in the coronary sinus/aortic thromboxane $B_2$ ratio in response to provocation: 1 had unstable angina and recent chest pain, 5 had a recent myocardial infarction, and 1 had both of these. There were no other clinical features unique to these patients. The remaining patients with similar diagnoses did not develop a marked increase in coronary sinus thromboxane $B_2$ or the coronary sinus/aortic thromboxane $B_2$ ratio with provocation. None of the 35 patients with stable ischemic heart disease or nonischemic chest pain syndromes had a substantial increase in coronary sinus thromboxane $B_2$ or the coronary sinus/aortic thromboxane $B_2$ ratio ($p < 0.001$ for both coronary sinus thromboxane $B_2$ and the coronary sinus/aortic thromboxane $B_2$ ratio in comparison with the 17 patients with recent unstable angina or myocardial infarction). Thus, generous amounts of thromboxane $B_2$ are released into the coronary circulation after provocation in some patients with unstable angina or recent myocardial infarction but not in those with stable ischemic heart disease or nonischemic chest pain syndromes.**

Since thromboxane $A_2$ exerts potent effects on vascular smooth muscle tone and platelet aggregability,[1] there has been speculation about its etiologic role in ischemic heart disease. We previously reported[2] that transcardiac ratios (coronary sinus/ascending aorta) of thromboxane $B_2$ (the stable nonenzymatic metabolite of thromboxane $A_2$) were elevated in patients with unstable angina pectoris and recent chest pain but not in those with stable angina or other cardiac disorders. Although transcardiac thromboxane $B_2$ ratios are increased in patients with unstable angina and recent chest pain, it is unknown whether these increases are a consequence of ongoing myocardial ischemia. Previous studies have suggested that most patients with coronary artery disease have increases in thromboxane $B_2$ during myocardial ischemia.[3] Therefore, this study was performed to determine whether the transcardiac thromboxane $B_2$ increases that occur in association with unstable angina are unique to this syndrome or are merely a result of recent myocardial ischemia. To accomplish this, we examined the effects of an increase in myocardial oxygen demand by rapid cardiac pacing, cold pressor stimulation, and isometric handgrip exertion on transcardiac thromboxane $B_2$ levels in patients with and without coronary artery disease.

## Methods

From May to December 1980, 52 patients (22 women and 30 men, aged 31 to 75 years) undergoing cardiac catheterization for the evaluation of chest pain at Parkland Memorial Hospital, Dallas, Texas, were studied after informed consent was obtained. In all patients, a 7Fr or 8Fr woven Dacron® (Goodale-Lubin) catheter was advanced from a brachial vein to the coronary sinus and its position was confirmed fluoroscopically and oximetrically. Similarly, a 7Fr or 8Fr polyurethane (pigtail) catheter was introduced percutaneously into the femoral artery and positioned in the ascending aorta adjacent to the coronary ostia. All blood samples were obtained before systemic heparinization or injection of iodinated contrast material. There was no attempt to control or alter the patients' medications before catheterization, but careful records were maintained of all medications administered within 1 week of study.

Provocation-induced ischemic electrocardiographic alterations were said to be present if there was ≥1 mm of horizontal or downsloping S-T segment depression 0.08 second after the J point in comparison with the baseline tracing.[4] After provocation, all patients underwent single plane left ventriculography and selective coronary arteriography.

**Techniques of provocation:** *Rapid cardiac pacing:* In 23 patients, a 6Fr pacing catheter was advanced to the right ventricular apex from the femoral vein. After aorta and coronary sinus specimens were obtained for quantitation of thromboxane $B_2$ and lactate and a baseline 12-lead electrocardiogram was recorded, ventricular pacing was initiated at 100 beats/min. Every 3 minutes, pacing was discontinued for 15 seconds. A 12-lead electrocardiogram was recorded, and then pacing was reinstituted at a rate 10 to 15 beats/min faster. Pacing was continued until the occurrence of angina, marked S-T segment depression on a nonpaced electrocardiogram, or a peak pacing rate of 160 beats/min, at which time blood specimens again were obtained from the aorta and coronary sinus. Immediately after blood sampling, pacing was discontinued, and a 12-lead electrocardiogram was recorded. Five and 10 minutes after the discontinuation of pacing, aorta and coronary sinus specimens again were obtained and a 12-lead electrocardiogram was recorded. Thus, in these 23 patients, aorta and coronary sinus blood specimens for measurement of thromboxane $B_2$ and lactate were obtained before, during, and after rapid cardiac pacing.

*Cold pressor stimulation:* In 19 patients, baseline aorta and coronary sinus blood specimens were obtained for quantitation of thromboxane $B_2$, and a 12-lead electrocardiogram was recorded. Then, the patient's hand was immersed in crushed ice for 3 minutes. During the final 20 seconds of exposure to cold, aorta and coronary sinus blood sampling was repeated, as was the 12-lead electrocardiogram.

*Isometric exercise:* In 10 patients, baseline aorta and coronary sinus blood specimens were obtained for measurement of thromboxane $B_2$, and a 12-lead electrocardiogram was recorded. Then, after the patient's maximal hand strength was determined with a hand dynamometer (Stoelting), the patient maintained 30% of this maximal force for 3 minutes. As with cold pressor stimulation, aorta and coronary sinus blood specimens, as well as a 12-lead electrocardiogram, were obtained during the final 20 seconds of handgrip exertion.

**Chemical analyses:** The blood specimens for thromboxane analysis were drawn into heparinized plastic syringes and transferred quickly into iced 10 ml tubes containing indomethacin (10 μg) and heparin (1,000 U). They were immediately centrifuged at 2,000 *g* for 15 minutes at 4°C. The su-

pernatants were separated and stored at −20°C for subsequent analysis. Thromboxane was measured by radioimmunoassay.[2]

The blood samples for lactate determination were immediately deproteinated in iced perchloric acid, centrifuged, decanted, and stored frozen. Lactate concentration was assayed enzymatically with the Sigma Chemical kit (St. Louis, Missouri); spectrophotometric measurements were performed at 340 nm.

**Analysis of data:** For each of the 52 patients, thromboxane $B_2$ values before, during, and after (in the case of rapid pacing) provocation were expressed as the ratio of coronary sinus to aorta. Previous studies from our laboratory[2] have demonstrated that the normal thromboxane $B_2$ coronary sinus/aorta ratio is $\leq 3.0$. Thus, for the purposes of this study, an increase in the thromboxane $B_2$ coronary sinus/aorta ratio with provocation from within the normal range to $>3.0$, or an increase in the ratio by $\geq 3.0$, was considered abnormal. Similarly, a 3-fold increase in the absolute coronary sinus thromboxane $B_2$ level with provocation was considered abnormal. Baseline and provocation thromboxane $B_2$ coronary sinus/aorta ratios were compared using the Wilcoxon paired-sample test.[5] The frequency of provocation-induced increases in coronary sinus and transcardiac thromboxane $B_2$ levels among patients with (1) unstable angina (with recent chest pain) and recent myocardial infarction, (2) stable angina, and (3) nonischemic chest pain syndromes were analyzed using the Fisher exact test.[5] Baseline and provocation heart rates and blood pressures were compared using the paired-sample $t$ test.[5] The aortic thromboxane $B_2$ concentrations in patients with and without recent ingestion of cyclooxygenase inhibitors were compared using the Mann-Whitney test.[5] A p value $<0.05$ was considered significant. All values are expressed as the mean ± standard deviation.

The percent myocardial lactate extraction was calculated with the formula $100 \times (AO_L - CS_L)/AO_L$, where $AO_L$ represents the aortic lactate concentration and $CS_L$ represents the coronary sinus lactate concentration. Using this formula, a value less than zero indicates myocardial lactate production.[6] Since this assay in our laboratory has a variability of 3%, we accepted a percent myocardial lactate extraction of $\leq -3.0$ as evidence of myocardial lactate production.

## Results

**Rapid cardiac pacing:** Of the 23 patients subjected to rapid pacing (Table I), 16 had chest pain and 12 had S-T segment depression consistent with ischemia (8 with and 4 without concomitant chest pain). Pacing was continued to 160 beats/min in 3 patients without the occurrence of pain or electrocardiographic changes. Myocardial lactate production occurred during pacing in 12 patients. Subsequently, selective coronary arteriography revealed that 18 of the 23 patients had atherosclerotic coronary artery disease.

In 3 of the 23 patients, coronary sinus thromboxane $B_2$ increased abnormally during or immediately after rapid cardiac pacing. Of these 3 patients, all had chest pain, 1 had ischemic electrocardiographic alterations, none had myocardial lactate production, and all 3 had atherosclerotic coronary artery disease. One had unstable angina[7] and chest pain within the previous 48 hours, and the other 2 had a myocardial infarction within 6 weeks of study. Four patients with unstable angina or recent infarction did not have an increase in transcardiac thromboxane $B_2$ in response to pacing (1 with unstable angina, 2 with a recent infarction, and 1 with both). Among these 4, 3 had chest pain, all 4 had ischemic electrocardiographic changes consistent with ischemia, and 2 had myocardial lactate production.

Of the 23 patients subjected to rapid cardiac pacing, 16 had neither unstable angina nor a recent infarction. Of these, 10 had chest pain during pacing, 7 had electrocardiographic changes consistent with myocardial

ischemia, 10 had myocardial lactate production, and 11 had underlying atherosclerotic coronary artery disease. However, none of these patients developed a pacing-induced abnormal increase in coronary sinus thromboxane $B_2$.

Among the 12 patients who had pacing-induced myocardial lactate production, none had a concomitant abnormal elevation in coronary sinus thromboxane $B_2$.

**Cold pressor stimulation:** Of the 19 patients provoked with exposure to cold, none developed chest pain or S-T segment alterations indicative of myocardial ischemia (Table II). Before cold pressor provocation, heart rate was 68 ± 9 (mean ± standard deviation) beats/min, and during cold pressor, it was 71 ± 9 beats/min (p = NS [not significant]). Systolic arterial pressure increased from 153 ± 25 mm Hg before cold pressor to 188 ± 40 mm Hg during cold pressor (p <0.01). None of the 19 patients demonstrated an abnormal increase in the coronary sinus thromboxane $B_2$ level in response to cold pressor stimulation. Five patients had unstable angina or recent infarction (2 with unstable angina and chest pain within 48 hours of study, 1 with a myocardial infarction within 6 weeks of study, and 2 with both of these), and 14 had stable angina or nonischemic chest pain syndromes.

**Isometric exercise:** During sustained handgrip, 1 of the 10 patients had chest pain, and none had S-T segment changes suggestive of ischemia (Table III). During the 3 minutes of handgrip, heart rate increased from 78 ± 16 to 88 ± 19 beats/min (p = 0.02), and systolic arterial pressure increased from 135 ± 15 to 175 ± 14 mm Hg (p <0.01). In 2 of the 10 patients, isometric exercise induced an abnormal increase in the coronary sinus thromboxane $B_2$ level (from 24.7 and 132.0 at baseline to 86.3 and 862.0, respectively, at peak handgrip). Both of these patients had had a myocardial infarction within the previous 6 weeks; neither had chest pain during handgrip exertion. The coronary sinus level remained unchanged in the remaining 3 patients with unstable angina and recent pain (1 patient) or recent myocardial infarction (2 patients). The 5 patients with stable angina pectoris or nonischemic chest pain syndromes demonstrated no substantial change in coronary sinus thromboxane $B_2$ in response to handgrip.

**Effects of provocation in patients with unstable angina or recent myocardial infarction:** Seventeen of the 52 patients subjected to provocation had unstable angina and chest pain within 48 hours of study (5 patients), a myocardial infarction within 6 weeks of study (9 patients), or both (3 patients). In 5 of these 17 patients (29%), the coronary sinus thromboxane $B_2$ level increased abnormally (>3-fold) with provocation (3 with pacing and 2 with isometric exertion), whereas it remained unchanged in the other 12 patients. Of the 5 patients with a substantial increase in coronary sinus thromboxane $B_2$, 1 had unstable angina and 4 had recent infarctions. Therefore, 1 of 8 patients with unstable angina and recent chest pain and 4 of 12 patients with recent myocardial infarctions had a marked increase in coronary sinus thromboxane $B_2$ in response to an increase in myocardial oxygen demand. In contrast, of the 35 patients with stable angina or nonischemic chest pain syndromes, none demonstrated a 3-fold increase in the coronary sinus thromboxane $B_2$ level with provocation (p <0.001) (Fig. 1).

In terms of transcardiac changes in thromboxane $B_2$, a ratio of the coronary sinus/ascending aortic thromboxane $B_2$ concentrations can provide a useful index of intracoronary thromboxane $B_2$ production.[2] Expressing the present data in this fashion demonstrates that a significant increase in the thromboxane $B_2$ coronary sinus/ascending aortic ratio occurred with provocation in 7 of the 52 patients (13%). Of these 7, 4 were provoked with pacing, 1 with cold pressor stress, and 2 with isometric exertion. One of these 7 had recent unstable angina, 5 had recent infarctions, and 1 had both. Of the 52 patients in the entire study population, the 7 with provocable increases were among 17 patients (41%) with similar diagnoses, whereas none of the remaining 35 patients had significant increases in the thromboxane $B_2$ coronary sinus/aortic ratio (p <0.001). Thus, in this study, similar results were obtained by evaluation of changes in coronary sinus/aortic ratios.

**Effect of medications:** Of the 52 patients, 45 (87%) were receiving long-acting nitrates, 21 (40%) were receiving propranolol (mean daily dose 140 mg, range 30

Abbreviations as in Table I.

to 320), and 4 (8%) were receiving metoprolol (100 to 200 mg/24 hours). Nitrates and propranolol did not appear to influence the thromboxane $B_2$ concentrations (Tables I to III). Nine patients received cyclooxygenase inhibitors at some time within 5 days of study (aspirin in 4, ibuprofen in 1, aspirin plus ibuprofen in 1, indomethacin in 1, sulfinpyrazone in 1, and sulindac in 1); these 9 patients had lower plasma concentrations of these hormones (baseline aortic thromboxane $B_2$ concentration 24.5 ± 17.1 pg/ml) than the 44 patients who had not received them (74.9 ± 57.8 pg/ml) ($p < 0.001$). The exclusion of the 9 patients who had recently received cyclooxygenase inhibitors did not influence the overall results of the study (Tables I to III). Interestingly, 2 of these patients had an abnormal increase in the coronary sinus thromboxane $B_2$ level with provocation (Table I, Group 1, Patients 4 and 7).

## Discussion

Recent studies have suggested that unstable angina pectoris is a syndrome characterized by spontaneous reductions in coronary blood flow[8,9] induced by either coronary arterial spasm or intracoronary platelet aggregation with the transient formation of platelet "plugs." Since thromboxane $A_2$ is a powerful promoter of increased vascular tone and platelet aggregation,[10] it is of interest that its stable metabolite, thromboxane $B_2$, is elevated in the coronary circulation of patients with unstable angina.[2] In contrast, stable (exertional) angina is a syndrome characterized by episodic increases in myocardial oxygen demand in the setting of limited oxygen supply due to coronary atherosclerosis. Although it is unknown whether coronary arterial spasm or enhanced platelet aggregation is of etiologic importance in this syndrome, previous studies from our laboratory have demonstrated that patients with stable (exertional) angina do not have increased transcardiac levels of thromboxane $B_2$.[2] Thus, there is inferential evidence that unstable angina and stable (exertional) angina differ in pathogenesis and, consequently, in their association (or lack of association) with transcardiac thromboxane levels.

In the present study, marked (>3-fold) increases in coronary sinus thromboxane $B_2$ or the coronary sinus/aortic thromboxane $B_2$ ratio in response to provocation were observed in only 5 (10%) or 7 (13%) of the patients, respectively. In a retrospective attempt to ascertain common features among these patients, it was apparent that substantial provocation-induced thromboxane $B_2$ elevations occurred only in 2 types: those with unstable angina and recent chest pain (within 48 hours of study) and those with recent myocardial infarction (within 6 weeks of study). Such increases in thromboxane $B_2$ were not observed in those with stable (exertional) angina or nonischemic chest pain syndromes. There were no other clinical features unique to those who developed such an increase in thromboxane $B_2$.

Rapid cardiac pacing, cold pressor stimulation, and isometric exertion were used in the present study to induce myocardial ischemia. Cardiac pacing increases heart rate, exposure to cold increases systemic arterial pressure, and sustained handgrip increases both heart rate and systemic arterial pressure.[11–13] Thus, all 3 methods of provocation increase the rate-pressure product, thereby augmenting myocardial oxygen demand.[14] In addition, activation of the sympathetic nervous system with alpha-adrenergic stimulation (induced by cold pressor stress and isometric exercise) causes an increase in coronary vascular resistance.[15,16] This coronary vasoconstriction in patients with coronary artery disease may result in myocardial ischemia, which is demonstrable at times even in the absence of chest pain and electrocardiographic changes.[17,18] Aside from their effects on myocardial oxygen demand and coronary vascular resistance, these methods of provocation activate platelets in patients with ischemic heart disease.[19–21] In addition, it has been suggested that rapid cardiac pacing in individuals with atherosclerotic coronary artery disease may increase the production of prostaglandins E and F[22] as well as thromboxane $B_2$.[3,23]

Lewy et al[3] performed cardiac pacing in 14 patients with unstable or accelerated angina. They concluded that thromboxane $A_2$ was produced during pacing-induced myocardial ischemia and that fluctuations in thromboxane $A_2$ levels paralleled alterations in lactate production. Our results are at variance with their conclusions. Specifically, our data suggest that provocation causes a marked increase in coronary sinus thromboxane $B_2$ in some patients with myocardial ischemia but

not in others, and that this increase in thromboxane $B_2$ is unrelated to myocardial lactate production. In the present study, there was a substantial increase in thromboxane $B_2$ with provocation in some patients with unstable angina and chest pain within 48 hours of study and in some with a recent myocardial infarction (within 6 weeks of study). In contrast, thromboxane $B_2$ did not increase markedly with provocation in those with stable ischemic heart disease, even though ischemia (as suggested by chest pain, electrocardiographic alterations, and myocardial lactate production) was produced in both groups of patients. Thus, in the present study, an abnormal increase in coronary sinus thromboxane $B_2$ during provocation appears to be related to the presence of clinical instability or recent myocardial infarction rather than to provoked myocardial ischemia per se.

The apparent lack of objective signs of ischemia in some patients with thromboxane $B_2$ production during provocation may reflect limitations inherent to this type of clinical study. In our experience, chest pain is an unreliable indicator of myocardial ischemia. Nevertheless, we are reluctant to provoke patients with coronary artery disease beyond the onset of chest pain. Furthermore, provocation-induced electrocardiographic alterations and net myocardial lactate production are specific but not sensitive indicators of myocardial ischemia; that is, their absence in some patients with coronary sinus thromboxane $B_2$ elevations does not exclude the presence of ischemia concomitantly in these patients.[24–27] Therefore, further investigation into the relation between myocardial ischemia and intracoronary thromboxane $B_2$ release is needed to resolve this issue.

The question of why some patients with unstable angina (and recent chest pain) and recent myocardial infarction increase their coronary sinus thromboxane $B_2$ in response to provocation, whereas others with these syndromes do not, remains unanswered. At least part of the answer may be a function of the different degrees of ischemia induced in these patients. Alternatively, 3 of 8 patients with unstable angina pectoris had resting coronary sinus thromboxane $B_2$ levels >500 pg/ml. Of these 3, 2 did not have a further increase in the coronary sinus thromboxane $B_2$ concentration. Therefore, patients with an elevated resting coronary sinus thromboxane $B_2$ level may be less affected (in terms of thromboxane $B_2$ production) by an increase in myocardial oxygen demand than those with a "normal" resting level.

The range of thromboxane $B_2$ values obtained in this study is large. However, many factors (such as the presence of ischemic heart disease,[28,29] atherosclerosis,[30,31] and stress[32,33]) affect thromboxane $A_2$ levels and platelet thromboxane $A_2$ generation. Thus, it is not surprising that 52 patients with and without atherosclerotic vascular disease and its associated risk factors have a wide range of aortic and coronary sinus thromboxane $B_2$ concentrations. However, the observed increases in coronary sinus thromboxane $B_2$ could have occurred (1) in the coronary circulation, or (2) in the coronary sinus catheter itself; the present study cannot distinguish between these 2 possibilities. Despite this, there is reason to believe that the release of thromboxane $A_2$ is an intracoronary event, since intracoronary platelet aggregates have been observed in association with several ischemic cardiac syndromes.[34–36] Other recent studies have demonstrated an increase in platelet-specific proteins in peripheral blood samples in patients with unstable angina pectoris, suggesting again that platelets may be involved in the pathophysiology of this syndrome.[37,38] In addition, recent studies from our laboratory have demonstrated no consistent alteration in thromboxane $B_2$ attributable to sampling through long catheters.[39]

*In summary*, provocation with rapid cardiac pacing, cold pressor stimulation, and isometric exercise caused a marked increase in coronary sinus thromboxane $B_2$ levels in some patients with unstable angina pectoris or a recent myocardial infarction. In contrast, patients with a similar degree of coronary artery disease but without unstable angina or a recent myocardial infarction, as well as patients with a nonischemic chest pain syndrome, demonstrated no substantial increase in coronary sinus thromboxane $B_2$ with provocation. The increases in coronary sinus thromboxane $B_2$ during cardiac pacing did not correlate with the presence of objective signs of myocardial ischemia. Although the present study cannot distinguish between cause and effect, thromboxane $A_2$ may play a role in the mediation of unstable ischemic coronary events, such as unstable angina pectoris, acute myocardial infarction, and sudden cardiac death. Further studies are needed to clarify the precise role of thromboxane $A_2$ in these clinical syndromes, as well as the physiologic significance, if any, of the coronary sinus and transcardiac changes in thromboxane $B_2$ observed in this study. Whether provocative testing can identify a subset of patients with unstable ischemic heart disease at risk for thromboxane $A_2$-mediated catastrophic events (which might be prevented by prophylactic treatment with a thromboxane synthetase inhibitor or receptor antagonist) remains to be determined.

# Precordial S-T Segment Depression in Inferior Myocardial Infarction

## Evaluation by Quantitative Thallium-201 Scintigraphy And Technetium-99m Ventriculography

LAWRENCE ONG, MD, BENILDA VALDELLON, BS, JAMES COROMILAS, MD, ROBERT BRODY, MPH, PETER REISER, MD, and JOHN MORRISON, MD

**The relation of initial precordial S-T segment depression to anterior ischemia and eventual prognosis was studied in 70 patients with acute inferior myocardial infarction (MI). Early quantitative thallium-201 scintigraphy and technetium-99m ventriculography were used to evaluate anterior ischemia. In comparison with patients without S-T segment depression, those with depression had lower global ejection fraction (EF), 45 ± 10 versus 52 ± 7 ($p < 0.01$), lower inferoposterior regional EF, 40 ± 14 versus 52 ± 13 ($p < 0.005$), and larger thallium-201 defect index, 21 ± 7 versus 16 ± 6 ($p < 0.005$). In contrast, anteroseptal regional EFs were similar in the 2 groups, 54 ± 13 versus 56 ± 12 (p not significant [NS]), and the frequency of anteroseptal thallium-201 defects or redistribution abnormalities was not significantly different, 17 of 47 versus 5 of 23 and 8 of 31 versus 4 of 11 (p = NS). The predictive value of precordial S-T segment depression for mortality was low (21%) compared with the Killip class (75%), chest radiographs (67%), and EF (60%). Multiple logistic regression confirmed that the presence of S-T segment depression did not significantly improve the prediction of mortality when considered with these other risk factors. Thus, *precordial S-T segment depression is a marker of larger MI size and not of anterior ischemia.* When examined with other variables reflecting MI size and left ventricular function, precordial S-T segment depression was not a significant independent risk factor.**

A large proportion of patients with acute inferior wall myocardial infarction present with simultaneous S-T segment elevation in the inferior leads and S-T segment depression in the anterior precordial leads. These patients appear to have a higher morbidity and mortality than those presenting with inferior S-T segment elevations alone.[1,2] It has been proposed that this S-T segment depression may be an indication of simultaneous anterior ischemia or subendocardial infarction, thus accounting for the increased risk seen in these patients.[2] In support of this hypothesis, increased anterior and septal wall motion abnormalities have been noted in this subset of patients.[2] However, others, have noted primarily increased posterior wall motion abnormalities in association with this electrocardiographic finding.[3] Thus, the presence or absence of "distant" ischemia in these patients is not entirely clear. The analysis of regional wall motion may not be sufficiently specific to resolve this issue because wall motion abnormalities in experimental myocardial infarction (MI) without other evidence of ischemia can occur adjacent to, and remote from, the site of MI.[4]

It has also been suggested that precordial S-T segment depression constitutes an important risk factor for post-MI morbidity and mortality. However, when precordial S-T segment depression is evaluated as an independent prognostic factor, it becomes apparent that patients with this finding also demonstrate greater release of creatine kinase and lower left ventricular (LV) ejection fraction (EF).[2,3] Therefore, the apparent prognostic value of these anterior precordial changes may be due to the indirect influence of other variables

reflecting increased MI size and greater LV dysfunction. This proposed risk factor has not been systematically evaluated while controlling for these confounding variables.

In this study, the relation of precordial S-T segment depression in acute inferior MI to distant anterior wall ischemia was examined by 2 independent methods: quantitative thallium-201 scintigraphy and technetium-99m radionuclide ventriculography. Subsequently, the independent prognostic significance of this electrocardiographic risk factor was compared with that of other risk factors using univariate and multivariate techniques.

## Methods

**Patient population:** Seventy patients with acute inferior MI were studied. Myocardial infarction was confirmed by clinical history, by Q-wave formation (>0.04 ms) with S-T segment elevation in at least 2 of 3 electrocardiographic leads (2, 3, or aVF), and by a typical increase and decrease in serum creatine kinase levels. Exclusion criteria included (1) the presence of pulmonary edema or cardiogenic shock, (2) previous anterior wall MI by history or electrocardiogram, and (3) the presence of a bundle branch block pattern.

Patients were classified according to the clinical degree of LV failure on admission (Killip class)[5] after review of the chart by 2 of the authors. Class I was defined as the absence of any signs or symptoms of LV failure. Class II included patients with mild to moderate failure as denoted by the presence of rales or LV gallop. Patients were considered to have significant radiographic evidence of failure if pulmonary congestion, such as vascular redistribution or interstitial edema, was present on initial chest X-ray. Patients also were classified according to the presence or absence of precordial S-T segment depression in electrocardiographic leads $V_1$ through $V_4$. Patients with at least 1 mm S-T segment depression in at least 2 of these leads on admission electrocardiography were classified as Group A. Those without these changes were classified as Group B.

In each patient, serial blood samples were taken for serum creatine kinase determination on admission and every 4 to 6 hours thereafter until levels returned to baseline. Total serum creatine kinase activity was determined according to the method of Rosalki.[6]

Quantitative thallium-201 perfusion scintigraphy and technetium-99m equilibrium-gated radionuclide ventriculography were performed in all patients within 48 hours of the onset of chest pain (mean 11 ± 8 [standard deviation]). Thallium-201 imaging was performed in the anterior and left anterior oblique 45° views 20 to 30 minutes after intravenous injection of 1.6 mCi of thallium-201. Initial studies were acquired with 500,000 counts per view, using a low energy converging hole collimator. In 42 patients, delayed views were obtained 3 hours after injection using the same acquisition time as the corresponding initial view. Images were acquired in a 128 × 128 matrix and processed using a dedicated PDP 11/60 computer (Digital Equipment). After interpolative background subtraction,[7] the perimeter of the myocardial image was circumscribed in a rectangular region manually. Using algorithms, 8 equal rectangular segments designed to fit the left ventricle in each projection were automatically generated and superimposed on the image (Fig. 1). On each image, the segment with the highest average count density was used as a relative index of normal. Using this system, we found a threshold of 25% reduction in thallium-201 activity from normal to optimally distinguish normal from abnormal segments in patients undergoing cardiac catheterization. A perfusion defect in the anteroseptal region was present if >2 abnormal segments were found in segments 1 to 3 of the anterior view or 6 to 8 of the left anterior oblique 45° view (Fig. 1). A thallium-201 defect index (TI) was constructed to assess defect size using the formula:

$$TI = \frac{\sum_{i=1}^{N} \%\,ADPi}{16}$$

where N = the total number of abnormal segments and % ADPi = the percent reduction in thallium-201 activity of the $i$th abnormal segment. This index has been reproducible in our laboratory with a high correlation between duplicate intra- and interobserver determinations (r = 0.97 and 0.96, respectively; n = 15).

In the 42 patients with sequential studies, an increase of ≥15% in thallium-201 activity for a given segment was considered evidence of thallium-201 redistribution. In a group of 17 patients with previous inferior MI undergoing cardiac catheterization, we found the presence of significant (≥2 segments) resting thallium-201 redistribution to have a sensitivity of 67% and a specificity of 100% in detecting multivessel disease.[8]

Multiple gated blood pool imaging of the left ventricle was accomplished immediately after completion of thallium-201 scintigraphy. Studies were performed with the patient in the modified left anterior oblique 45° position. According to the procedure of Pavel et al,[9] patients received an initial intravenous injection of 7.7 mg of stannous pyrophosphate (Mallinckrodt) in 1 ml of physiologic saline solution. Twenty minutes later the patient received an intravenous injection of 20 mCi of technetium-99m pertechnetate (Union Carbide). Data collection in the gated synchronized mode was begun 10 minutes after administration of the radionuclide.

Data analysis was accomplished using algorithms that were modifications of those described by Green et al[10] and Maddox et al.[11] Scintillation X-Y coordinates were sorted additively

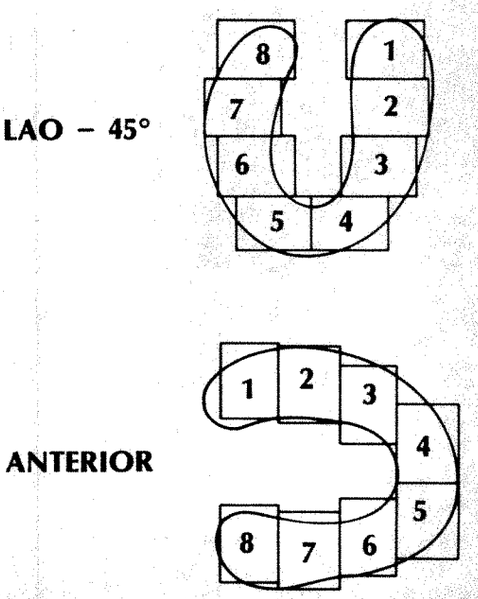

**FIGURE 1.** For computer scoring of each set of scintigraphic views, each view was divided into 8 segments, as shown. LAO = left anterior oblique.

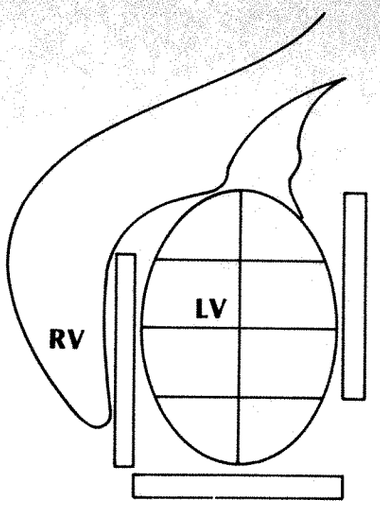

**FIGURE 2.** For calculation of regional ejection fractions, the left ventricular region of interest in the left anterior oblique projection was automatically divided into regions, as shown. LV = left ventricle; RV = right ventricle.

in forty-two 64 × 64 matrix frames after each R wave for approximately 900 cardiac cycles. Data collection continued until 8 million counts had been accumulated (15,000 to 30,000 counts per frame within the region of interest). A time-activity curve was generated from the 42 frames and the end-systolic and end-diastolic frames were identified. A left ventricular region of interest was defined with a user-dependent, irregular region-of-interest program. An automated computer macroalgorithm was then used to find the greatest vertical and horizontal dimensions of the region of interest and to construct the associated rectangle by which it would be circumscribed. The circumscribing rectangle was divided into 8 segments and superimposed on the region of interest. Portions of the rectangle that were outside the region of interest were erased. Three rectangular background areas were defined by computer and placed at the region of interest's lateral, septal, and apical sides (Fig. 2). The 2 segments overlying the cardiac base were discarded because of proximity to the atria and great vessels. The remaining 6 segments were combined into 3 larger segments representing the anteroseptal, apical, and inferoposterior regions. Regional EFs were calculated from the corresponding time-activity curve using weighted background subtraction, as described by Maddox et al.[11]

In 12 hospitalized patients with healed previous MI, the coefficient of variation for replicate EFs obtained 3 or more days apart in each patient was 3.5%. In these same patients, the coefficient of variation for regional ejection fractions ranged from 4 to 10% with this technique. In addition, our laboratory previously reported high correlations between radionuclide-derived regional EFs and corresponding angiographically determined segmental wall motion (r = 0.70 to 0.88).[12]

**Patient follow-up and mortality:** Fourteen of the 70 patients died, 7 during hospitalization and 7 after discharge. Three of the latter deaths occurred 1.5 to 6 months after MI, and 4 occurred 6 to 24 months after MI. All deaths were judged cardiac in nature: 3 inhospital deaths were related to sudden pump failure; 4 occurred after the onset of cardiogenic shock. Two posthospital deaths were sudden; 3 occurred after documented reinfarction; and 2 were related to pump failure after coronary bypass surgery. The 56 surviving patients were followed up 6 to 30 months (mean 14) after MI.

**TABLE I Clinical Characteristics of Patients**

| | Group A (ST↓) (n = 47) | Group B (No ST↓) (n = 23) |
|---|---|---|
| Age (yr): Mean and range | 60 (35–78) | 59 (45–72) |
| Interval (h) from chest pain to admission | 3.4 (1–12) | 3.4 (1–10) |
| Interval (h) from chest pain to study | 11 (2–48) | 11 (2–18) |
| Killip II | 8 | 0 |
| CXR findings | 6 | 0 |
| Peak creatine kinase (mean ± SD) | 1,856 ± 1,133 | 1,135 ± 705* |
| Deaths | 13 | 1 |

* $p < 0.005$.
CXR findings = vascular congestion on initial chest X-ray; SD = standard deviation; ST↓ = initial precordial S-T segment depression of ≥1 mm in at least 2 leads from $V_1$ to $V_4$.

**Data analysis:** The significance of a difference between means was tested by the Student's *t* test. The significance of an association between variables was tested by continuity-corrected chi-square analysis.

To assess the relative influence of each risk factor when considered simultaneously with others, a multivariate analysis using multiple logistic regression was performed (BMD-PLR). Regressions were performed using mortality at 3 weeks, 6 months, and overall mortality as the endpoint. In this analysis, all prognostic variables and their interactions were offered as candidates for the model; the first variable selected was the risk factor with the strongest influence on mortality. Subsequent variables were selected in a stepwise manner if their addition to the model resulted in a significant improvement in the model as assessed by the "improvement in fit" chi-square.[13] This statistic was derived from the log of the ratio of the maximized likelihood functions of the current to candidate model and was considered significant if >3.84 (chi-square for 1 degree of freedom at $\alpha = 0.05$).

## Results

Of 70 patients, 47 had significant precordial S-T segment depression on admission (Group A) and 23 did not (Group B). Clinical characteristics of each group are presented in Table I. The mean times of evaluation from onset of symptoms were similar in the 2 groups. Group A had a higher mean peak creatine kinase level and more patients with clinical and radiographic evidence of congestive heart failure on admission. More deaths occurred in Group A.

**Radionuclide studies:** Group A patients had a mean left ventricular EF of 45 ± 10, significantly lower than the mean EF in Group B patients, 52 ± 7, $p < 0.01$ (Table II). Of 46 Group A patients, 9 had a severely depressed left ventricular EF (<40%), compared with only 1 of the 22 Group B patients. In the past, we noted a good correlation between left ventricular EF and creatine kinase-MB infarct size.[12] Therefore, the greater degree of left ventricular dysfunction in Group A patients suggested the presence of larger MIs. The possibility of "distant" regional wall motion abnormalities contributing to global dysfunction remained.

**TABLE II Radionuclide Characteristics**

| | Group A (ST↓) | Group B (No ST↓) |
|---|---|---|
| Left ventricular EF | 45 ± 10 | 52 ± 7† |
| Anteroseptal REF | 54 ± 13 | 56 ± 12* |
| Inferoposterior REF | 40 ± 14 | 52 ± 13‡ |
| Defect index | 21 ± 7 | 16 ± 6‡ |
| Anteroseptal defects | 17/47 (36%) | 5/23 (22%)* |
| Anteroseptal redistribution | 8/31 (26%) | 4/11 (36%)* |

* p = NS.
† p <0.01.
‡ p <0.005.
Values are expressed as mean ± standard deviation.
Defect index = thallium-201 defect index; REF = regional ejection fraction; ST↓ = initial precordial S-T segment depression of ≥1 mm in at least 2 leads from $V_1$ to $V_4$.

**TABLE III Univariate Analysis: 6-Month Mortality**

| Risk Factor | Sensitivity n | Sensitivity % | Specificity n | Specificity % | Predictive Value n | Predictive Value % | $\chi^2$ |
|---|---|---|---|---|---|---|---|
| Killip II | 6/10 | 60 | 58/60 | 97 | 6/8 | 75 | 21.88 |
| LVEF | 6/10 | 60 | 56/60 | 95 | 6/10 | 60 | 15.79 |
| CXR findings | 4/10 | 40 | 56/60 | 95 | 4/6 | 67 | 10.40 |
| Defect index | 4/10 | 40 | 55/60 | 92 | 4/9 | 44 | 5.10 |
| ST↓ | 10/10 | 100 | 23/60 | 38 | 10/47 | 21 | 4.10 |
| CK | 8/10 | 80 | 22/60 | 37 | 8/46 | 17 | 0.45 |

CK = peak creatine kinase >1,000 IU/liter; CXR findings = vascular congestion on chest X-ray; Defect index = thallium-201 defect index >27.0; LVEF = left ventricular ejection fraction <40%; ST↓ = initial precordial S-T segment depressions of ≥1 mm in at least 2 leads from $V_1$ to $V_4$.

Using regional EF analysis, we assessed possible differences in regional wall motion abnormalities between the 2 groups. Group A patients had a mean inferoposterior EF of 40 ± 14, which was significantly lower than that in Group B patients whose mean inferoposterior EF was 52 ± 13, p <0.005. This result indicated greater wall motion abnormalities in the region of infarction in Group A patients. In contrast, there was no significant difference in mean anteroseptal regional EF between Group A and Group B patients, 54 ± 13 versus 56 ± 12, p = NS. Therefore, increased wall motion abnormalities in the region of MI, rather than wall motion abnormalities distant to the site of infarction, appeared to account for the greater LV dysfunction in Group A patients.

Group A patients had a larger mean thallium-201 perfusion defect index than did patients in Group B, 21 ± 7 versus 16 ± 6, p <0.005 (Table II), which also suggests the presence of larger infarcts in Group A patients. Using the presence of thallium-201 defects or thallium-201 redistribution abnormalities in anterior or septal segments as evidence of ischemia, we found no association between precordial S-T segment depression and anterior ischemia. Of 46 patients in Group A, 17 had thallium-201 defects in segments distant to the infarct as compared with 5 of 22 patients in Group B (p = NS). Of the 42 patients with resting thallium-201 redistribution studies, 8 of 31 Group A patients had distant thallium-201 redistribution abnormalities as compared with 4 of 11 patients in Group B (p = NS). Thus, as suggested by the results of the wall motion studies, Group A patients had larger contiguous areas of infarction or ischemia, but no increase in abnormalities in the septum or anterior wall distant to the site of MI.

**Risk factor analysis:** The presence of precordial S-T segment depression in this patient population appeared to be a marker for larger MIs. Other variables reflecting infarct size and left ventricular dysfunction have previously been demonstrated to be important prognostic risk factors in acute MI.[5,14–16] To evaluate the relative prognostic importance of precordial S-T segment depression, this risk factor was compared with other clinical, enzymatic, and radionuclide variables including Killip classification, presence of pulmonary vascular redistribution or interstitial edema on initial chest X-ray, peak creatine kinase, initial left ventricular EF, and thallium defect size.

**Univariate analysis:** The sensitivity, specificity, and predictive value for overall mortality was computed for each risk factor from 2 × 2 contingency tables. The predictive value of a risk factor was equivalent to the proportion of patients with the risk factor whose mortality was correctly predicted. Sensitivity was equivalent to the proportion of patient deaths in which the risk factor was present and specificity was equivalent to the proportion of survivors in which the risk factor was absent. In the analysis presented, 6 month mortality was the end-point used. Analysis of inhospital and overall mortality revealed similar findings.

Univariate analysis indicated that routine clinical methods of risk assessment had the highest predictive values for 6 month mortality. The presence of mild to moderate congestive failure on physical examination (Killip II classification) had a predictive value of 75% for this endpoint and the presence of vascular congestion on chest X-ray had a predictive value of 67% (Table III). In comparison, the presence of precordial S-T segment depression was a poor prognostic factor with a predictive value of 21%. Although this risk factor was present in 100% of the patients that did not survive 6 months, it was also present in over 60% of the patients that did survive that period, indicating a high false-positive rate. Both radionuclide EF and thallium-201 defect size were significant prognostic descriptors on univariate analysis. The EF appeared to be more sensitive and specific. The predictive value of a depressed EF of <40% for 6-month mortality was 60%. Peak creatine kinase level was not significantly associated with mortality because right ventricular infarction and right ventricular contribution to creatine kinase were present in many patients.

**Multivariate analysis:** To evaluate their relative influences on mortality, the prognostic risk factors were then submitted to multivariate analysis using a stepwise logistic regression. With this technique, the variable with the greatest independent influence in predicting mortality is selected first; other variables with significant prognostic influence are then added to the model

**TABLE IV Stepwise Logistic Regression Analysis**

| | Significant Risk Factors (In Order of Selection) | Regression Coefficients* (b) | Standard Error of b [S(b)] | b/S(b)† |
|---|---|---|---|---|
| In-hospital mortality | LVEF | 1.255 | 0.501 | 2.504 |
| | Killip II | 1.252 | 0.513 | 2.438 |
| 6-month mortality | LVEF | 1.446 | 0.615 | 2.351 |
| | Killip II | 1.445 | 0.640 | 2.259 |
| | CXR findings | 1.883 | 0.832 | 2.263 |
| Mortality at last follow-up | Killip II | 1.159 | 0.421 | 2.751 |
| | LVEF | 0.746 | 0.386 | 1.933 |

CXR findings = vascular congestion on chest X-ray; LVEF = left ventricular ejection fraction <40%.
* Based on the multiple logistic function $p = 1/\{1 + e^{-(a + b_1X_1 + b_2X_2 + \ldots b_nX_n)}\}$ where p = probability of death, $b_i$ = partial regression coefficients associated with risk factors $X_i$.
† b/s(b) >1.96 tests the hypothesis $H_A: b \neq o$ at $\alpha < 0.05$.

in a stepwise fashion until no further significant improvement in the prediction of mortality occurs. In-hospital, 6-month, and overall mortality were investigated.

In agreement with univariate analysis, the most important risk factors appeared to be Killip class II, a depressed initial EF of <40%, and findings of pulmonary congestion on initial chest X-ray (Table IV). The EF was selected as the most important risk factor in predicting in-hospital and 6-month mortality. Although this risk factor was also selected for mortality at last follow-up, the associated regression coefficient was of borderline significance. Killip II classification was a significant independent risk factor for all 3 end-points and the most important risk factor in the analysis of overall mortality. The presence of vascular redistribution or interstitial edema on initial chest X-ray improved the prediction of mortality at 6 months. The presence of precordial S-T segment depression was not selected as a significant independent risk factor at any of the 3 time intervals investigated.

## Discussion

The importance of noninfarcted but potentially ischemic areas in acute MI has recently been recognized. Patients who experience postinfarction angina with "distant" ischemic changes on electrocardiogram appear to be at high risk[17]; the presence of S-T segment depression on post-MI stress testing also appears to be a marker for increased risk.[18] Precordial S-T segment depression is frequently noted initially in acute inferior MI. These changes may be due to anterior subendocardial ischemia or a reciprocal phenomenon reflecting posterolateral injury. Previous electrocardiographic and autopsy correlations have demonstrated the presence of posterolateral infarction in patients with these electrocardiographic changes.[19,20] Recently, Shah et al[2] noted an association between precordial S-T segment depression and anteroseptal wall motion abnormalities. They proposed that anterior ischemia could account for the greater left ventricular dysfunction and higher morbidity and mortality seen in these patients. However, the presence of anteroseptal wall motion abnormalities has not been a universal finding. Goldberg et al[3] studied a similar group of patients and found this electrocardiographic phenomenon to be associated only with increased posterolateral hypokinesis. The interpretation of wall motion abnormalities in acute MI is subject to several problems.[21] Methods used to judge the presence and degree of hypokinesia on technetium-99m ventriculograms vary widely from center to center. Although exercise-induced wall motion abnormalities demonstrate high sensitivity and specificity in detecting coronary artery disease,[22] these changes may not be as sensitive or as specific in the context of resting studies performed during acute MI.

Because of the foregoing problems, we attempted to evaluate the presence of anterior wall ischemia in patients with acute inferior wall infarction and precordial S-T segment depression using 2 independent modalities: early quantitative thallium-201 perfusion scintigraphy and technetium-99m radionuclide ventriculography. No significant differences were found between Group A and Group B patients when we examined anteroseptal wall motion, the presence or absence of anteroseptal thallium-201 perfusion defects, or thallium-201 redistribution abnormalities. We did find that Group A patients had larger inferoposterior perfusion defects, lower global EFs, and greater posterior wall hypokinesis. These results suggest that a greater extent of posterolateral infarction rather than anterior ischemia is the cause of precordial S-T segment depression in this setting.

We then compared precordial S-T segment depression to other risk factors reflecting infarct size and left ventricular dysfunction. Our univariate analysis indicated that although mortality was higher in Group A patients, the specificity and predictive value of precordial S-T segment depression for mortality were poor. On multivariate analysis, risk factors such as Killip class, chest X-ray findings, and radionuclide EF were found to have a greater influence on prognosis. Indeed, when these factors were considered, the presence of S-T segment depression did not add prognostic information.

*Conclusion:* The presence of precordial S-T segment depression in acute inferior MI is related to the extent and location of the underlying infarction. These changes do not indicate a separate ischemic process and do not have an independent influence on post-MI prognosis.

I believe that man will not merely endure: he will prevail. He is immortal, not because he alone among creatures has an inexhaustible voice, but because he has a soul, a spirit capable of compassion and sacrifice and endurance.

William Faulkner

# INSTRUCTIONS TO AUTHORS

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY and they become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. The Publisher assumes no liability for any material published in the *Journal.* All accepted manuscripts are subject to editing to aid understanding and conserve space.

**ADDRESS MANUSCRIPTS TO:** William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 6935 Arlington Road, Suite 406, Bethesda, Maryland 20814. The *covering letter* should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make: for example, the elimination of 1 or more figures or tables or a portion of the text to increase the likelihood of publication of their work in the *Journal.* Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The suggested reviewers will be carefully considered along with other experts in the field. Additionally, the editor would listen if the authors provided the names of any investigators they consider unlikely to give nonbiased reviews of their work.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page consisting of the article's title, the names of the authors, and the institution from which the work originated, (2) a second title page including only the article's title, (3) summary, (4) text, (5) references, (6) acknowledgment, (7) figure legends, and (8) tables. Number all pages in the above sequence, beginning with the title page as 1, the summary as 2, and so on (leave the second title page unnumbered). Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references) with at least 25 mm (1 inch) margins.

The second title page, the one which omits the names of the authors and the institution, will permit the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be obtained. The authors may state which type of review they wish in the covering letter.

**TITLE PAGE, SUMMARY, AND ABSTRACT:** Include the first or middle and last names with other initials of all authors. Provide a short *running title* of 3 to 6 words. Insert at the bottom the name and address of the institution from which the work originated, and information about grant support if necessary. Add at the bottom the phrase "*Address for reprints:*" followed by full name and address with zip code. Limit the **summary** to 250 words. Also, submit an **abstract** of 150 words or less to be used in the Table of Contents. List 2 to 6 **key words** for subject indexing at the end of the summary.

**STYLE:** Use appropriate **subheadings** throughout the body of the text, such as in the Methods, Results, and Comments sections. **Abbreviations** are permitted, but no more than 2 or 3 per manuscript. Spell out the first time they appear in the text followed by the abbreviation in parentheses. Consult the *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* published in the *Annals of Internal Medicine* June 1982; 96: 766–771, and also the *Stylebook/Editorial Manual of the American Medical Association* for current usage. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence.

**REFERENCES:** In references, list **all authors,** inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts if possible, but indicate by the abbreviation (*abstr*) when doing so. Do not use periods after authors' initials. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications do not constitute references. In referring to a manuscript that has been submitted but not yet published, use the phrase "unpublished observations" in parentheses.

> **Journal:** Vismara LA, Vera Z, Miller RR, Mason DT. Efficacy of disopyramide phosphate in the treatment of refractory ventricular tachycardia. Am J Cardiol 1977; 39:1027–1034.
>
> **Chapter in Book:** Schiebler GL, Van Mierop LHS, Krovetz LJ. Diseases of the tricuspid valve. In: Moss AJ, Adams F, eds. Heart Disease in Infants, Children and Adolescents. Baltimore: Williams & Wilkins, 1968: 134–139.
>
> **Book:** Berne E. Principles of Group Treatment. New York: Oxford University Press, 1966:26.

**FIGURES:** Submit 3 glossy nonmounted *prints* of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all *charts* (line drawings). Make decimals, broken lines, etc. strong enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by number and title of the article (omit the authors' names so that blinded reviews can be obtained). Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce any previously published figure. Limit figures to the number necessary to present the message clearly. Type each figure legend on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author. If color figures are submitted, identify in the covering letter who should be billed for the color charges.

**TABLES:** Place each table on a separate page, double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate positive or present; a zero (0) for negative or absent, and a dash (—) for "no information available" or "not done."

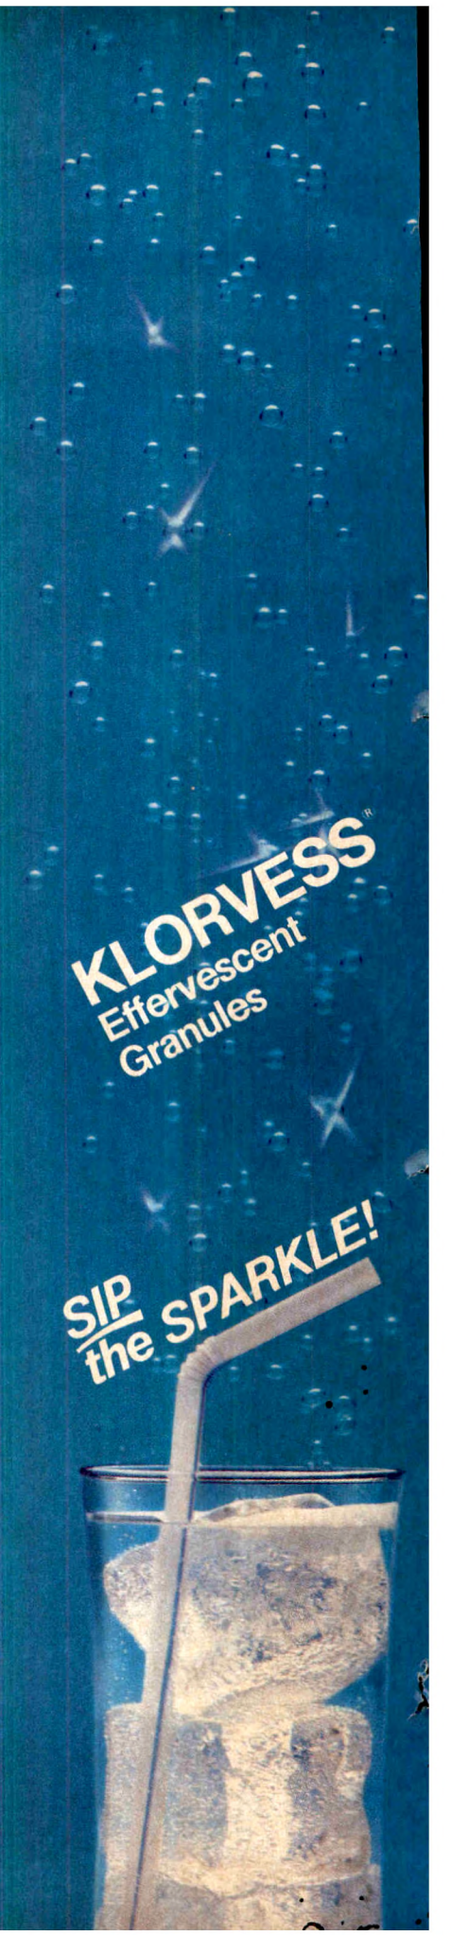
**REPRINTS:** Price schedules and order cards for reprints will be mailed to the author on publication of the article. Individual reprints must be obtained through the author.

# When patients need more potassium than tablets can easily offer...

©1982 Sandoz, Inc.

# Consider the simplicity of KLORVESS® EFFERVESCENT GRANULES

Each packet (2.8 g) provides 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, and L-lysine monohydrochloride 0.913 g.



***The patient on higher doses of antihypertensive medication,*** diuretics and/or digitalis, may need additional potassium supplementation...40 mEq/day or more. KLORVESS Effervescent Granules offer the following advantages:

- ***Each packet delivers 20 mEq of potassium***...compared with slow-release tablets that contain 10 mEq or less.
- ***Sparkling citrus flavor offers a high degree of patient compliance.*** Patients may even use KLORVESS as a "chaser" for other medications. Granules mix easily with cold water...no need for expensive juices to make palatable.
- ***Convenient effervescent granules dissolve almost immediately***...no waiting.
- ***Sugar-free, sodium-free, carbohydrate-free, dye-free formulation***...ideal for hypertensive, diabetic, or overweight patients.

# Give your patients the KLORVESS® sparkle

## Klorvess® Effervescent Granules and Klorvess® (potassium chloride) 10% Liquid

*Brief summary of prescribing information*

**DESCRIPTION:** *Klorvess Effervescent Granules:* Each packet (2.8 g) contains 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, L-lysine monohydrochloride 0.913 g in a sodium-, sugar- and carbohydrate-free effervescent formulation. Dissolution of the packet contents in water provides the potassium and chloride available for oral ingestion as potassium chloride, potassium bicarbonate, potassium citrate and L-lysine monohydrochloride.

*Klorvess (potassium chloride) 10% Liquid:* Each tablespoonful (15 ml) contains 20 mEq of potassium chloride (provided by potassium chloride 1.5 g) in a palatable, cherry-with-pit flavored vehicle, alcohol 1%.

**INDICATIONS:** For the prevention and treatment of potassium depletion and hypokalemic-hypochloremic alkalosis. Deficits of body potassium and chloride can occur as a consequence of therapy with potent diuretic agents and adrenal corticosteroids.

**CONTRAINDICATIONS:** Severe renal impairment characterized by azotemia or oliguria, untreated Addison's disease, Familial Periodic Paralysis, acute dehydration, heat cramps, patients receiving aldosterone-inhibiting or potassium-sparing diuretic agents, or hyperkalemia from any cause.

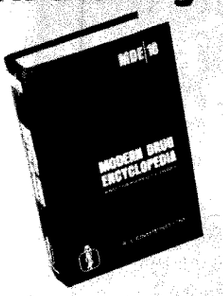
**PRECAUTIONS:** In response to a rise in the concentration of body potassium, renal excretion of the ion is increased. In the presence of normal renal function and hydration, it is difficult to produce potassium intoxication by oral potassium salt supplements. Since the extent of potassium deficiency cannot be accurately determined, it is prudent to proceed cautiously in undertaking potassium replacement. Periodic evaluations of the patient's clinical status, serum electrolytes and the EKG should be carried out when replacement therapy is undertaken. This is particularly important in patients with cardiac disease and those patients receiving digitalis. High serum concentrations of potassium may cause death through cardiac depression, arrhythmia or cardiac arrest. To minimize gastrointestinal irritation associated with potassium chloride preparations, patients should dissolve the packet contents of *Klorvess Effervescent Granules* in 3 to 4 ounces of cold water, fruit juice or other liquid or dilute each tablespoonful of *Klorvess (potassium chloride) 10% Liquid* in 3 to 4 ounces of cold water. Both of these solutions should be ingested slowly with or immediately after meals.

**ADVERSE REACTIONS:** Abdominal discomfort, diarrhea, nausea and vomiting may occur with the use of potassium salts. The symptoms and signs of potassium intoxication include paresthesias, heaviness, muscle weakness and flaccid paralysis of the extremities. Potassium intoxication can produce listlessness, mental confusion, a fall in blood pressure, shock, cardiac arrhythmias, heart block and cardiac arrest. The EKG picture of hyperkalemia is characterized by the early appearance of tall, peaked T waves. The R wave is decreased in amplitude and the S wave deepens; the QRS complex widens progressively. The P wave widens and decreases in amplitude until it disappears. Occasionally, an apparent elevation of the RS-T junction and a cove plane RS-T segment and T wave will be noted in AVL.

**DOSAGE AND ADMINISTRATION:** *Klorvess Effervescent Granules:* Adults—One packet completely dissolved 2 to 4 times daily depending upon the requirements of the patient.

*Klorvess (potassium chloride) 10% Liquid:* Adults—One tablespoonful (15 ml) completely diluted in cold water 2 to 4 times daily depending upon the requirements of the patient.

Both of these solutions should be ingested slowly with meals or immediately after eating.



**OVERDOSAGE:** Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours. In digitalized patients too rapid a lowering of plasma potassium concentration can cause digitalis toxicity.

**HOW SUPPLIED:** *Klorvess Effervescent Granules*—packages of 30 packets (2.8 g each). *Klorvess (potassium chloride) 10% Liquid* (dark red)—as a cherry-with-pit flavored liquid in pint and gallon bottles. Klorvess Effervescent Granules and Liquid are also available in institutional packaging as follows: *Klorvess Effervescent Granules*—packages of 1000 packets; *Klorvess Liquid*—36 (3 x 12) x 4 oz Unit-of-Use bottles and 100 (4 x 25) x 15 ml Unit-Dose bottles.

# How thorough and unbiased is your drug reference?

## If it's not MODERN DRUG ENCYCLOPEDIA, you can't be sure.

### MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 16th Edition

**Arthur J. Lewis,** MD, Executive Editor
**Gertrude Dittus Gonzales,** R.Ph., B.S. Pharm., Executive Editor
**Charles L. Winek,** Ph.D., Contributing Editor

The all new 16th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

**Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:**

- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a-z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension.
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

**The 1,000 page main section** arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

**Three a-z indexes provide** instant access to all the material found in the main section as follows:

- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to read information on prescription drugs.

**Yorke Medical Books**
Box C-757, Brooklyn, New York 11205 AJCC3

Please send me a copy of the all-new 16th Edition of MODERN DRUG ENCYCLOPEDIA. If this new edition is the best drug information reference for practitioners available, I will remit $49.00 plus shipping. Otherwise, I will return it within 30 days and owe nothing.

☐ I am enclosing $49.00 now as full payment.
Publisher pays shipping. Same return guarantee

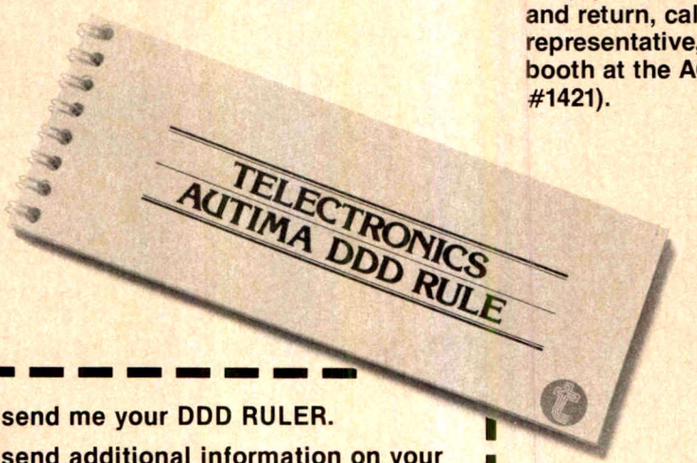
# the first Rule for easy interpretation of Dual Chamber ECG's

# the first DDD pacemaker to give you that rule is Autima by TELECTRONICS

AUTIMA DDD Rule provides easy analysis of "DDD" electrocardiograms.



**The Rule Interprets:**
The function of AUTIMA DDD Pulse Generators operating in a Dual Chamber mode.

**The Rule Measures:**
The V-A and V-V interval for confirmation of programmed standby rate and AV delay.

**The Rule Indicates:**
When the programmed maximum ventricular rate is reached.

**The Rule Displays:**
The PVARP for each combination of standby rate and AV delay.

**For your free AUTIMA DDD RULE, simply fill out the attached card and return, call your nearest representative, or drop by our booth at the ACC (Rivergate #1421).**

☐ **Please send me your DDD RULER.**

☐ **Please send additional information on your AUTIMA DDD PACING SYSTEM**

TELECTRONICS®

A91

## AUTIMA® , Model 2251
## Dual Chamber Pacemaker

**INDICATIONS**
**Indications include:**

1. Maintenance of critical atrial contribution to cardiac output in patients with ranging degrees of A-V block.
2. Generating an increased rate and atrioventricular (A-V) synchrony in cases of heart failure related to bradycardia.
3. Overdriving certain tachyarrhythmias by suppressing ectopic foci in both atrium and ventricle by improvement of cardiac output through A-V synchrony, by entering and blocking reentrant circus loops, and by maintenance of a fixed P-R interval.

**Such indications may include:**

- Symptomatic bradycardia
- Sinus bradycardia with A-V block
- Sick Sinus Syndrome
- Certain drug-resistant reentrant tachycardia
- Atrial and ventricular ectopic arrhythmias

**CONTRAINDICATIONS AND SIDE EFFECTS**
Patients suffering from either atrial fibrillation or atrial flutter, even when well controlled or intermittent, may be detrimentally affected by an atrial sensing mode. A dual chamber pacemaker may also be inappropriate for certain patients with retrograde conduction, as it can lead to a form of tachycardia that is related to the pacing system.

Muscle or nerve stimulation, body rejection phenomena, local tissue reaction, skin necrosis, or embolism and cardiac tamponade may occur as with any implantable pulse generator.

**PRECAUTIONS**
See physicians manual for the effects of electrical/magnetic interference, defibrillation, diathermy, random component failure, and battery depletion.

**For further information**, contact your Telectronics representative or call us toll free at (800) 525-7042. In Colorado call (303) 779-4670.

TELECTRONICS

# CARDIOLOGY: 1982

**The Second Issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery**

*written by:*

**William C. Roberts, M.D.**
*Chief, Pathology Branch/National Heart, Lung & Blood Institute/National Institutes of Health/and Clinical Professor of Pathology & Medicine (Cardiology)/Georgetown University School of Medicine, Washington, D.C.*

**Lawrence H. Cohn, M.D.**
*Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston*

**ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066**

## What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

## CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

***"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended."*** Philip Reichert, M.D. New York State Journal of Medicine, September, 1981

***"...recommend...to any reader interested in the literature of cardiology."*** Irwin R. Callen, M.D. JAMA, November, 1981

**SPECIAL DISCOUNT OFFER**

Place a standing order to receive each edition of CARDIOLOGY: 1982 on 30 day approval and receive a 10% discount on this and all future editions.

☐ **YES,** please enter my standing order for CARDIOLOGY: 1982. I understand that each edition (published once a year) will be automatically shipped to me on 30 day approval, and I will receive a 10% discount on this and all future editions. (1982 edition discount price $40.50)

In Holter studies...

# An office-based system gives you the clinical data you're used to getting...without specially-trained operators.

*After more than six years of development and rigorous clinical evaluation, a microcomputer based system called AEGIS™ is now available for ambulatory monitoring.*

AEGIS has been designed to analyze in real time: ventricular ectopic beats (VEB), ventricular couplets (VC), ventricular tachycardia (VT), supraventricular premature beats (SVPB), and supraventricular tachycardia (SVT). Missed beats, marked pauses, sustained ventricular tachycardia, bradycardia and tachycardia are also differentiated by the system. When the 24-hour monitoring activity is completed, AEGIS provides the attending physician with a comprehensive summary report and confirming rhythm strips in minutes. The system is fully-automated so no specially-trained office staff is required, therefore turnaround time and cost of the procedure are substantially reduced.

**Microcomputer Technology**

The AEGIS Real Time Analyzer, a powerful 8 bit microcomputer system, combines the recording and analyzing activities in one unit that analyzes each heartbeat in real time, detecting, categorizing and counting arrhythmias as they actually occur. Because the analysis is in real time, the system is able to apply substantially more instructions per QRS than much more powerful computer systems operating at 60 to 240 times real time.

**Accurate, consistent arrhythmia detection**

AEGIS analyzes arrhythmias detecting departures in rate, rhythm and morphology from each patient's normal reference. The AEGIS computer can find and reference a patient's "normal" beat in less than two minutes even under a wide variety of difficult conditions such as chronic bigeminy, atrial fibrillation and bundle branch block. Furthermore, the "normal" reference beat is continually updated throughout the analysis period to account for changes in the position of the heart due to body movement.

Abnormal morphologies are detected via both feature extraction and template matching. (AEGIS is unique in its use of both methods of analysis.) When deviations exceed specified criteria, a morphology change is noted.

Rate, rhythm and morphology information is then applied to decision algorithms to determine the classification of each specific morphology change.

**Overcoming problems caused by artifacts**

To overcome the problem of artifacts and interference distorting information, AEGIS utilizes a series of highly refined classification algorithms developed from a data base of several hundred patients with a variety of morphologies, amplitudes and artifacts. A dual channel system, AEGIS also has the unique capability of being able to sense when artifacts are overwhelming the usefulness of information and to switch automatically to the other lead signal for processing.

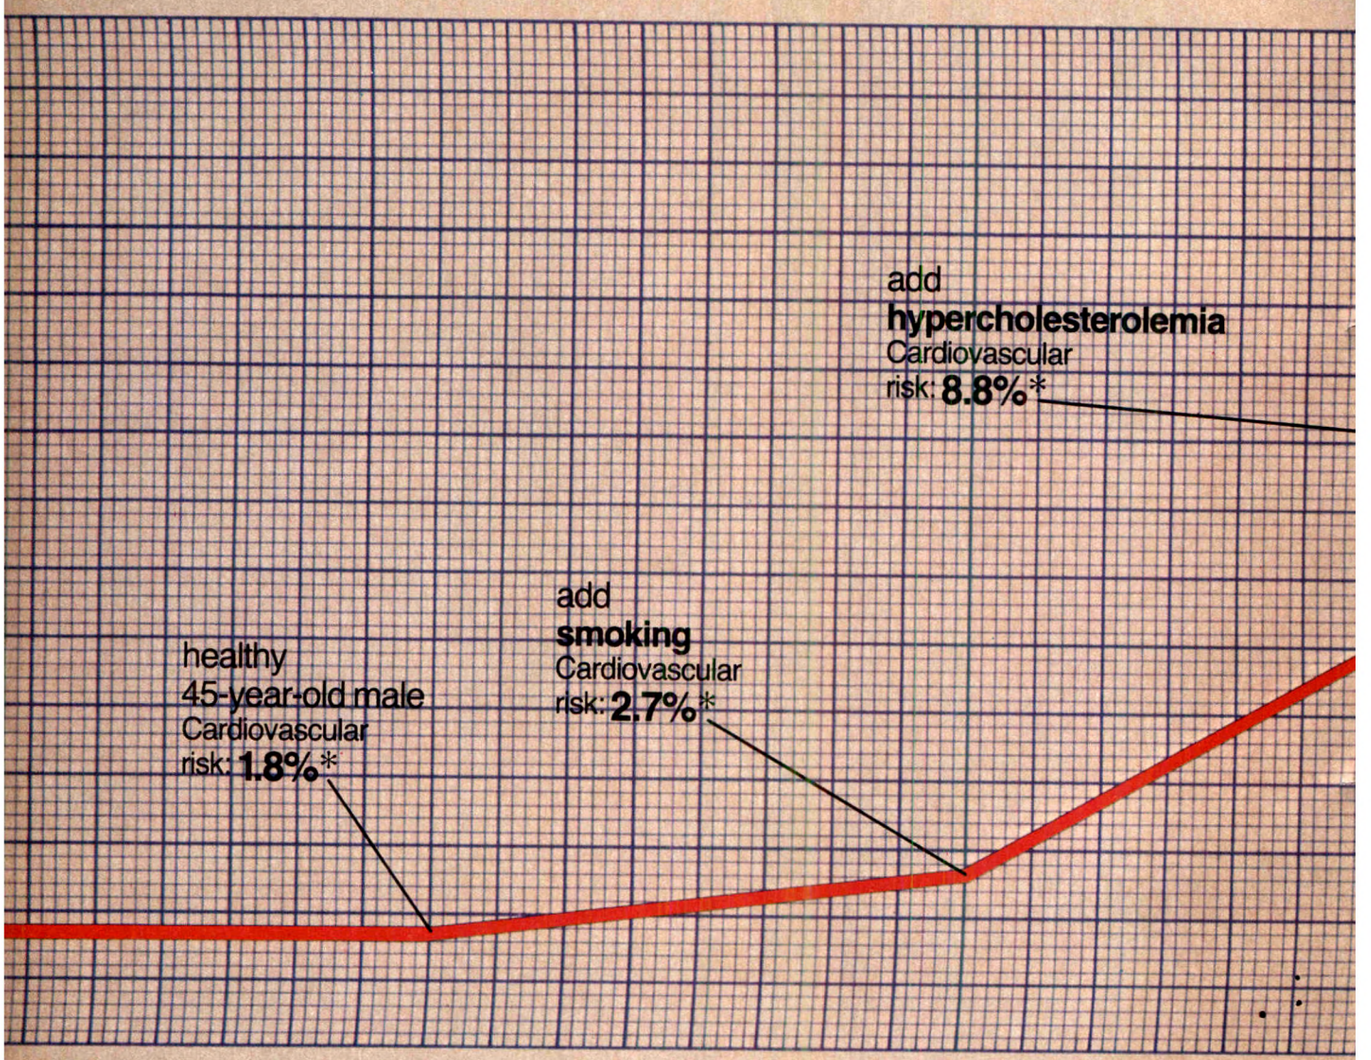
**Decision-making capability**

The AEGIS 8 bit microcomputer system is augmented by an analog preprocessor which performs filtering, automatic gain control and QRS detection functions. Thus, the microcomputer has more time and memory available for real time decision making. In fact, AEGIS is able to apply many more computer cycles in this decision making than far more expensive scanner systems operating at high speeds.

**Simplification**

Because all analysis occurs within the compact 2.2 pound AEGIS Real Time Analyzer, the conventional high-speed scanner is replaced by a simple, automatic playback unit called a Report Generator. The need for a specially trained operator is eliminated.

Also eliminated are the dependence of reports on the qualitative perceptions of individuals and the inaccuracies or inconsistencies that result from operator variability and fatigue.



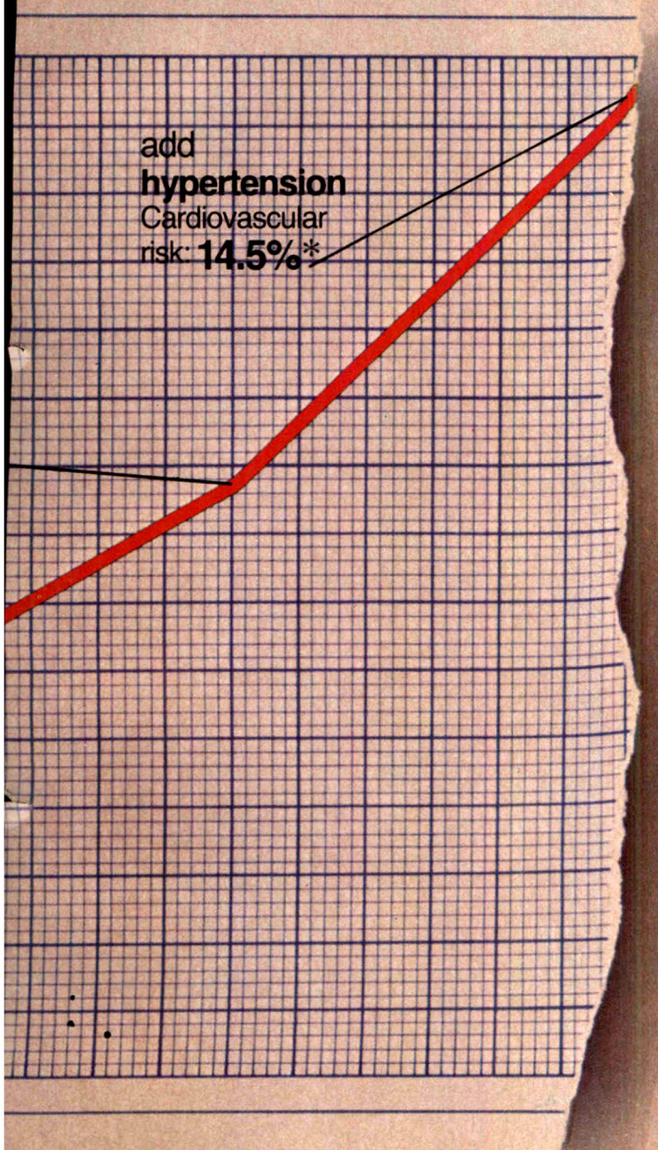
**Advantages to the physician**

The AEGIS System eliminates the turnaround time involved in using a scanning service—diagnostic results are printed in the physician's office, almost immediately.

All components have built-in quality control checks for rigorous verification of the system's integrity. Patient hook-up is identical to that of conventional Holter ECG recording systems; and, with minimal training, anyone can operate the Report Generator. Once begun, the printout process requires no operator attendance and rhythm strips as well as summary categorization reports are completed in minutes.

AEGIS can significantly reduce the cost of complete Holter analysis, and since it is a software based system, the physician can keep it updated as new technological advances are made. **AEGIS Ambulatory Monitoring Systems, Medical Concepts, Inc., Mt. Laurel, NJ 08054 • Call 800-257-5750.**

# In hypertensive patients:



Other risk factors in CHD are diabetes, obesity, lack of exercise, stress, heredity, sex, age, race.

*Percent equals chances in 100 of developing coronary heart disease within 6 years.

Adapted from *Coronary Risk Handbook:* Estimating risk of coronary heart disease in daily practice. 1973, American Heart Assoc., Inc.

# Consider the Risks

▪ When selecting antihypertensive therapy, clinical consideration should be given to the effects of the specific drug on coronary risk factors. Blood pressure control should be achieved without adversely affecting blood lipids.

## Minipress Effectively Controls Hypertension Without Adverse Effect on Blood Lipids†

▪ Minipress effectively treats hypertension. Patients have benefited from the effectiveness of Minipress in over 5 years of clinical use in this country.[1-5]

▪ Minipress has been shown not to have an adverse effect on blood lipids, according to The Oslo Study and other reports.[6-9] Because Minipress lowers high blood pressure and does not produce lipid changes which are potentially atherogenic, it provides your patient with a net reduction in risk.

†Minipress is not indicated for the treatment of hyperlipidemia.

*Please see Minipress brief summary on following page.*

# Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

© 1982, Pfizer Inc.

# Minipress® (prazosin HCl) Capsules 1mg, 2mg, 5mg

## B.I.D. Dosage Convenience

**BRIEF SUMMARY**

**MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use***

**INDICATIONS:** MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.

**WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.**

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.

Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.

More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.

***Usage in Pregnancy:*** Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.

***Usage in Children:*** No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.

**ADVERSE REACTIONS:** The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established.)

Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.

Cardiovascular: edema, dyspnea, syncope, tachycardia.

Central Nervous System: nervousness, vertigo, depression, paresthesia.

Dermatologic: rash, pruritus, alopecia, lichen planus.

Genitourinary: urinary frequency, incontinence, impotence, priapism.

EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.

Other: diaphoresis.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.

In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.

**DOSAGE AND ADMINISTRATION:** The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:

***Initial Dose:*** 1 mg two or three times a day. (See Warnings.)

***Maintenance Dose:*** Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however, a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

***Use With Other Drugs:*** When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

**HOW SUPPLIED:** MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

## INFECTIONS
### IN THE ABNORMAL HOST

Edited by Michael H. Grieco, M.D.
Text by 47 Specialists. Illustrated with 147 Drawings and Photos, 78 in Full Color

**Infections in the Abnormal Host** discusses in 36 revealing chapters the mechanics of host defenses . . . the various underlying disorders and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation.

Consultation and study of **Infections** will help you understand, diagnose, and manage the many infections which strike patients whose defense mechanisms are down.

**Check this list of chapters**

**PART I HOST DEFENSES**

• Introduction to the Abnormal Host and Complicating Infections • The Neutrophil in Host Defense: Congenital, Acquired and Drug-induced Abnormalities • The Complement System in Human Disease • Structure and Function of Immunoglobulins • Human Lymphocyte Subpopulations: Surface, Intracellular, Enzymatic Markers and Functions • Congenital and Acquired Primary Disorders of B and T Lymphocyte Function • Drug-induced B and T Lymphocyte and Monocyte Dysfunction • Cutaneous, Pulmonary, Gastrointestinal and Genitourinary Defense Mechanisms and Relationship to Nosocomial Infections • The Effects of Malnutrition on Host Responses and the Metabolic Sequelae of Infections • Humoral and Cellular Responses to Infection

**PART II INFECTIONS ASSOCIATED WITH THE ABNORMAL HOST**

• Pyogenic Bacterial Infections • Higher Bacterial and Fungal Infections • Mycobacterial Infections • Viral and Chlamydial Infections • Protozoal and Helminthic Infections • Infections Complicating the Transfusion of Blood, Blood Products, Animal Exposure and Animal Products • Infections Complicating the Alcoholic Host • Infections in Parenteral Narcotic and Drug Abusers • Infections Complicating Uremia and Organ Transplantation • Infections in Patients with Neoplastic Diseases • Infections Complicating Diabetes Mellitus • Diagnosis and Treatment of Diffuse Pneumonias • Host Deficiency States and Central Nervous System Infections • Genitourinary Infections • Infections Complicating the Rheumatic Diseases • Endovascular and Prosthetic Implant Infections • Intraocular Manifestations of Systemic Infections • Selected Histopathologic Responses • The Microbiology Laboratory in Diagnosis and Therapy • Infections Complicating Surgical or Functional Splenectomy and Gastrectomy

**PART III MANAGEMENT**

• Antimicrobial Therapy in the Compromised Host: Resistance, Pharmacology and Toxicity • Chemotherapy for Viral and Chlamydial Infections • Chemotherapy for Protozoal and Helminthic Infections • Infection Prevention in Patients with Cancer and Granulocytopenia • Immunologic Reconstitution • Gamma Globulin and Vaccine Therapy • Index

# Radionuclide-Determined Changes in Pulmonary Blood Volume and Thallium Lung Uptake in Patients With Coronary Artery Disease

RICHARD A. WILSON, MD, ROBERT D. OKADA, MD, CHARLES A. BOUCHER, MD, H. WILLIAM STRAUSS, MD, and GERALD M. POHOST, MD

**Exercise-induced increases in radionuclide-determined pulmonary blood volume (PBV) and thallium lung uptake have been described in patients with coronary artery disease (CAD) and have been shown to correlate with transient exercise-induced left ventricular dysfunction. To compare these 2 techniques in the same patients, 74 patients (59 with and 15 without significant CAD) underwent supine bicycle exercise twice on the same day—first for thallium myocardial and lung imaging and then for technetium-99m gated blood pool imaging for the PBV ratio determination. Thallium activity of lung and myocardium was determined to calculate thallium lung/heart ratio. Relative changes in PBV from rest to exercise were expressed as a ratio of pulmonary counts (exercise/rest). Previously reported normal ranges for thallium lung/heart ratio and PBV ratio were used. The PBV ratio and thallium lung/heart ratio were abnormal in 71 and 36%, respectively, of patients with CAD ($p < 0.01$). Both ratios were normal in all patients without CAD. Although the resting ejection fractions did not differ significantly in patients with normal versus those with abnormal PBV ratios or thallium lung/heart ratios, abnormal PBV ratios and thallium lung/heart ratios were associated with an exercise-induced decrease in ejection fraction. Propranolol use was significantly higher in patients with abnormal than in those with normal thallium lung/heart ratios ($p < 0.01$). No significant difference in propranolol use was present in patients with abnormal or normal PBV ratios. In conclusion: (1) the prevalence of an abnormal thallium lung/heart ratio is less than that of the PBV ratio in patients with CAD; (2) both tests are normal in normal control subjects; (3) propranolol does not cause abnormal results in normal control subjects; however, propranolol may influence lung thallium uptake in patients with CAD; and (4) when both tests are abnormal, there is a high likelihood of multivessel disease.**

Exercise-induced changes in pulmonary blood volume (PBV) have been noninvasively determined in patients using multigated blood pool imaging by previous work from this laboratory.[1] Most patients with coronary artery disease (CAD) had an increase in PBV during supine exercise. No such changes were found in patients without CAD and in patients with disease confined to the right coronary artery. The increase in PBV was found to be due to transient exercise-induced left ventricular dysfunction.[2]

Other studies have described increased thallium lung activity on the initial postexercise thallium images in some patients with CAD.[3–5] A study by Boucher et al[3] showed that increased thallium lung activity reflected transient elevations in the pulmonary capillary wedge pressure during exercise and suggested that transient left ventricular failure caused increased thallium lung uptake. Thus, 2 noninvasive radionuclide techniques are now available for the detection of transient left ventricular failure during exercise in patients with CAD. This study compares these 2 techniques in the same patient population. The purposes were to determine (1) the additive prevalence of either or both abnormal ratios in patients with CAD, and (2) the significance of both ratios being abnormal or normal.

From the Cardiac Unit, Massachusetts General Hospital, Boston, Massachusetts. This study was supported in part by Grant HL-21751, HL-07416, and HL-12322 from the National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland. Manuscript received August 6, 1982; revised manuscript received December 3, 1982, accepted December 6, 1982.

## Methods

**Patient population:** We prospectively studied 74 patients (60 men and 14 women) who were referred for evaluation of chest pain syndromes. The mean age was 51 ± 10 (standard deviation) years (range 28 to 75). Patients with congestive heart failure, recent myocardial infarction, unstable angina, or physical disability limiting exercise were excluded. None

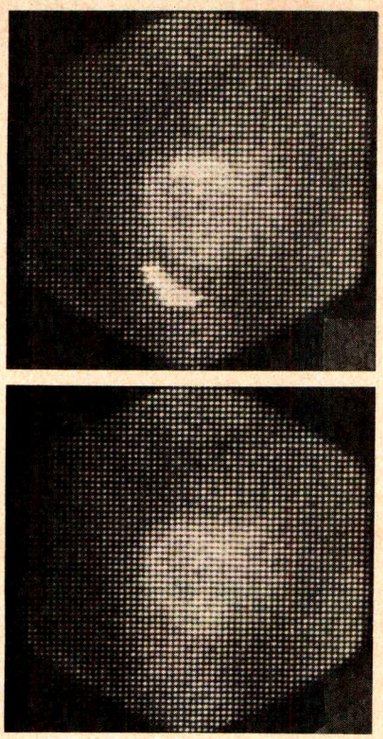

**FIGURE 1.** Representative thallium-201 images of a patient with CAD and increased lung uptake in the anterior projection immediately after maximal supine stress testing. The **bottom image** demonstrates the regions of interest used for the calculation of the lung-to-heart ratio. The patient had significant 3-vessel CAD. The thallium lung-to-heart ratio was 0.78.

of the patients were New York Heart Association functional class III or IV.

**Thallium stress imaging:** Patients were exercised supine in the fasting state on a table equipped with a bicycle ergometer (Cardiac Stress Systems, Engineering Dynamics, Lowell, Massachusetts). Electrocardiographic lead II was monitored continuously during exercise, and leads II, III, aVF, and $V_5$ were monitored at 2- to 3-minute intervals during exercise. Arm cuff blood pressure was recorded every minute. The exercise work load was initiated at 150 kpm/min and increased by 150 kpm/min every 2 minutes until chest pain, dyspnea, leg fatigue, or S-T segment depression ≥2 mm by electrocardiography developed. Thirty seconds before the anticipated termination of exercise, 1.5 mCi of thallous chloride-201 (New England Nuclear, North Billerica, Massachusetts) was injected by way of an indwelling venous catheter. Thallium imaging was performed with the patient in the supine position using an Ohio Nuclear series 120 gamma camera (Ohio Nuclear, Solon, Ohio) equipped with a low energy all-purpose collimator, employing a 30% energy window centered around the 60 to 80 keV mercury x-ray peak of thallium. Imaging was begun immediately after the cessation of exercise. Initial images were collected in a 128 × 128 byte mode matrix format in the anterior and 50° left anterior oblique projections for 6 minutes each. Delayed images were collected at 2 to 3 hours after exercise in the same projections for 6 minutes each. Approximately 200,000 counts were collected per image. Images were collected using a portable cardiac computer system (MUGA-CART, Medical Data Systems, Ann Arbor, Michigan). Field uniformity of the camera was checked and corrected each day using a Cobalt-57 disc source for flood images.

**Exercise gated blood pool imaging:** After the delayed thallium images were obtained, rest and exercise gated blood pool imaging were performed. Three milligrams of stannous pyrophosphate (Pyrolite, New England Nuclear, North Billerica, Massachusetts), followed 30 minutes later by 20 mCi of technetium-99m–labeled pertechnetate, were given intravenously for in vivo labeling of red blood cells. The scintillation camera was repeaked at 140 keV with a 25% window and initial rest studies were performed with the patient in the supine position. Images were recorded in the anterior projection and in the left anterior oblique projection which displayed the ventricular septum most homogeneously (approximately 50° left anterior oblique). Since the technetium-99m photon flux was calculated to be 130 times greater than the thallium photon flux in the technetium energy window, the imaging effects of the previously administered thallium were minimal. The cardiac cycle was divided into 28 equal segments. At least 200,000 counts were collected in each of the 28 frames at rest. Depending on heart rate, imaging time ranged from 5 to 10 minutes. Patients then exercised again to the same endpoints as in the first study. Multigated blood pool images were taken in the 50° left anterior oblique position for 3 minutes during peak exercise. The mean number of counts/frame was 150,000 ± 29,000 (standard deviation) for blood pool images obtained during exercise.

**Lung thallium-201 analysis:** The anterior thallium studies were condensed from a 128 × 128 byte mode matrix to a 64 × 64 word mode matrix and displayed on a cathode ray tube for quantitative analysis. Two independent observers identified a region of interest over 1 of the 3 segments of myocardium in the anterior view (anterolateral, apical, or inferior) with the highest count density and a region of interest over the left upper lung field (Fig. 1). A printout of the counts per picture element for each region of interest was then obtained for the initial thallium images. The mean ± 1 standard deviation total counts in the lung and myocardial regions of interest were 5,152 ± 2,157 and 9,588 ± 4,223, respectively. Lung thallium activity was expressed as a percentage of the maximal myocardial counts for each image (thallium lung/heart ratio). For the purposes of this study, the upper limit of normal for the thallium lung/heart ratio was defined as 2 standard deviations above the mean for a previously reported group of control patients (<0.545).[5]

**Pulmonary blood volume ratio analysis:** The ratio of PBV counts between exercise and rest was determined from the 50° left anterior oblique end-diastolic frame as previously described.[2] The PBV ratio was determined in this projection since this projection is the only one routinely acquired during exercise in most laboratories. Two independent observers determined pulmonary blood volume counts at exercise and rest without knowledge of cardiac catheterization results. The PBV ratio was calculated as the pulmonary counts during exercise divided by counts at rest after correction for differences in acquisition times. Thus, a ratio <1.0 corresponded to a decrease in PBV during exercise, and a ratio >1.0 to an increase in PBV with exercise. The ratios determined by the 2 observers were averaged to produce a single value for each patient. A PBV ratio was considered abnormal if it was ≥1.06, which represents the upper limit of 2 standard deviations above the mean value for a group of previously reported control patients.[1] An example of the regions of interest at rest and exercise used to calculate the PBV ratio is shown in Figure 2.

**Ejection fraction analysis:** The rest multigated blood pool imaging ejection fraction was determined from the left anterior oblique projection utilizing a semiautomatic edge detec-

**TABLE I Percentage of Patients With Abnormal Thallium Lung/Heart Ratios and Pulmonary Blood Volume Ratios in Groups of Patients With and Without Coronary Artery Disease**

| | n | % of Patients With Abnormal Tl L/H | % of Patients With Abnormal PBV |
|---|---|---|---|
| No CAD | 15 | 0 | 0 |
| Single-vessel RCA | 6 | 33 | 17 |
| Single-vessel LAD or CIRC | 15 | 27 | * 73 |
| 2- or 3-Vessel | 38 | 39 | * 79 |
| All CAD | 59 | 36 | * 71 |

CAD = coronary artery disease; CIRC = circumflex coronary artery disease; LAD = left anterior descending coronary artery disease; RCA = right coronary artery disease; Tl L/H = thallium lung/heart ratio.
Brackets indicate statistically significant differences between groups ($p < 0.05$).
* $p < 0.05$.

tion program. A box was positioned to encompass the entire left ventricle at end-diastole. Beginning at the center of the ventricle, the program searched outward in a radial fashion until a matrix point was reached that satisfied 1 of 2 criteria. The first criterion was that the 2-dimensional second derivative be equal to zero. The second criterion was that the number of counts at a matrix point be less than a given threshold value selected by the observer. In this manner, the left ventricular edge was defined for each frame. A background region of interest was selected by the program for a region outside the end-systolic frame. The ejection fraction was calculated as end-diastolic counts minus end-systolic counts divided by end-diastolic count minus background counts.

**Cardiac catheterization and angiography:** All patients underwent left heart catheterization, coronary angiography, and left ventriculography within 1 week of the radionuclide studies. Coronary arteriograms were read by 2 independent observers. Significant stenosis was defined as ≥50% reduction in the intraluminal diameter of a coronary artery in at least 2 projections.

**Statistical analysis:** Comparisons of patient groups with normal or abnormal PBV ratios and thallium lung/heart ratios were made using chi-square analysis or Fisher's exact test. Data for groups of patients were expressed as mean ± standard error of the mean. Comparison between quantitative thallium lung/heart ratios and between PBV ratios and patient groups was made by a one-way analysis of variance and the Newman-Keuls multiple comparison test.

## Results

**Clinical and angiographic findings:** Of the 74 patients, 59 had significant CAD: 21 patients had single-vessel CAD (15 had isolated left anterior descending or circumflex CAD and 6 had isolated right CAD) and 38 patients had multivessel (2- or 3-vessel) CAD. Forty-one patients with and 5 patients without CAD were taking propranolol during the study period. Twenty-eight patients with CAD had a history of previous myocardial infarction.

**Thallium lung/heart ratio analysis:** Table I shows the percentage of patients with abnormal thallium lung/heart ratios in groups of patients with CAD. All 15 patients (100%) with no significant CAD had normal thallium lung/heart ratios using a previously reported

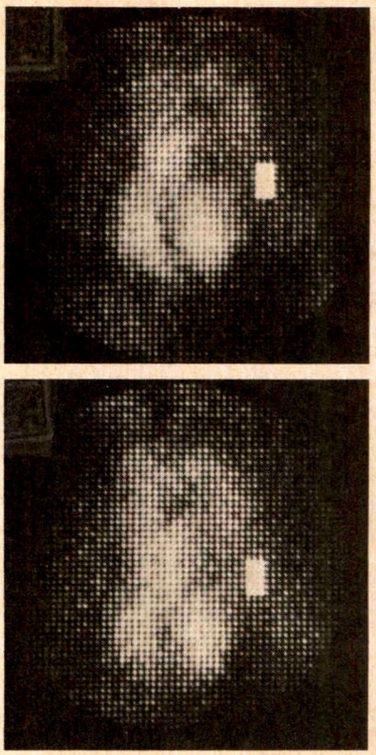

**FIGURE 2.** End-diastolic frames from multigated blood images recorded in the left anterior oblique position at rest (**top**) and peak exercise (**bottom**). Regions of interest are included. The ratio of pulmonary blood volume during exercise compared with that at rest was 1.10 in this patient with CAD. Note that this exercise-induced increase in pulmonary activity is not apparent on visual comparison of the images at exercise and rest.

normal range. Of the 59 patients with significant CAD, 21 (36%) had abnormal thallium lung/heart ratios. The percentage of patients with abnormal thallium lung/heart ratios in the group with no CAD was significantly different from (1) the group with single-vessel left anterior descending or circumflex disease (27%), (2) the group with multivessel disease (39%) ($p < 0.05$), and (3) the group of patients with CAD as a whole (36%) ($p < 0.01$). The prevalence of an abnormal thallium lung/heart ratio was not significantly different in patients with a history of a previous myocardial infarction (39%) and those without such a history (32%).

Figure 3 shows the thallium lung/heart ratios (mean ± standard error of the mean) for groups of patients. There were significant differences between the normal (no CAD) group (0.37 ± 0.02) and (1) the group with CAD as a whole (0.50 ± 0.01) ($p < 0.001$), (2) the group with single-vessel left anterior descending or circumflex disease (0.48 ± 0.03) ($p < 0.01$), and (3) the group with multivessel disease (0.52 ± 0.02) ($p < 0.01$). Although the thallium lung/heart ratio tended to be lower for patients with disease confined to single-vessel right CAD (0.44 ± 0.04) than for those with multivessel disease (0.52 ± 0.02), these differences did not reach statistical significance.

**Pulmonary blood volume ratio analysis:** Table I indicates the percentage of patients with abnormal PBV ratios for each group. All 15 normal subjects (100%) had PBV ratios that were within the previously reported normal range from this laboratory. Of the 59 patients with significant CAD, 42 (71%) had abnormal PBV ratios. The percentage of patients with abnormal PBV ratios with CAD confined to the right coronary artery (17%) was significantly lower than the percentage of patients with abnormal results and either single-vessel left anterior descending or circumflex CAD (73%) or multivessel disease (79%) ($p < 0.05$). The prevalence of an abnormal PBV ratio was not significantly different in patients with a history of a previous myocardial infarction (68%) and those without such a history (74%).

Figure 4 demonstrates the PBV ratio for the different patient groups. There were significant differences in the PBV ratios in normal patients ($0.96 \pm 0.01$) compared with patients with either single-vessel left anterior descending or circumflex disease ($1.15 \pm 0.04$) ($p < 0.01$), or compared with patients with multivessel CAD ($1.13 \pm 0.04$) ($p < 0.05$). Although the PBV ratios for single-vessel right CAD ($1.00 \pm 0.04$) tended to be lower than the PBV ratios for either single-vessel left anterior descending or circumflex disease ($1.15 \pm 0.04$) or for multivessel disease ($1.13 \pm 0.04$), these differences did not reach statistical significance.

**Pulmonary blood volume and thallium lung/heart ratios:** PBV ratios were abnormal in 42 of 59 (71%) while thallium lung/heart ratios were abnormal in 21 of 59 (36%) patients with significant CAD ($p < 0.001$) (Table I). The combined prevalence of either an abnormal PBV or thallium lung/heart ratio (81%) was higher than the prevalence of an abnormal PBV ratio alone (71%) in the patients with CAD. However, the ratios were both normal in all normal controls. PBV ratios were abnormal in 1 of 6 (17%) patients, and thallium lung/heart ratios were abnormal in 2 of 6 patients with single-vessel right CAD. However, PBV ratios in patients with single-vessel left anterior descending or circumflex disease were more likely to be abnormal compared with thallium lung/heart ratios in the same group (11/15 = 73% and 4/15 = 27%, respectively) ($p < 0.05$). Similarly, the PBV ratio was more likely to be abnormal in patients with multivessel disease (30/38 = 79%) compared with the thallium lung/heart ratio (15/38 = 39%) ($p < 0.001$).

Thirteen of 15 CAD patients (87%) with an abnormal PBV and thallium lung/heart ratio, 20 of 33 CAD patients (64%) with either an abnormal PBV or thallium lung/heart ratio, and 5 of 11 CAD patients (45%) with neither an abnormal PBV nor thallium lung/heart ratio had multivessel CAD ($p < 0.05$). Thus, there was a very high likelihood of multivessel disease when both the PBV and thallium lung/heart ratios were abnormal.

**Ejection fraction analysis:** The mean resting left ventricular ejection fraction seen by gated blood pool imaging was $65.0 \pm 2.1\%$ for the patients without CAD and $63.0 \pm 1.5\%$ for all the patients with CAD (difference not significant [NS]). The mean resting ejection fraction for patients with isolated right CAD ($70.5 \pm$

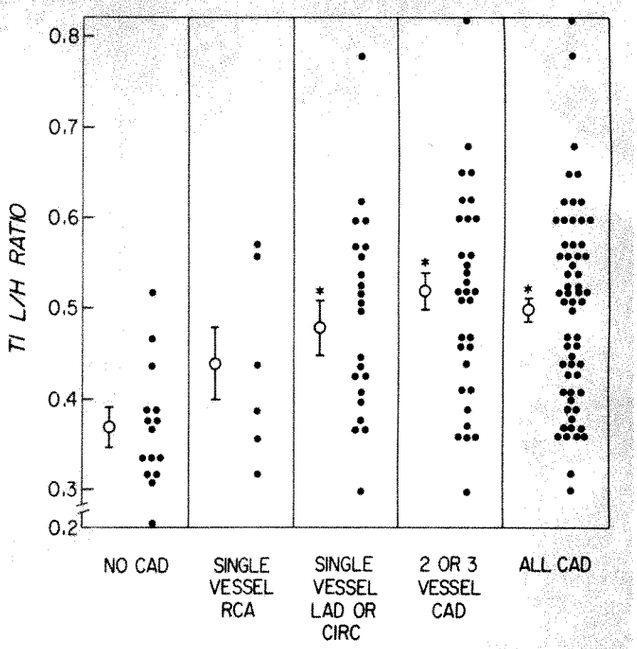

**FIGURE 3.** Pulmonary blood volume (PBV) ratios (exercise PBV/rest PBV) in patients with and without coronary disease (no CAD = no significant CAD; single-vessel LAD or CIRC = single-vessel left anterior descending or circumflex CAD; 2- or 3-vessel CAD = multivessel CAD; all CAD = all patients with significant CAD). * $p < 0.05$ compared with the no CAD group. TI L/H Ratio = thallium lung/heart ratio.

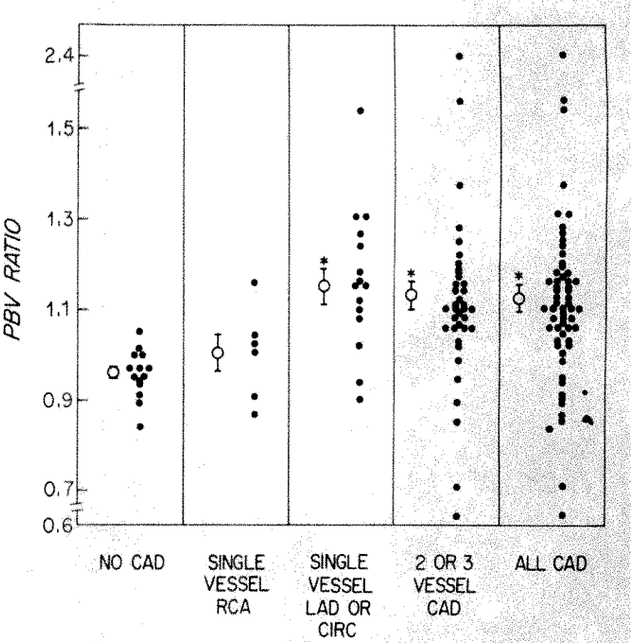

**FIGURE 4.** Thallium lung-to-heart ratios on the immediate postexercise image for patients with and without CAD (no CAD = no significant CAD; single-vessel RCA = significant CAD confined to the right coronary artery; single-vessel LAD or CIRC = significant single-vessel CAD confined to either the left anterior descending or circumflex coronary arteries; 2- or 3-vessel CAD = significant CAD involving 2 or 3 major coronary arteries [RCA, LAD, CIRC]; all CAD = all patients with significant CAD). Values are expressed as mean ± standard error of the mean for each group. * $p < 0.01$ compared with no CAD group.

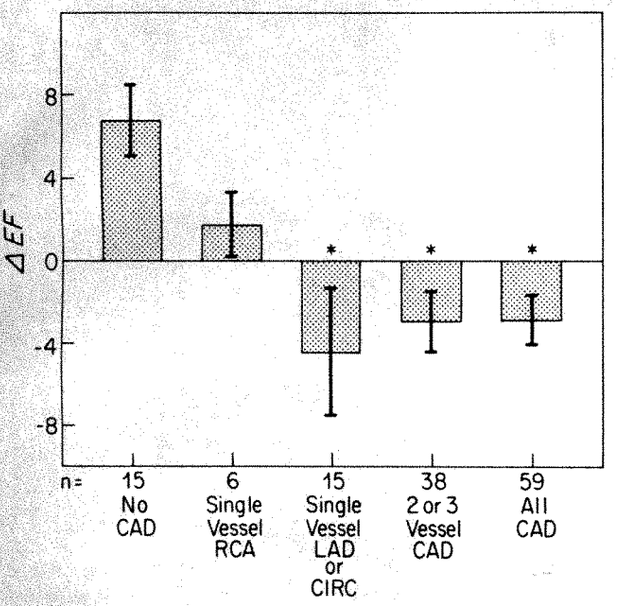

**FIGURE 5.** Change in the ejection fraction from rest to exercise (ΔEF %) (the rest ejection fraction minus exercise ejection fraction) in groups of patients (no CAD = no significant CAD; single-vessel RCA = CAD confined to the right coronary artery; single-vessel LAD or CIRC = CAD confined to the left anterior descending or circumflex coronary arteries; 2- or 3-vessel CAD = multivessel CAD; all CAD = all patients with significant CAD). Values are expressed as mean ± standard error of the mean for each group. * $p < 0.05$ compared with no CAD group.

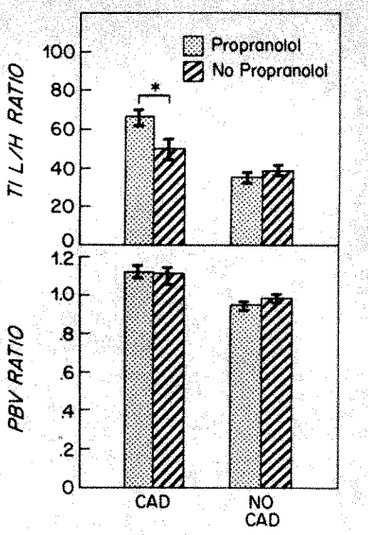

**FIGURE 6.** Effects of propranolol on thallium lung/heart (Tl L/H) and PBV ratios. Patients who were or who were not taking propranolol were grouped according to the presence (CAD) or absence (no CAD) of significant CAD. The thallium lung/heart ratio of patients with CAD who were taking propranolol was significantly higher than the thallium lung/heart ratio of patients not receiving propranolol (* $p < 0.001$), respectively. Values are expressed as mean ± standard error of the mean.

2.2%) was significantly higher than the mean resting ejection fraction for patients with multivessel CAD (61.1 ± 1.8%) ($p < 0.01$) but not isolated left anterior descending or circumflex CAD (64.9 ± 3.7%) (p = NS). However, the change in the ejection fraction from rest to exercise was significantly different in patients with and without CAD (Fig. 5). Patients without CAD and those with single-vessel right CAD had an increase in the ejection fraction with exercise. Patients with either single-vessel left anterior descending or circumflex disease or patients with multivessel disease had a decrease in the ejection fraction with exercise ($p < 0.05$ compared with normal subjects). The resting ejection fraction was not significantly different in the patients with normal or abnormal thallium lung/heart ratios or PBV ratios. However, the change in ejection fraction from rest to exercise was significantly lower in patients with abnormal than in those with normal thallium lung/heart ratios (−4.5 ± 1.8 and +0.6 ± 1.4, respectively) ($p < 0.05$) and in patients with abnormal than in those with normal PBV ratios (−3.4 ± 1.6 and +2.5 ± 1.4, respectively) ($p < 0.01$).

**Effect of propranolol on thallium lung/heart ratios and pulmonary blood volume ratios:** Of the 74 patients, 46 (62%) were taking propranolol at the time of the study. Of these 46, 5 had normal coronary arteries and 41 did not. The thallium lung/heart ratios of the patients taking propranolol were significantly higher than the thallium lung/heart ratios of the patients not taking propranolol (Fig. 6). However, the PBV ratios of patients receiving propranolol were not significantly different from those in patients not taking propranolol. The age, resting ejection fraction, the change in ejection fraction with exercise, and the number of diseased coronary arteries were not significantly different in the patients with CAD taking propranolol and those not receiving propranolol (Table II). However, the percentage of the maximal age-predicted heart rate achieved during exercise was significantly lower in patients taking propranolol than in those not taking propranolol ($p < 0.001$). Of the 21 patients with abnormal thallium lung/heart ratios, 19 (90%) were taking propranolol at the time of the study. This percentage was significantly different from the 51% (27 of 53) of patients with normal thallium lung/heart ratios who were receiving propranolol ($p < 0.01$). However, the percentage of patients with abnormal PBV ratios who were taking propranolol—69% (29 of 42)—was not significantly different from the 53% (17 of 32) of patients with normal PBV ratios who were receiving propranolol.

Of the 15 patients with no significant CAD, 5 were taking propranolol and 10 were not. None of the 15 had abnormal PBV or thallium lung/heart ratios. The thallium lung/heart ratios of the 5 patients receiving propranolol were not significantly different from the 10 patients not taking propranolol (0.36 ± 0.02 and 0.39 ± 0.03, respectively) (Fig. 6). In addition, the PBV ratios of the 5 patients taking propranolol were not significantly different from the 10 patients not taking propranolol (0.95 ± 0.02 and 0.98 ± 0.02, respectively). Age, resting ejection fraction, change in ejection fraction from rest to exercise, and percentage of age-predicted

maximal heart rate achieved were not different in normal patients who were taking or who were not taking propranolol (Table III). The percentage of patients with CAD taking propranolol with abnormal thallium lung/heart ratios was significantly higher than the percentage of patients not receiving propranolol with abnormal thallium lung/heart ratios (Table IV). There was no significant difference in the percentage of patients who were and who were not taking propranolol with abnormal PBV ratios.

## Discussion

**Pulmonary blood volume ratio:** The results of this study indicate that increases in radionuclide-determined PBV during exercise in patients with CAD are common, occurring in 71% of patients. Factors that may increase PBV include decreases in myocardial contractility,[6–10] increases in left ventricular diastolic stiffness,[11] and diminished left ventricular relaxation.[12] By increasing left ventricular end-diastolic pressure, these factors may cause an increase in pulmonary venous pressure[8,10,13–18] and volume.[19] Two previous studies, 1 using upright exercise and carbon-11–labeled carbon monoxide inhalation,[20] and the other using supine exercise and an invasive indicator-dilution technique,[21] have shown increases in PBV with exercise in patients with CAD. A more recent study from this laboratory using gated blood pool imaging with technetium-labeled red blood cells also found significant increases in PBV ratio with exercise in patients with CAD.[1]

In the present study, the 6 patients with single-vessel right CAD tended to have a normal PBV ratio (only 1 of 6 patients had an abnormal PBV ratio). It is postulated that this finding is due to exercise-induced right ventricular ischemia which decreases right ventricular function more than left ventricular function, thereby preventing an increase in PBV ratio.[1] In support of this hypothesis is the observation that patients with 2-vessel disease involving the right coronary artery tended to have lower PBV ratios than patients with 2-vessel disease not involving the right coronary artery.[1] Also, patients with right CAD have been shown to have an exercise-induced decrease or no change in the right ventricular ejection fraction while patients without right CAD tend to have increased right ventricular ejection fractions.[22,23] However, abnormal right ventricular performance with exercise may also be related to an abnormal left ventricular response to exercise.[24]

**Thallium lung/heart ratio:** Increased lung thallium activity has been qualitatively[3,4,25,26] observed and quantified[4,5] on initial myocardial images in patients with CAD after treadmill[4,25,26] and supine bicycle exercise.[5] Although the thallium-201 pulmonary extraction fraction is normally 9% on the initial transit through the pulmonary vasculature,[26–30] a previous study has shown that increased lung extraction of thallium occurs in a model of left heart failure in which left atrial pressure or pulmonary transit time or both were increased.[4] Furthermore, Boucher et al[3] have

CAD = coronary artery disease; NS = not significant.

shown that increased thallium lung activity occurred in patients with simultaneously measured increases in the pulmonary capillary wedge pressure during exercise. In that study, the mean value of the pulmonary capillary wedge pressure during exercise in the group of patients with increased thallium lung activity was 24 ± 3 mm Hg (mean ± standard deviation). This degree of pressure elevation has been shown to cause transudation of fluid into the pulmonary interstitial space,[21] thus raising the possibility that thallium may also leave the pulmonary intravascular compartment in response to elevated pulmonary capillary wedge pressures. Although direct evidence for the location of thallium uptake in the lungs has not yet been obtained, it has also been noted[3] that the clearance of thallium from the lung within 2 hours is consistent with the known rapid clearance of interstitial lung water.[31] It is unlikely that the increased pulmonary activity is due to blood pool activity since the extraction efficiency of thallium from the blood is 85% on each pass through the circulation and since no activity is seen in the left ventricular cavity. It also appears unlikely that the increases seen in the thallium lung/heart ratio in this and in previous studies[3–5] are due mainly to a decrease in myocardial counts since Bingham[4] found little decrease in absolute myocardial counts used in the denominator of the ratio. It is possible, however, that global ischemia due to severe 3-vessel CAD could result in diminished thallium uptake in all areas of myocardium so that the thallium lung/heart ratio would be elevated.

**Combined pulmonary blood volume and thallium lung/heart ratio results:** In the present study, the PBV ratio was abnormal in 71% of patients with CAD, while the thallium lung/heart ratio was abnormal in 36% of patients with CAD. At least 1 of the 2 ratios was abnormal in 81% of patients with CAD. Both ratios were normal in all of the normal patients without CAD. Thus, the finding of either or both ratios being abnormal is associated with a high likelihood of CAD, whereas the finding of both ratios being normal is associated with a low likelihood of CAD. The current study also demonstrates that when both ratios are abnormal, there is a high likelihood of multivessel disease.

The lower prevalence of abnormal thallium lung/heart ratios in patients with CAD compared with the PBV ratio requires further investigation. Several possible reasons for the different prevalences exist: (1) The PBV ratio detects excess blood volume in the pulmonary vasculature which occurs rapidly with increasing left ventricular end-diastolic pressure. However, the thallium lung/heart ratio may depend on uptake of thallium by the lung which may take longer. (2) The thallium lung/heart ratio uses only the initial postexercise image while the PBV ratio uses rest and exercise images, which tends to cancel out some of the random variables in the determination of the PBV ratio. In addition, the thallium may not have been injected at peak exercise. (3) The thallium lung/heart ratio often uses the anterolateral myocardial wall activity for the denominator of the ratio. If this myocardial region is contaminated by overlying lung activity, thereby making the denominator of the ratio larger, the ratio would tend to be smaller because the lung counts contribute to the myocardial region of interest, thus contributing to a lower prevalence of an abnormal result. (4) Rapid washout of thallium from the lung would also tend to lower the thallium lung/heart ratio if the initial set of images were delayed since the lung thallium content has already decreased. (5) Less stringent upper limits of normal (±2 standard deviations above the mean) may also increase the prevalence of an abnormal thallium lung/heart ratio in patients with CAD; however, this may also be accompanied by an increased incidence of abnormal results in patients without CAD.

Although our results were obtained in patients with coronary artery disease, patients with other diseases affecting the left ventricle would also be expected to demonstrate abnormal PBV and thallium lung/heart ratios. Exercise-induced increases in left ventricular filling pressure would also be expected in patients with volume or pressure overload states, or in patients with decreased left ventricular compliance such as those with cardiomyopathies or constrictive conditions.

**Effect of propranolol on thallium lung/heart ratios and pulmonary blood volume ratios:** Patients taking propranolol at the time of the study were found to have higher thallium lung/heart ratios than patients not receiving propranolol. This difference may be due to patients with more symptoms, more severe disease, or both, being treated with propranolol so that this observation could be explained without invoking a direct causal effect of propranolol on the thallium lung/heart ratio. However, there was no significant difference in the PBV ratio in patients taking or not taking propranolol. Thus it appears that propranolol may affect the thallium lung/heart ratio determination but cause little or no effect on the PBV ratio. The lower heart rate attained during exercise in patients receiving propranolol may have resulted in a lower cardiac output, prolonged pulmonary transit time, and increased contact time of the thallium bolus with the lungs[4] compared with patients with CAD not taking propranolol. Such an increased transit time has been shown to increase lung thallium uptake in experimental models.[4] On the other hand, such an increased transit time would not be expected to change the PBV ratio.

Although propranolol may influence the thallium lung/heart ratio in patients with CAD, it did not appear to influence the thallium lung/heart ratio in patients without significant CAD. However, the small number of normal patients in this study does not allow the exclusion of the possibility that a larger group of normal patients receiving propranolol may show statistically higher thallium lung/heart or PBV ratios (or both) than normal patients not taking propanolol.

*In summary*, in the population studied, abnormal PBV ratios and abnormal thallium lung/heart ratios are quite specific markers of CAD. An abnormal PBV ratio is more prevalent in patients with CAD compared with an abnormal thallium lung/heart ratio. When both ratios are abnormal in the same patient, there is a high likelihood of multivessel CAD. Propranolol may influence the thallium lung/heart ratios in patients with significant CAD.

**Acknowledgment:** We express our appreciation to Maureen McCarthy, Daniel Merrill, and William Shea for their excellent technical assistance, and to Kathy Hogan and Betty LaMarca for excellent secretarial work.

# Sinus Node Coronary Arteries Studied With Angiography

MICHAEL K. KYRIAKIDIS, MD, COSTAS B. KOUROUKLIS, MD, JOHN T. PAPAIOANNOU, MD, STAMATIS G. CHRISTAKOS, MD, GEORGE P. SPANOS, MD, and DIMITRIS G. AVGOUSTAKIS, MD

**Coronary angiograms of 309 consecutive patients undergoing coronary angiography were reviewed to investigate the blood supply to the sinus node area. Blood was supplied from the right coronary artery in 59% of cases, from the left coronary artery in 38%, and from both coronary arteries in 3%. The posterior sinus node artery was demonstrated in 32 patients (27% of the 119 patients with the sinus node artery originating from the left circumflex and 10.5% of all patients).**

Since its original description by Keith and Flack,[1] the sinus node has been known to have a special arterial blood supply. Many postmortem studies have demonstrated that the sinus node artery (SNA), which is the largest atrial coronary branch, originates from the right coronary artery in approximately 60% of hearts and from the left circumflex in the remaining 40%.[2–7] Of 300 human hearts studied at necropsy, Nerantzis and Avgoustakis[7] observed a posterior sinus node artery (which they named "the S-shaped sinus node artery") in 21% of the cases in which the sinus node artery arose from the left circumflex artery. The present angiographic study was undertaken to investigate the blood supply to the sinus node area.

## Methods

We reviewed our hospital records and the coronary arteriograms of 309 consecutive patients who underwent coronary arteriography between April 1980 and December 1981. Of the 309 patients, 205 had coronary heart disease and the remaining 104 had valvular heart disease. There were 232 male and 77 female patients ranging in age from 19 to 70 years (mean 51). Coronary arteriography was performed with either the Sones or Judkins technique in standard projections.

The origin and course of the sinus node artery as demonstrated in postmortem studies was as follows. The right sinus node artery originated from the proximal right coronary artery, passed across the anteromedial wall of the right atrium, and penetrated the atrial septum below the interatrial bundle. The left sinus node artery arose from the proximal portion of the left circumflex and coursed through the anterior ramus of the interatrial muscle bundle and then through the bundle itself. The posterior sinus node artery arose from the left circumflex artery at any point throughout its length, curved gently upward and backward in the region of the left atrium between the atrial appendage and the left superior pulmonary vein, and reached the atrial septum. From the atrial septum each of these types reached the base of the superior vena cava which it encircled as it penetrated the center of the sinus node.[3,8]

## Results

In the 309 patients studied, 261 had a right dominant coronary arterial system (posterior descending artery originating from the right coronary artery), 45 had a left dominant coronary arterial system (posterior descending artery originating from the left circumflex), and 3 had a balanced type with 2 posterior descending arteries, 1 arising from the right coronary artery and 1 from the left circumflex.

The sinus node artery originated from the right coronary artery in 182 patients (59%), the left circumflex

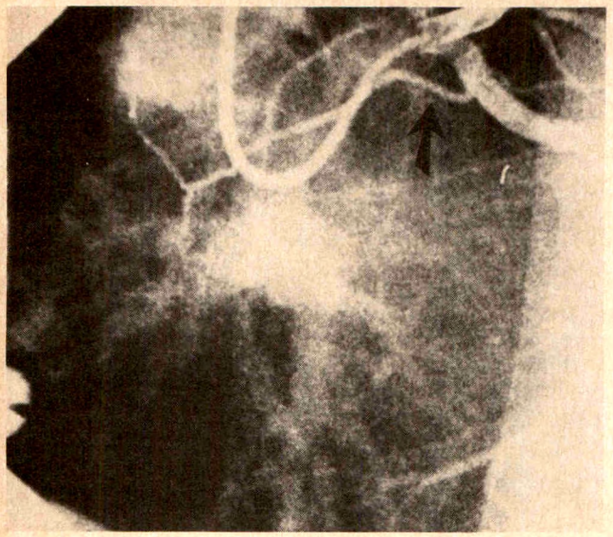

**FIGURE 2.** Left coronary arteriogram in the left anterior oblique projection. The sinus node artery (**arrow**) arises from the proximal portion of the left circumflex artery and courses cephalad along the body of the left atrium, behind the aorta, to the sinoatrial node.

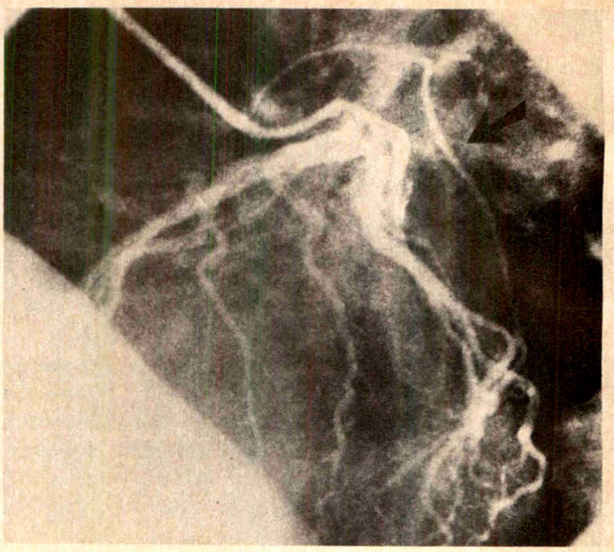

**FIGURE 3.** Left coronary arteriogram in the left anterior oblique projection showing the posterior sinus node artery (**arrow**) arising from the posterolateral part of the left circumflex and passing below the lower left pulmonary vein to the sinoatrial node.

in 119 patients (38%), and both coronary arteries in 8 patients (3%).

The posterior sinus node artery was found in 32 patients (27% of the 119 patients with the sinus node artery originating from the left circumflex and 10.5% of all patients). The posterior sinus node artery constituted the sole arterial blood supply to the sinus node in 26 of the 32 cases, and in the remaining 6 there were 2 sinus node arteries arising from both the right coronary artery and the left circumflex.

The posterior sinus node artery originated from the upper part of a divided left circumflex in 10 cases. It constituted a branch of the left circumflex in 16 cases and in 6 it formed the main continuation of this artery, following in every case the same basic route to the sinus node area.

## Discussion

A detailed knowledge of the atrial circulation and its anatomy is important for a better understanding of cardiac physiology and from a surgical point of view. Fainting, syncope, and cardiac arrhythmias are characteristic clinical features of acute infarcts because of transient ischemia of the sinus node.[9,10] Incisions in the right or left atrial wall during mitral valve surgery, clamping and excision of the right atrial appendage as during closed operation on the mitral valve, or insertion of a decompression catheter into this region may result in damage to the sinus node artery.[8]

The sinus node artery has 3 anatomic variations demonstrating a different origin, course, and relation to the surrounding structures.[8] The right sinus node artery originates from the right coronary artery (Fig. 1), passes across the anteromedial wall of the right atrium, and then surrounds the superior vena cava, giving branches to the sinus node and the near tissues. The left sinus node artery arises from the proximal portion of the left coronary artery (Fig. 2) and courses through the anterior wall of the left atrium to reach the sinus node. The posterior sinus node artery originates from the posterolateral part of the left coronary artery (Fig. 3) and courses over the lateral wall of the left atrium between the atrial appendage and the left superior pulmonary vein ending in the sinus node area. The posterior sinus node artery constitutes a branch of the left circumflex, an upper part of a divided left circumflex artery, or in the minority of cases a main continuation of the left circumflex artery.[7]

# Beneficial Effects of Ibuprofen in Pacing-Induced Myocardial Ischemia

PAUL WALINSKY, MD, J. BRYAN SMITH, PhD, ALLAN M. LEFER, PhD, and LESLIE WIENER, MD

**Lysosomal membrane instability and platelet activation are both associated with acute myocardial ischemia. The effect of ibuprofen on cathepsin D as a marker of lysosomal membrane "leakiness" and thromboxane $B_2$ as a marker of platelet activation was evaluated in 44 patients with angina pectoris. Samples of blood analyzed for cathepsin D, thromboxane $B_2$, and lactate were withdrawn from the coronary sinus and brachial artery before and after pacing to 140 beats/min for 4 minutes. Myocardial ischemia was assessed by determination of transmyocardial lactate extraction or production. Ibuprofen (800 mg) or placebo was administered orally 2 hours before cardiac catheterization. Patients were classified into 4 groups on the basis of administration of placebo or ibuprofen and the presence or absence of myocardial ischemia as determined by demonstration of lactate extraction or production after atrial pacing.**

**In patients with lactate extraction, no significant efflux of cathepsin D or thromboxane $B_2$ occurred after pacing. In patients with lactate production given placebo, a 64 ± 25% increase in the thromboxane $B_2$ level and a 113 ± 37% increase in cathepsin D activities occurred in the coronary sinus effluent sampled after pacing. In contrast, in patients with comparable coronary artery disease and comparable lactate production who were given ibuprofen, no release of thromboxane $B_2$ ($p = 0.05$ compared with patients given placebo) or cathepsin D ($p < 0.01$ compared with patients given placebo) occurred after pacing-induced ischemia. These findings suggest that ibuprofen stabilizes membranes and prevents platelet-activated release of thromboxane $A_2$ in pacing-induced myocardial ischemia.**

Sampling of coronary venous efflux after atrial pacing has been an effective clinical means of understanding metabolic changes and pathophysiologic mechanisms that accompany myocardial ischemia. We previously demonstrated coronary venous efflux of thromboxane $B_2$, the stable hydrolytic product of thromboxane $A_2$, and of cathepsin D after atrial pacing in patients with significant coronary artery disease.[1,2] These patients had evidence of myocardial ischemia based on concurrent demonstration of lactate production after atrial pacing.

Thromboxane $A_2$, a platelet aggregator and coronary vasoconstrictor, could potentially exacerbate myocardial ischemia by both obstructive and vasoconstrictive mechanisms.[3] Cathepsin D, a lysosomal hydrolase, could also exacerbate myocardial ischemia by its proteolytic effect.[4] Moreover, cathepsin D, a marker of damage to the lysosomal membrane, could reflect the release of additional lysosomal hydrolytic enzymes that may be responsible for propagation of ischemic damage.

Ibuprofen, a nonsteroidal anti-inflammatory agent, has been reported effective in enhancing lysosomal membrane stability and in decreasing release of thromboxane $A_2$ by inhibition of cyclo-oxygenase.[5,6] Ibuprofen has also been demonstrated to limit the extent of ischemic damage in an animal model of acute myocardial ischemia.[7] These effects of ibuprofen are effective in experimental myocardial ischemia but have not yet been assessed in patients with coronary artery disease.

The purpose of this study, therefore, was to evaluate the effect of ibuprofen in patients with coronary artery disease and to assess its effect on the pacing-induced release of cathepsin D and thromboxane $B_2$.

## Methods

Forty-four patients were included in the current study. These patients had been admitted to Thomas Jefferson University Hospital for cardiac catheterization for evaluation of an anginal syndrome. Coronary artery spasm was not suspected in any patient. Patients with either stable or unstable angina were included in the study, and randomized into placebo or ibuprofen groups. Two hours before catheterization, patients were given either 800 mg of ibuprofen orally, or placebo; they received no other medication before the procedure. All other medications were withheld for 12 hours before catheterization, including beta-adrenergic blocking drugs and nitrates. Before coronary arteriography and ventriculography, atrial pacing was performed. A size 7 Gorlin catheter was advanced from the brachial vein and positioned in the coronary sinus. A size 20 longdwell cannula was inserted into the right brachial artery.

Samples of blood were simultaneously withdrawn from the coronary sinus and brachial artery to be analyzed for lactate, thromboxane $B_2$, and cathepsin D. Samples, withdrawn in a heparinized syringe, were obtained at rest and immediately after atrial pacing. The sample to be analyzed for lactate was immediately transferred into a chilled glass tube containing polyethyleneglycol. The sample to be analyzed for thromboxane $B_2$ and cathepsin D was immediately placed in a chilled 5 ml vacutainer tube (Becton-Dickson) prefilled with 7.5% of EDTA and 100 $\mu$m of sodium meclofenamate. These tubes were placed in an ice bath and handled as described herein.

Atrial pacing was initiated at a rate of 90 beats/min and gradually increased to a rate of 140 beats/min. Pacing was maintained at 140 beats/min for 4 minutes. Although pacing could be continued for 4 minutes in most patients, it was occasionally discontinued early because the patient had severe chest pain. However, in no patient was pacing maintained for less than 2 minutes. After atrial pacing, selective coronary angiography and ventriculography were performed. There were no complications or sequelae consequent to the atrial pacing procedure, and there were no adverse effects related to administration of ibuprofen.

Patients were excluded from this study if there was any history of ingestion or parenteral administration of any steroidal or nonsteroidal anti-inflammatory agent in the previous 7 days. Informed consent was obtained from all patients before inclusion in the study.

Lactate extraction was determined as follows: Lactate extraction = $[(\text{lactate}_{\text{arterial}} - \text{lactate}_{\text{venous}})/\text{lactate}_{\text{arterial}}] \times 100$.

Statistical analysis was performed by a 2-way analysis of variance with log transformation comparing the percent change in values obtained after pacing with the prepacing control values.

Lactate analysis was performed as previously described.[8] Analysis of plasma samples for thromboxane $B_2$ was determined by specific radioimmunoassay as described by Lewy et al.[9] Cathepsin D activity was assessed by the spectrophotometric method of Anson using hemoglobin as substrate at a pH of 3.5.[10] All samples were performed in duplicate to ensure reproducibility.

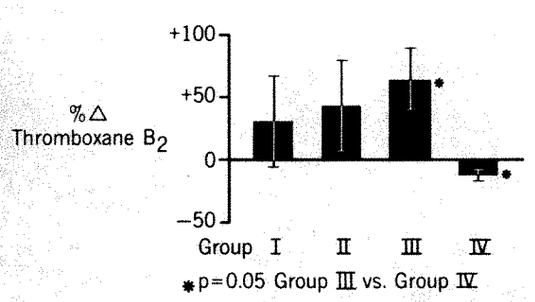

**FIGURE 1.** Percent change in concentrations of thromboxane $B_2$ in venous effluent sampled from the coronary sinus. Thromboxane $B_2$ concentrations immediately after pacing are compared with prepacing values (mean ± standard error of the mean). There is a significant difference between Groups III and IV as determined by a 2-way analysis of variance.

## Results

Patients were classified into 4 groups on the basis of whether they received ibuprofen or placebo as well as on the basis of manifestation of transmyocardial lactate extraction or production after atrial pacing. Groups I and III received placebo whereas Groups II and IV received ibuprofen. Groups I and II demonstrated lactate extraction after atrial pacing, whereas Groups III and IV demonstrated lactate production after pacing. There were 12 patients in Group I, 9 patients in Group II, 10 patients in Group III, and 13 patients in Group IV (Table I).

Clinical characteristics of the 4 groups are listed in Table I. There was no significant difference in age, male/female ratio, or incidence of previous myocardial infarction in the 4 groups. There was no difference in the medical regimen of patients in the 4 groups. Comparable numbers of patients were taking beta-adrenergic blocking drugs and nitrate preparations.

Catheterization variables are also listed in Table I. There was no difference in left ventricular ejection

fraction or left ventricular end-diastolic pressure among the 4 groups. There were no differences in the number of vessels with >50% obstruction in patients in Groups I and II or Groups III and IV. Patients in Group IV had a greater number of vessels with >50% obstruction than both Groups I and II ($p < 0.05$). Group I and II patients had comparable lactate extraction after pacing, suggesting no evidence of myocardial ischemia in the region drained. Groups III and IV patients manifested comparable degrees of lactate production, suggesting severe myocardial ischemia.

In Figure 1, the percent change in thromboxane $B_2$ concentrations in the coronary sinus is demonstrated. Thromboxane $B_2$ concentrations immediately after pacing are compared with the values measured before pacing. In Groups I and II, consisting of patients without significant myocardial ischemia, there was a slight increase in thromboxane $B_2$ concentrations after pacing (31 ± 36% and 43 ± 36%, respectively). However, this was not statistically significant. In contrast, Group III exhibited a 64 ± 25% increase in thromboxane $B_2$ values immediately after atrial pacing. In Group IV patients, who had a comparable degree of myocardial ischemia and coronary vascular disease as Group III patients, there were no significant changes in thromboxane $B_2$ concentrations after pacing (−11 ± 4%). Ibuprofen thus greatly inhibited the pacing-induced release of thromboxane $B_2$ in patients with severe coronary artery disease. ($p = 0.05$, Group III versus Group IV).

Figure 2 summarizes the percent change in cathepsin D activities in the coronary sinus. Cathepsin D activities immediately after pacing are compared with activities measured before pacing. In Groups I and II, no increase in cathepsin D activities was noted (13 ± 14% and 29 ± 9%, respectively). In Group III, a 113 ± 37% increase in cathepsin D values after pacing was observed. This increase in cathepsin D values differed significantly ($p < 0.01$) from the response observed in Group IV patients, who received ibuprofen (−14 ± 15%).

## Discussion

We have demonstrated that atrial pacing in patients with significant myocardial ischemia results in an increase in thromboxane $B_2$ values, confirming our earlier findings.[1] Occasionally in patients without demonstration of significant ischemia, plasma thromboxane $B_2$ concentrations were also elevated after pacing. However, this was not a consistent finding. The source of the thromboxane that is generated after atrial pacing is not clear. Presumably it is generated in and around the atherosclerotic plaque and may be related to the stimulation of platelets and the pacing-induced change in hydraulics of flow in the diseased vessel. Possible alternative sources of circulating thromboxane $B_2$ include the pulmonary artery, the ischemic myocardium itself, or small coronary vessels.[11]

Similarly, circulating cathepsin D activities were elvated in patients with severe myocardial ischemia as had been shown in a previous study.[2] Although no evidence of acute myocardial infarction was noted in our patients, the degree of ischemia that was induced may lead to leakiness of the lysosomal membrane resulting in lysosomal enzyme release. Alternatively, there may have been preexisting lysosomal injury related to the underlying severe coronary disease. The stress of atrial pacing may then have been adequate stimulus to induce the further change in the lysosomal membrane required to enable hydrolase leakage out of the lysosome, similar to hypoxia or ischemia, which are known lysosomal-labilizing stimuli.[12]

A variety of anti-inflammatory agents both steroidal and nonsteroidal may block thromboxane $A_2$ synthesis. Glucocorticoids act by blocking the action of phospholipases that release arachidonic acid and by stimulating the synthesis of a lipase that rapidly clears circulating arachidonic acid.[13,14] The nonsteroidal anti-inflammatory agents act by inhibiting cyclo-oxygenase-mediated conversion of arachidonic acid to prostaglandin endoperoxidases intermediary to the formation of thromboxane $A_2$.[15] Glucocorticoids have been also demonstrated effective in the stabilization of lysosomal membranes.[16] Among the nonsteroidal anti-inflammatory agents indomethacin, meclofenamic acid, and acetylsalicylic acid have been found unable to stabilize lysosomal membranes in acute myocardial ischemia in an experimental model.[17] Ibuprofen, on the other hand has been found effective in stabilizing lysosomal membranes and preserving myocardial integrity in acute myocardial ischemia.[18]

The combination of inhibition of thromboxane $A_2$ and stabilization of lysosomal membranes may be beneficial in the setting of acute myocardial ischemia. Hence this study was performed using the model of pacing-induced myocardial ischemia to assess the inhibitory effects of ibuprofen.

There was no significant increase in cathepsin D or thromboxane $B_2$ in the coronary sinus venous effluent samples in patients with no evidence of myocardial ischemia. In contrast, there was a significant increase in thromboxane $B_2$ and cathepsin D values noted immediately after atrial pacing in Group III patients exhibiting pacing-induced severe myocardial ischemia. In Group IV patients, with comparable coronary artery disease and with comparable myocardial ischemia, release of thromboxane $B_2$ and cathepsin D was inhibited by the administration of ibuprofen.

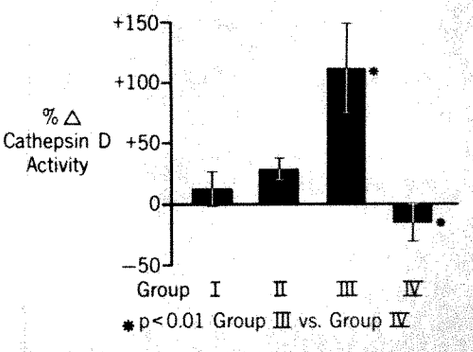

**FIGURE 2.** Percent change in cathepsin D activities in venous effluent sampled from the coronary sinus. Values for cathepsin D activities immediately after pacing are compared with prepacing values (mean ± standard error of the mean). There is a significant difference between Groups III and IV as determined by a 2-way analysis of variance.

Generation and release of thromboxane $B_2$ and lysosomal hydrolases may have deleterious effects in the setting of myocardial ischemia or myocardial infarction. Thromboxane $A_2$ has been demonstrated to be released after experimental myocardial infarction.[19] Inhibition of thromboxane $A_2$ release by a specific thromboxane synthetase inhibitor resulted in a decrease in ischemic damage after coronary artery occlusion in cats.[20] Conversely, administration of a synthetic thromboxane analog resulted in an increase in ischemic damage.[21]

Release of cathepsin D may also be deleterious in the setting of acute myocardial ischemia. Cathepsin D is a marker of lysosomal membrane disruption, and thus lysosomal enzymes other than cathepsin D may be released at the same time. These may induce additional proteolysis and lipolysis, resulting in membrane damage that may exacerbate myocardial edema and lead to further compromise of the coronary microcirculation. Thus, inhibition of both of these phenomena by ibuprofen may be significant. Whether a specific thromboxane synthetase inhibitor, as recently described, would be of more specific benefit with regard to thromboxane inhibition remains to be determined.[22]

Several therapeutic procedures have been studied in patients with acute myocardial infarction and ischemia and have been demonstrated effective experimentally in the reduction of infarct size and limitation of ischemia, including beta-adrenergic blocking agents, hyaluronidase, nitroglycerin, glucocorticoids, cobra venom factor, and intraaortic balloon counter pulsation.[23–28] In addition, recanalization of coronary artery thrombus in acute myocardial infarction has also been demonstrated feasible and holds promise in limitation of infarct size.[29] Ibuprofen, by virtue of the mechanisms described in this study, should be added to the list of agents that may be effective in the limitation of infarct size in patients. Such an effect has been demonstrated in an animal model.[7] In addition, ibuprofen may also complement other established therapy after coronary artery thrombolysis by limiting the extent of myocardial ischemic damage and by stabilizing platelets with the subsequent inhibition of thromboxane $A_2$ generation.

# Improved Exercise Ventilatory Responses After Training in Coronary Heart Disease During Long-Term Beta-Adrenergic Blockade

NEIL F. GORDON, MBBCh, PIETER E. KRÜGER, BA HONS, and JONES F. CILLIERS, MA

**Exercise ventilatory responses of 7 men with well-documented myocardial infarction receiving long-term beta-adrenergic blockade were studied before and after 4 months of endurance training. Observations were obtained during graded levels of upright treadmill exercise continued until 85% of the predetermined symptom-limited heart rate (working heart frequency limit). This submaximal testing procedure revealed a significant slowing of the heart rate ($p < 0.005$) together with an increased oxygen pulse ($p < 0.05$) after training, for what was previously a maximal work load for the working heart frequency limit. In addition, all patients achieved an increased exercise duration and work load, accompanied by significant increases in maximal oxygen uptake ($p < 0.01$), oxygen pulse ($p < 0.025$), and respiratory exchange ratio, for their working heart frequency limit after exercise conditioning. These results show that prolonged physical training results in physiologic adaptations to cardiac rehabilitation in the presence of long-term beta-adrenergic blockade.**

Exercise training is a recommended mode of therapy for suitable patients after myocardial infarction. Endurance conditioning may produce a number of physiologic adaptations of demonstrable or potential benefit in these patients.[1] The major improvements are thought to result from peripheral alterations brought about by the repetitive use of skeletal muscles at an exercise intensity above a threshold level of metabolic activity.[2]

A recent study based on respiratory exchange data expressed doubts about the capability of patients with coronary heart disease who are receiving long-term beta-adrenergic blockade to attain this desired metabolic level during training.[3] At the same time, data on the ability of such patients to achieve a significant training effect are both scarce and conflicting in nature. Two studies demonstrated prolonged maximal symptom-free exercise duration after training in the presence of beta-adrenergic blockade,[4,5] whereas 1 report showed no benefits from conditioning.[6] None of these studies included direct measurement of exercise ventilatory responses in the experimental design, a factor necessary for unequivocal evidence of an improved aerobic capacity. Accordingly, this investigation was undertaken to examine the ventilatory adjustments to exercise that accompany gains in fitness when patients with a well-documented myocardial infarction (MI) receiving long-term beta-adrenergic blockade undertake 4 months of physical conditioning.

## Methods

Seven ambulatory male survivors of a well-documented acute MI involved in a cardiac rehabilitation exercise program were selected for study. Six patients were receiving a nonselective beta-blocking agent, and 1 patient a $beta_1$-selective blocking drug, as part of their medication in the following daily doses: 160 mg of propranolol hydrochloride in 4 patients, 160 mg of sotalol hydrochloride in 1 patient, 20 mg of timolol maleate in 1 patient, and 50 mg of atenolol in 1 patient. These doses remained unchanged throughout the investigation. Physical characteristics pertaining to the patients include age 50 ± 8 years (mean ± standard deviation), height 180 ± 5 cm, and weight 84.4 ± 10.1 kg. The interval between MI and enrollment in the exercise program ranged from 3 months to 2 years.

Before the study all patients underwent a symptom-limited stress test in the presence of their usual cardioactive medications with use of the modified Bruce protocol and electrocardiographic monitoring by means of a Marquette computer-assisted system. The heart frequency limit to be used during subsequent testing and conditioning, the working heart

frequency limit, was calculated as follows: Working heart frequency limit = 85/100 × symptom-limited heart rate.

For at least 2 hours before the determination of maximal oxygen uptake for each patient's working heart frequency limit, termed *working maximal oxygen uptake*, all patients avoided meals and stimulants such as tea, coffee, cola beverages, and cigarettes. In addition to their previous treadmill experience, patients were given a familiarization trial. Measurement of working maximal oxygen uptake was performed with a Morgan exercise test system using progressive work loads on a Quinton (model 18-60) clinical research treadmill. After a 20-minute rest in the seated position, patients commenced walking at a treadmill speed of 2.5 km/hour with a gradient of 2°. The speed was increased by 0.5 km/hour every 3 minutes in order to permit a gradual increase in heart rate, until the working heart frequency limit was reached. Analyses of oxygen and carbon dioxide levels were performed every minute during exercise with a Morgan m/262D oxygen analyzer and a Morgan (model 801) carbon dioxide analyzer, both of which had been calibrated before each test with tanked calibrated gas. Heart rate and electrocardiogram were monitored continuously on an oscilloscope using the bipolar chest lead $CM_5$. In addition, a standard 12-lead electrocardiogram was recorded together with the blood pressure on completion of each work load. Blood pressure was measured with the auscultatory method and was therefore not used as an experimental variable because of possible inaccuracy of this technique during ambulation. The final work load for which the heart frequency was equal to or below the working heart frequency limit was used for data collection.

Measurement of working maximal oxygen uptake was repeated using an identical protocol after 4 months of exercise training comprising 3 sessions per week each of 90 minutes' duration. These supervised classes consisted of a 20-minute warm-up of muscular and flexibility exercises followed by an aerobic exercise such as walking, jogging, or cycling, and ending with a cool-down period. All patients were encouraged to train at an exercise intensity that would bring the heart rate as close as possible to the working heart frequency limit without exceeding it. Patients commenced with a "low-dose" individualized exercise prescription that was gradually increased as their cardiorespiratory and musculoskeletal systems adapted to the exercise.

Significances of differences were analyzed by means of the paired $t$ test.

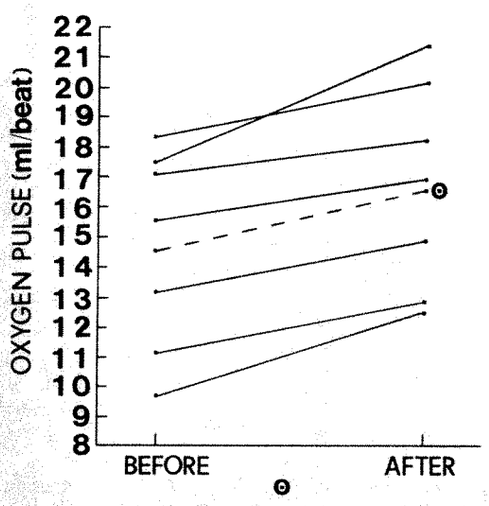

**FIGURE 1.** Oxygen pulse for work load which was initially the maximal for the working heart frequency limit, before and after 4 months endurance training in 7 patients receiving long-term beta-adrenergic blockade after myocardial infarction. **Black circles,** 13.1% increase, $p < 0.05$ versus before training.

## Results

Table I lists the mean values of paired comparisons of experimental variables for the work load which was initially the maximal work load for the patients' working heart frequency limit. The data demonstrate a 12.8% ($p < 0.005$) reduction in heart rate after training. The prescribed training had no effect on oxygen uptake at this level. However, relating oxygen uptake to heart rate, oxygen pulse was increased by 13.1% ($p < 0.05$) (Fig. 1).

All patients attained a markedly increased absolute treadmill duration for their working heart frequency limit after training. Exercise conditioning resulted in significant increases in working maximal oxygen uptake (26%, $p < 0.01$) (Fig. 2), oxygen pulse (24.1%, $p < 0.025$), minute ventilation (32.2%, $p < 0.01$), carbon dioxide output (30.3%, $p < 0.025$), and respiratory exchange ratio. The heart rate used for data collection in the initial test was 103.9 ± 15.8 beats/min, as compared with 103.6 ± 15.5 beats/min in the second test (the working heart frequency limit was 104 ± 14.8 beats/min). The means and standard deviations are found in Table II.

The aforementioned results were accompanied by major improvements in training times and distances during the course of study. No complications arose during training or testing.

## Discussion

Propranolol, a nonselective beta-blocking agent, has been associated with reduced lactate and carbon dioxide production during exercise in normal subjects as well as in patients with coronary heart disease.[3,7] After the ingestion of 40 mg of propranolol, patients with coronary heart disease in 1 study were unable to reach a respiratory exchange ratio >0.85, the level of metabolic activity believed necessary to create a peripheral training effect.[3] Inhibition of glucose metabolism related to beta-adrenergic blockade was a suggested mechanism for this decreased respiratory exchange ratio. In our trial, all patients derived a significant training effect despite an initial mean respiratory exchange ratio of 0.80 ± 0.07 for their working heart frequency limit. An explanation for this is provided in the finding by Twentyman et al[8] of a propranolol-induced decreased carbon dioxide output early in exercise, followed by an increased output at a later stage involving a greater work load. They suggest that reduced muscle perfusion due to decreased cardiac output together with a possible direct effect of propranolol on the muscle blood supply[9] results in increased anaerobic metabolism and a delayed rate of carbon dioxide removal from the exercising muscles, thereby lowering measured carbon dioxide output during early exercise. Elevated local metabolite concentrations override the effects of beta-adrenergic blockade on the muscle blood supply later in exercise, causing an increased blood flow facilitating carbon dioxide removal. Under these conditions the respiratory exchange ratio is obviously a poor indicator of the muscular metabolic activity at a given time. In agreement with this explanation, after 4 months of training our patients were able to achieve an increased exercise duration and maximal treadmill speed for their working heart frequency limit, thereby reaching a mean elevated respiratory exchange ratio of 0.86 ± 0.03 ($p < 0.05$). Similar increases in the physical working capacity in patients with coronary heart disease after training during long-term therapy with beta-adrenergic blockade were noted by Obma[4] and Pratt[5] and their co-workers. Malmborg's[6] finding of no such improved exercise ability is most likely the result of an inadequate training stimulus.

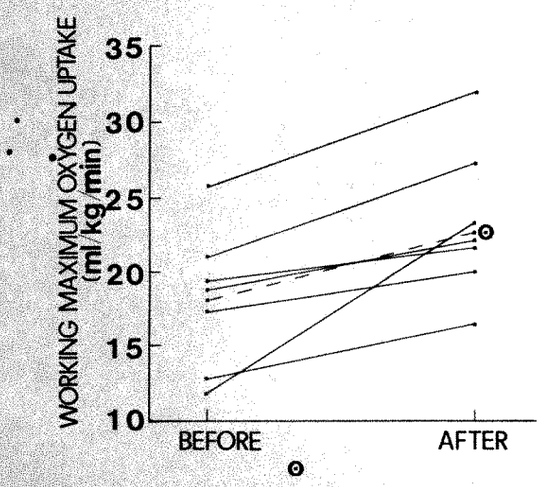

**FIGURE 2.** Working maximal oxygen uptake before and after 4 months endurance training in 7 patients receiving long-term beta-adrenergic blockade after myocardial infarction. **Black circles,** 26% increase, $p < 0.01$ versus before training.

The reasoning behind a heart rate exercise prescription is that myocardial work reflects oxygen consumption, which in turn is proportional to the heart rate. This is true under most circumstances of everyday life, the major exceptions being isometric and arm work. Patients participating in the cardiac rehabilitation program at our center are advised never to exceed their working heart frequency limit, whether it be in training or any of a multitude of life-style activities. The individual's working maximal oxygen uptake reflects his or her maximal "safe" permissible energy expenditure, thus limiting the variety of recreational as well as occupational pursuits. An increased working maximal oxygen uptake widens this choice and thus improves the quality of life, the major goal of cardiac rehabilitation in our opinion. If a heart rate prescription is employed, it becomes unnecessary to determine oxygen uptake using maximal testing. Respiratory data collected at the level of maximal exercise have to be interpreted with caution in patients with coronary heart disease because this maximal oxygen uptake is symptom-limited and therefore does not have the same physiologic meaning as a true maximal oxygen uptake measured in a normal person. In addition, working maximal oxygen uptake

is a submaximal measurement and can therefore be used to assess aerobic performance on a regular basis with a high level of safety in patients with coronary heart disease. With this technique we demonstrated a 12.8% ($p < 0.005$) decrease in heart rate after training, for what was initially the maximal work load for the working heart frequency limit. This slowing of the heart rate was accompanied by a 13.1% ($p < 0.05$) increase in oxygen pulse. The heart rate response to submaximal exercise may be lower after exercise training due either to an improved external mechanical work efficiency,[10] (in which case the oxygen consumption–heart rate relation [that is, oxygen pulse] remains unchanged), or to an enhanced capacity for oxygen transport and utilization (resulting in an increased oxygen pulse). Oxygen pulse is representative of the volume of oxygen consumed by the tissues with each heart beat, and can be shown, with use of the Fick principle, to equal stroke volume times arteriovenous oxygen difference. Increases in both variables account for the increased oxygen pulse during submaximal exercise in normal persons with physical training,[11] whereas an increased arteriovenous oxygen difference is believed to be the major factor in patients with coronary heart disease.[12] Beta-adrenergic blockade itself results in an increased arteriovenous oxygen difference,[13] but although its mechanism of action is to reduce venous oxygen content by increasing peripheral oxygen extraction, exercise training in addition to this effect causes an increased arterial oxygen content,[12] and may thereby further widen an already increased arteriovenous oxygen difference in patients with coronary heart disease receiving long-term beta-adrenergic blockade. Although arteriovenous oxygen difference was not directly measured in our study, the increased oxygen pulse during submaximal exercise most likely reflects an exercise conditioning induced increase in arteriovenous oxygen difference, despite the presence of long-term beta-adrenergic blockade. Whatever the mechanism, this increased oxygen pulse provides unequivocal evidence of a significant physiologic training effect in patients with coronary heart disease receiving long-term beta-blocking agents while participating in a cardiac rehabilitation exercise program.

After 4 months of endurance conditioning patients in our study increased their working maximal oxygen uptake by 26%, providing further evidence that a cardiac rehabilitation exercise program is not contraindicated by the use of beta-blocking drugs. This improvement in working maximal oxygen uptake is in fact similar to the increases "maximal oxygen uptake" noted in previous studies of coronary patients not receiving beta-blockade.[12,14]

Exercise conditioning-related improvements in redistribution of peripheral blood flow, oxygen transport capacity, and skeletal muscle oxygen extraction and utilization, are the likely mechanisms of this increased aerobic capacity.

**Implications:** This study has documented an unequivocal physiologic adaptation to endurance training in 7 patients receiving long-term beta-adrenergic blocking agents after myocardial infarction. The small patient sample used together with the lack of a control group do not detract from our findings which suggest that appropriately selected patients with coronary heart disease may derive the full benefits from a suitable cardiac rehabilitation exercise program in the presence of long-term beta-blockade. Whether it may in fact be preferable for such patients to receive beta-adrenergic blockade has still to be demonstrated.

## What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

## CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

***"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended."*** Philip Reichert, M.D. New York State Journal of Medicine, September, 1981

***"...recommend...to any reader interested in the literature of cardiology."*** Irwin R. Callen, M.D. JAMA, November, 1981

**SPECIAL DISCOUNT OFFER**

Place a standing order to receive each edition of CARDIOLOGY: 1982 on 30 day approval and receive a 10% discount on this and all future editions.

☐ **YES,** please enter my standing order for CARDIOLOGY: 1982. I understand that each edition (published once a year) will be automatically shipped to me on 30 day approval, and I will receive a 10% discount on this and all future editions. (1982 edition discount price $40.50)

**Yorke Medical Books,** Box C-757, Brooklyn, NY 11205 AJCC3

☐ Please send me a copy of the 1982 edition at the full price of $45.00. I do not wish to place a standing order.

☐ Enclosed is my check for _____. Yorke pays postage and handling. (Same return privilege)
(New York residents add appropriate sales tax. Add $5.00 per book for orders outside the U.S. and Canada.)

# For **every** professional with an interest in Exercise and the Heart.

# EXERCISE in Cardiovascular Health and Disease

Edited by
**Ezra A. Amsterdam**, MD, Chief Coronary Care Unit, Univ. of Calif. School of Medicine
**Jack H. Wilmore**, PhD, Professor and Head Dept. of Physical Education & Athletics, Univ. Arizona
**Anthony N. DeMaria**, MD, Dir. Echocardiography Section, Univ. of Calif. School of Medicine

SEPTEMBER 1977, 408 PAGES, ILLUS.

This comprehensive work covers every aspect of exercise and its role in Diagnosis, Treatment, and Prevention of cardiac disease.

The scope of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE is so broad that it goes from something as basic as a detailed study of the heart muscle itself to the latest advances in cardiac rehabilitation.

***Special attention is given to such subjects as:***

- ☐ Present status of exercise testing and training in terms of physiological bases and clinical applications
- ☐ Nuclear cardiology
- ☐ Computer analysis of the exercise ECG
- ☐ Stress myocardial scintigraphy
- ☐ Various interpretations of exercise tests in the asymptomatic population

The editors have brought together a distinguished group of specialists—all of whom have made major contributions to the field. Included are outstanding scientists, clinicians, exercise physiologists, and physical educators.

**For you who have any interest—professional or personal—in exercise and the heart, we urge you to *look* at a copy of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE. That's right! You're invited to *look* it over before buying it.**

Send for your copy of Exercise in Cardiovascular Health and Disease today. *Then use it for 30 days without risk.*

**Yorke Medical Books** AJCC3
Box C-757, Brooklyn, New York 11205

Please send me a copy of EXERCISE in Cardiovascular Health and Disease for 30 days free examination and use. If I decide to keep it, your invoice will be honored ($38.00 plus shipping cost). Otherwise, the book will be returned for full refund or credit.

☐ Full payment enclosed, publisher pays shipping.
☐ Please bill me, plus cost of shipping.
☐ Charge my credit card: ☐ MasterCard ☐ Visa.

# Finally.
# A computer fast enough to make dynamic cardiac quantitation a practical reality.

Panasonic
PROMPT
IMAGE
FRANKL

# The Franklin Quantic 1200.

Now, for the first time, Franklin makes it possible to digitize complete cardiac cycles in real time and quantitate the massive amounts of information captured by video echocardiographic studies.

In fact, the Quantic 1200 uses all the significant information on every frame of a cycle to guide and correct the information on every other frame of the same cycle.

This allows the computer to:

- Automatically recognize and track the borders of the endocardium. (The operator has the flexibility to interrupt the process, draw new borders, and edit at any time.)
- Perform comparative analyses of normal and abnormal beats using segmental wall motion displays.
- And provide repeatable calculations on perimeters, areas, volumes, and ejection fractions.

All within a few short minutes.

So, now you can make decisions based on more complete and more precise information about the region, extent, magnitude, and timing of heart abnormalities from non-invasive images.

Furthermore, because the entire process is repeatable, relatively inexpensive, and non-invasive, the Franklin Quantic 1200 provides you with the first practical way to monitor and evaluate heart performance before and after therapy.

FRANKLIN

We make it possible.

# The Franklin Quantic 1200.

## It can give you more useful information, *faster.*

It is, in fact, the first computer fast enough and powerful enough to capture and digitize the massive amounts of data present in real time ultrasound video signals.

In addition, the Quantic 1200 is the only echocardiographic computer on the market with enough power to apply the extraordinarily complex algorithms researchers are currently developing for future clinical use. These include automatic edge detection, tissue characterization, image processing, frame-to-frame averaging, motion detection, and noise reduction.

Yet, for all its sophistication, the Quantic 1200 is even simpler to operate than many home/office minicomputers.

Compare these features with any other system at any price:

### SOFTWARE

Operator-friendly, screen-prompted software programs provide faster access to information and greater flexibility than any other system currently available.

Furthermore, because all programs are designed for maximum simplicity and ease of operation, no prior knowledge of computers is necessary for full clinical use of the Quantic 1200.

### CLINICAL PROGRAMS

Five of the most widely accepted algorithms used to calculate 2D echocardiographic measurements of areas, volumes, ejection fractions, and other essential derived physiological data.

A full complement of M-mode programs for calculations from both video and hard copy.

Automatic Border Recognition Algorithm developed for Franklin under exclusive license by one of the nation's leading university research centers. (Clinical human validation studies ongoing.)

Full cycle analysis programs including three segmental wall motion algorithms and one area/perimeter change analysis algorithm.

### REAL TIME FRAME GRABBER

Capable of capturing and digitizing complete cardiac cycles in real time.

### DIGITAL STORAGE

Hard disk for efficient storage and retrieval of 1200 discreet frames of video information.

### COMPUTER

Special purpose, 16 bit computer.
Half-million byte RAM memory (expandable).
High speed, high resolution graphics system.

### TWO MONITORS

Two high resolution, 9-inch screens; one for prompting, one for imaging.

### KEYBOARD

Typewriter quality, full alphanumeric keyboard for convenient labeling and data entry.

### JOY STICK

Precision, strain gauge joy stick, custom-designed by Franklin for the specific task of tracing borders of the endocardium.

### DIGITIZING PAD

High resolution, convenient digitizing pad and pen.

### PRINTER

High resolution, dot matrix graphics printer.

### PRINT SPOOLER

Stores and prints up to eight pages of summary. Operator never waits to perform other computer functions.

### OTHER FEATURES

- Fully programmable with optional floppy disk drive and software.
- Modular software upgrades on floppy disks will be available.
- Off-line video and hard copy capability.
- On-line real time capability.
- Video archiving.
- Compatible with all video ultrasound systems.
- Portable and compact.
- Rugged, reliable, solid state components.

# Disopyramide: Evaluation of Electrophysiologic Effects and Clinical Efficacy in Patients With Sustained Ventricular Tachycardia or Ventricular Fibrillation

BRUCE B. LERMAN, MD, HARVEY L. WAXMAN, MD, ALFRED E. BUXTON, MD, and MARK E. JOSEPHSON, MD

**The efficacy of disopyramide in the management of sustained ventricular tachycardia (VT) or ventricular fibrillation (VF) was evaluated in 50 patients by programmed ventricular stimulation: 38 patients had coronary artery disease (16 with left ventricular aneurysm), 8 had other cardiac diseases, and 4 had no apparent heart disease. Disopyramide was administered orally for 72 hours (dosage 400 to 1,600 mg/day), resulting in a plasma level of 3.6 ± 1.2 μg/ml (mean ± standard deviation [SD]). Disopyramide prevented induction of sustained ventricular tachyarrhythmias in 17 patients (34%) and failed to prevent induction in 33 patients (66%). Plasma levels were not significantly different regardless of response to disopyramide. The VT cycle length in patients responding to disopyramide was shorter than in nonresponding patients (225 ± 51 ms versus 281 ± 70 ms, p = 0.005). Disopyramide increased VT cycle length in those patients in whom it was ineffective (failed to prevent induction) from 281 ± 70 ms to 347 ± 64 ms (p <0.001). Ventricular refractory periods, QRS, and QTc durations significantly increased after disopyramide administration.**

**Of the 17 patients in whom tachyarrhythmias were noninducible on disopyramide, 11 were discharged on disopyramide and followed up for 19 ± 9 months; 9 of them remained free of VT. Heart failure developed in 2 of these patients. One other patient in whom disopyramide was ineffective had irreversible heart failure and died.**

**It is concluded that disopyramide (1) prevents induction of ventricular tachyarrhythmias in one third of patients studied and remains clinically effective in approximately 80%, (2) is more frequently effective in rapid tachycardias, (3) prolongs the VT cycle length when ineffective, and (4) may produce marked hemodynamic embarrassment in patients with significant left ventricular dysfunction.**

Disopyramide phosphate is a type I antiarrhythmic agent approved for use in the United States for treatment of ventricular arrhythmias in 1978. Nevertheless, previous investigations have failed to systematically analyze the ability of disopyramide to suppress inducible ventricular tachycardia (VT) and characterize its utility in a large group of patients with sustained ventricular tachycardia or ventricular fibrillation (VF).

Programmed ventricular stimulation is both sensitive and specific for the detection of clinical VT.[1-3] Response to conventional antiarrhythmic drugs during programmed ventricular stimulation has been shown to predict clinical response.[2-4] This report relates the immediate and long-term experience with disopyramide evaluated by programmed ventricular stimulation in 50 patients with sustained VT, VF, or both.

## Methods

**Patients:** Disopyramide was administered and electrophysiologic studies were performed in 50 patients with sustained ventricular arrhythmias between January 1977 and January 1982. There were 41 men and 9 women. Their average age was 54 years with a range of 28 to 73. Thirty-eight patients had coronary artery disease, including 29 with a history of a myocardial infarction, 16 of whom had a left ventricular aneurysm. Other cardiac diseases included cardiomyopathy in

From the Clinical Electrophysiology Laboratory, Hospital of the University of Pennsylvania, Cardiovascular Section, Department of Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania. This study was supported in part by National Institutional Training Grant HL07346, by Research Service Award HL07201, by Research Career Development Award HL00361, and by Grant HL24278 from the National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland; and by grants from the American Heart Association, Southeastern Pennsylvania Chapter, Philadelphia, Pennsylvania. Manuscript received May 27, 1982; revised manuscript received November 17, 1982, accepted November 18, 1982.

Address for reprints: Mark E. Josephson, MD, Box 683, 656 Ravdin Building, Hospital of the University of Pennsylvania, 3400 Spruce Street, Philadelphia, Pennsylvania 19104.

2, nonobstructive asymmetric septal hypertrophy in 1, mitral valve prolapse in 3, status postaortic valve replacement for aortic stenosis in 1, and status postrepair of tetralogy of Fallot in 1. Four patients had no clinical evidence of organic heart disease and had normal results on echocardiographic, radionuclide, or coronary arteriographic studies.

Forty-four patients were studied for evaluation of sustained VT and 6 for cardiac arrest whose first documented arrhythmia was VF. The number of clinical episodes of VT or VF before study ranged from 1 to >100. One to 5 (2.2 ± 1) conventional antiarrhythmic drugs had been tried empirically before electrophysiologic evaluation. No patient had an acute myocardial infarction within 4 weeks of study.

**Electrophysiologic study:** All studies were performed with the patient in the nonsedated, postabsorptive state after informed consent had been obtained. During the initial study, all antiarrhythmic drugs were discontinued for at least 5 half-lives before evaluation. Usually, 3 quadripolar and 1 tripolar catheter were inserted either percutaneously or by way of cutdown and advanced under fluoroscopic guidance into the high right atrium, coronary sinus, right ventricular apex-outflow tract, and atrioventricular junction for recording of the His bundle. The distal pair of quadripolar electrodes were used for stimulation and the proximal pair for recording the local atrial or ventricular electrogram. Intracardiac recordings were filtered at 30 to 500 Hz and simultaneously displayed with 3 electrocardiographic leads on a multichannel oscilloscope (Electronics for Medicine VR-16, White Plains, New York). The data were stored on magnetic tape (Honeywell model 5600) and later retrieved on photographic paper at speeds of 100 to 200 mm/s for illustrative purposes. Real-time recordings were made with an ink jet recorder (Siemens Elema Mingograph). Programmed ventricular stimulation was performed with a specially designed programmable stimulator and isolated constant current source (Bloom Associates Ltd, Narberth, Pennsylvania). Stimuli were delivered as rectangular pulses, 1 ms in duration at twice diastolic threshold.

The stimulation protocol consisted of single, double, and, in most cases, triple premature ventricular stimuli introduced during sinus rhythm at ventricular paced cycle lengths of 600 and 400 ms, and rapid ventricular pacing (≥5 seconds at cycle lengths of 350 to 250 ms) as previously described.[1-4] Stimulation was performed initially at the right ventricular apex and if the tachycardia was not induced, stimulation at the right ventricular outflow tract was employed. Left ventricular stimulation was not required in any patient in this study. After the induction of VT, programmed ventricular stimulation or rapid ventricular pacing was used for termination. If VT tachycardia degenerated into VF either spontaneously or as a result of pacing or ensuing loss of consciousness, direct-current cardioversion was employed.

After control study demonstrating reproducible initiation of ventricular tachyarrhythmia, disopyramide was adminis-

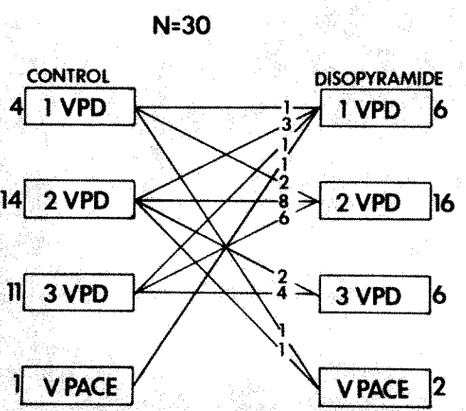

**FIGURE 1.** Mode of induction during the control study and after disopyramide administration. No difference in the induction mode as a result of disopyramide is demonstrated. VPD = ventricular premature depolarization; VPACE = ventricular pacing.

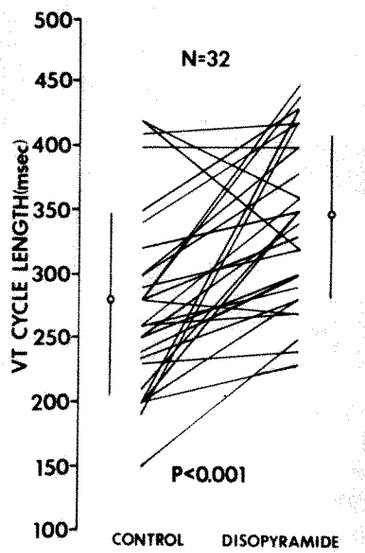

**FIGURE 2.** Effect of disopyramide on ventricular tachycardia (VT) cycle length. The mean VT cycle increased from 281 ms to 347 ms. (Note: 3 patients had identical control and postdisopyramide VT cycle lengths—320 ms and 350 ms, respectively—while 2 patients had similar control cycle lengths of 340 ms and postdisopyramide values of 420 ms.)

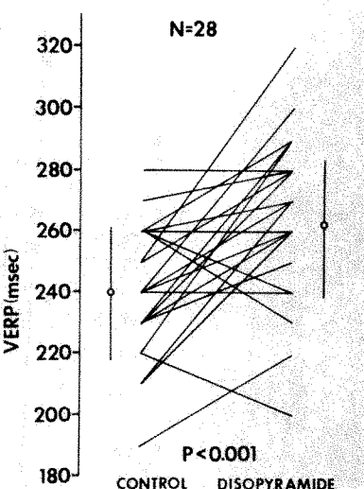

**FIGURE 3.** Effect of disopyramide on the ventricular effective refractory period (VERP). The mean ventricular effective refractory period increased from 240 to 264 ms. (Note: 4 patients had identical control and postdisopyramide ventricular effective refractory periods—240 and 270 ms. Three other pairs of patients also had identical values—190 to 220 ms, 280 to 280 ms, and 240 to 240 ms before and after disopyramide.)

tered orally at an initial dose of 100 to 200 mg every 6 hours for 72 hours. Programmed stimulation was then repeated at twice diastolic threshold using a quadripolar catheter placed in the right ventricular apex-right ventricular outflow tract. If the initial dose of disopyramide failed to prevent tachycardia induction, the dose of disopyramide was increased and the patient restudied after a new steady state level was achieved. No patient received any other antiarrhythmic agent during this period, with the exception of digoxin or propranolol for treatment of angina pectoris. The highest dose of disopyramide tested was 400 mg every 6 hours. Plasma levels of disopyramide were obtained immediately after the programmed ventricular stimulation protocol or shortly after the initiation of VT or VF.

In addition to mode of induction and cycle length of induced tachycardia, the effects of disopyramide on the ventricular effective refractory period, QRS duration, and QTc interval (Bazett's formula) were determined (the latter 2 were measured from the surface electrocardiogram).

**Statistical methods:** Statistical analysis was performed using the paired and unpaired $t$ test. Data are expressed as mean ± standard deviation.

**Definitions:** (*1*) *Sustained ventricular tachycardia:* Ventricular tachycardia that lasted at least 30 seconds either clinically or during induction with programmed ventricular stimulation, or required termination by programmed ventricular stimulation or cardioversion sooner because of hemodynamic deterioration. (*2*) *Effective response (disopyramide):* Prevention of sustained VT induced by programmed ventricular stimulation. (*3*) *Clinical effectiveness:* Absence of clinical or monitored sustained VT or VF during the follow-up period.

## Results

**Induction:** VT was induced in all 50 patients during the control study. In most patients tachyarrhythmias were induced with either double (26) or triple premature stimuli (13). Sixteen patients required direct-current cardioversion to terminate the arrhythmia, while programmed ventricular stimulation was successful in the remainder. Disopyramide prevented induction of sustained VT in 17 of 50 patients (34%). Eleven of these 17 patients had nonsustained VT (≥6 complexes) induced, none of which lasted more than 8 seconds. Six patients had <6 complexes induced. Three patients in whom the initial dose of disopyramide failed to prevent induction of sustained tachycardia had an effective response at a higher dose. Disopyramide did not significantly alter the mode of induction in those patients in whom it was ineffective (Fig. 1).

**Cycle length:** The cycle length of induced VT was 265 ± 70 ms. Disopyramide significantly increased the cycle length of VT in those patients in whom it was ineffective, from 281 ± 70 ms to 347 ± 64 ms ($p < 0.001$). In 3 patients, however, it decreased the VT cycle length by 20 to 30 ms (Fig. 2). The shorter the VT cycle length during the control study, the more frequently disopyramide prevented induction of VT: 225 ± 51 ms versus 281 ± 70, $p = 0.005$.

**Refractory periods:** Disopyramide increased the right ventricular effective refractory period from 240 ± 23 ms to 264 ± 27 ms, $p < 0.001$ (Fig. 3); however, in 4 patients a decrease was noted. There was no difference in the ventricular effective refractory period between those who were inducible with disopyramide and those who were not: 266 ± 33 ms versus 263 ± 23 ms, $p > 0.10$.

**QRS width:** The QRS interval after disopyramide increased from 104 ± 22 ms to 111 ± 22 ms, $p < 0.002$ (Fig. 4). There was no statistical difference in QRS duration between inducible and noninducible patients; 113 ± 7 ms versus 106 ± 6 ms, $p > 0.10$.

**QTc interval:** The QTc increased from 422 ± 48 ms to 461 ± 60 ms ($p < 0.001$) after disopyramide. There was no difference between patients with inducible and noninducible tachycardias: 480 ± 60 ms versus 450 ± 60 ms, $p = 0.11$ (Fig. 5).

**Plasma levels:** Disopyramide plasma levels were measured in 25 patients during programmed ventricular stimulation. The mean level was 3.6 ± 1.2 μg/ml. There was no significant difference between those in whom disopyramide prevented induction of ventricular tachyarrhythmias (10 patients) and in those 15 patients in whom it did not (3.7 ± 1.4 μg/ml versus 3.5 ± 1.1 μg/ml, $p > 0.10$).

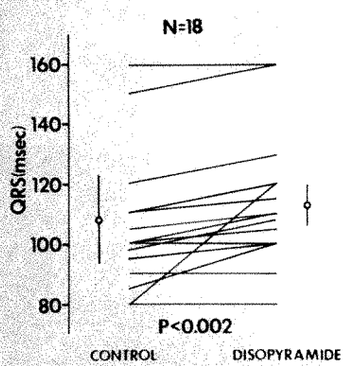

**FIGURE 4.** Effect of disopyramide on the QRS interval. The mean QRS increased from 104 to 111 ms. (Note: 3 pairs of patients had identical control and postdisopyramide QRS intervals—105 to 110 ms, 95 to 110 ms, and 80 to 80 ms, respectively.)

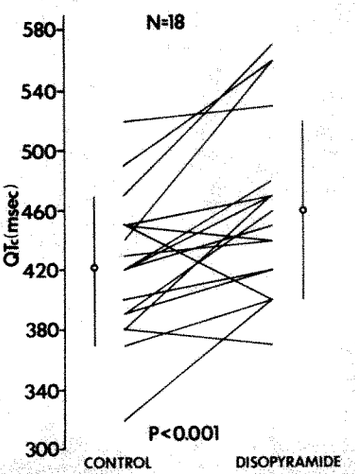

**FIGURE 5.** Effect of disopyramide on the QTc interval. The mean QTc interval increased from 422 ms during the control study to 460 ms after disopyramide administration.

**Adverse reactions:** Adverse effects associated with disopyramide administration developed in 10 of 50 (20%) patients. One patient with angiographic evidence of a left ventricular aneurysm was studied while taking disopyramide at a dosage of 200 mg every 6 hours, which was well-tolerated. VT was induced during programmed ventricular stimulation and the oral dose was increased to 300 mg every 6 hours. After the third dose, irreversible heart failure and electromechanical dissociation developed in the patient. There were 4 instances of dry mouth, 3 of urinary hesitancy, and 2 of blurred vision within 48 hours of receiving the drug. These symptoms decreased with a lower dose. In each case, the patient was discharged with this lower dose as long as an effective response to the drug at this dose was demonstrated during programmed ventricular stimulation.

**Long-term follow-up (Table I):** Eleven of 17 patients in whom disopyramide prevented induction of VT were discharged with the drug as their only antiarrhythmic agent. The remaining 6 patients were treated with other agents alone or in combination with disopyramide because (1) adverse effects required reducing the dosage below that shown effective, or (2) similar efficacy was demonstrated with another drug with less myocardial depressant effects than disopyramide. Amiodarone was added to disopyramide in 1 patient (Case 17) because rapid nonsustained polymorphic VT (<8 seconds) was induced while the patient was receiving disopyramide alone. This was considered an unsatisfactory response. The follow-up period for the 11 patients has been 19 ± 9 months. The maintenance dose of disopyramide ranged from 0.6 to 1.2 g/day (0.81 ± 0.24 g).

*Arrhythmias:* Nine of 11 patients remain free of VT. VT recurred in 2 patients. One patient (Case 9) had a recurrence of VT 6 weeks after starting disopyramide. Endocardial mapping, ventricular aneurysmectomy, and endocardial resection were subsequently performed. The other patient (Case 10) had VT 25 months after initiation of therapy (3 and 8 ventricular complexes were respectively induced in each patient during their initial disopyramide study). Another patient (Case 8) had an episode of VT complicated by a fatal anterior wall myocardial infarction 6 months after starting disopyramide. He was free of VT during the period preceding infarction.

Four patients were treated with disopyramide in combination with other antiarrhythmic agents. In Patient 12, VT was noninducible with disopyramide or with the combination of quinidine and propranolol. However, the development of blurred vision, urinary hesitancy, and diarrhea necessitated decreasing the effective dose of disopyramide and quinidine. VT was not induced when a lower dose of both drugs in combination was tested. Patient 12 has remained arrhythmia-free for 30 months with a regimen of disopyramide, quinidine, and propranolol. Another patient (Case 17) was discharged receiving the combination of disopyramide and amiodarone which prevented induction of sustained VT. The patient has been arrhythmia-free for 3 months. In another patient, disopyramide alone slowed the VT cycle length from 260 to 290 ms. Mexiletine, separately, increased the cycle length to 315 ms and the combination of both drugs at their original doses resulted in induction of 16 seconds of VT with a cycle length of 420 ms. This patient has not had an episode of VT during the 14-month follow-up period. The final patient had VT with a cycle length of 200 ms induced while taking disopyramide. Aprindine (not tested independently) in combination with disopyramide resulted in inducible VT at a cycle length of 440 ms. He was discharged receiving both drugs and died 1 month later of recurrent VT.

*Adverse effects:* Two patients died of intractable congestive heart failure at 13 and 25 months after disopyramide administration (Cases 1 and 10, Table I). Both had ejection fractions <40% and previous histories of congestive heart failure. The discharge maintenance doses were 200 and 300 mg, respectively, on a 6-hour regimen.

Minor adverse effects including dry mouth, blurred vision, or urinary hesitancy have either been tolerated or improved with time.

## Discussion

Electrophysiologic effects of disopyramide are similar to those of procainamide and quinidine. In man, it lengthens the atrial effective refractory period, decreases the effective refractory period of the atrioventricular node, and increases the relative refractory period of the His-Purkinje system.[5] In isolated canine Purkinje fibers, disopyramide diminishes $\dot{V}_{max}$, membrane responsiveness, spontaneous phase 4 depolarization, and maximal diastolic potential; it increases action potential duration.[6-8]

**Response to programmed ventricular stimulation:** Disopyramide prevented induction of VT in one third of patients studied. Programmed stimulation predicted long-term success in over 80% of patients discharged taking the drug. This is similar to the positive predictive value of programmed stimulation using other type I agents.[2-4]

Our data are consistent with findings from previous studies that examined the electrophysiologic efficacy of disopyramide in a similar patient population.[9-12] A 30 to 50% success rate has been reported using doses from 600 to 1,400 mg/day. These studies, however, have been limited by both the number of patients evaluated and the incomplete follow-up data provided.

The effect of disopyramide on the QRS interval, QTc interval, or ventricular effective refractory period did not distinguish between effective or ineffective responders. Interestingly, the faster the VT cycle length in the control study, the more likely an effective response was achieved. This observation has been noted by other investigators evaluating mexiletine.[13]

**Effect of disopyramide on VT cycle length:** Disopyramide significantly increased the cycle length of the tachycardia. This has important clinical implications. It suggests that even though the drug may fail to prevent reinduction of VT, it may result in a hemodynamically stable, and, therefore, better tolerated tachycardia.

**Electrocardiographic effects:** Disopyramide lengthened the QTc interval by a small but statistically significant amount. No marked prolongation associated

with torsade de pointes was observed. Disopyramide-related torsade de pointes, VT, and VF have been described in association with prolonged QRS and QT intervals or QT intervals alone.[14–17] Disopyramide levels were markedly elevated in the 2 cases in which they were reported, 7.2 μg/ml (dose 100 mg orally every 6 hours) and 7.5 μg/ml (dose 600 mg orally every 6 hours). Congestive heart failure and renal or hepatic insufficiency may predispose the patient to elevated plasma levels.

While a statistically significant increase in QRS duration was also observed, no significant degree of heart block was noted. A recent study using intravenous disopyramide in patients with bundle branch block demonstrated that although mean infranodal conduction time increased 18%, from 67 ± 35 ms to 79 ± 41 ms ($p < 0.001$), no spontaneous second- or third-degree atrioventricular block occurred. Mean peak serum levels were 5.1 ± 2.2 μg/ml.[18]

**Adverse effects:** Anticholinergic symptoms are the most common adverse effects associated with disopyramide administration. In our study, urinary hesitancy, dry mouth, and blurred vision usually occurred within 48 hours of receiving the drug; however, these symptoms were usually mild and resolved with time or with a reduction in dose. In no case was discontinuation of the drug necessary. Other associated symptoms such as nausea, vomiting, and headache were not present in our study.

A major concern with disopyramide is its effect on left ventricular function. Cathcart-Rake et al[19] recently reported that although doses of 800 mg/day of disopyramide caused a slight decrease in left ventricular ejection fraction as evaluated by M-mode echocardiography in normal volunteers, this did not result in development of clinically significant symptoms. However, a preliminary report by Desai et al[20] demonstrated electromechanical dissociation with disopyramide in 6 patients with congestive heart failure and renal insufficiency. Plasma levels, when available, were elevated. All patients had significant lengthening of the QTc interval at least 24 hours before death. Postmortem examination eliminated other potential causes for electromechanical dissociation. We saw 1 death due to electromechanical dissociation. Two patients receiving long-term disopyramide had worsening of congestive heart failure. Podrid et al[21] reported that in patients with a history of congestive heart failure, disopyramide may precipitate recurrence of failure in 50% while resolution usually occurs with discontinuation of the drug. Most instances of failure occurred within 3 weeks of initiating treatment. There was no significant difference in either dose or plasma levels in patients with and without congestive heart failure in their series.

**Conclusions:** Disopyramide prevented induction of sustained VT in one third of patients studied and remained effective therapy in 80% of patients treated chronically. Though minor adverse effects developed in 20% of patients receiving disopyramide, the major factor limiting its use was myocardial depression. This occurred only in those patients with preexisting ventricular dysfunction.

# Effects of Oral Digoxin on Ventricular Ectopy and Its Relation to Left Ventricular Function

ALAN H. GRADMAN, MD, MOIRA CUNNINGHAM, BS, PA, MARY A. HARBISON, BS, HARVEY J. BERGER, MD, and BARRY L. ZARET, MD

**The ventricular antiarrhythmic properties of oral digoxin were examined in 13 patients with chronic ventricular ectopy using serial 24-hour electrocardiographic monitoring. Mean premature ventricular complex frequency (per 1,000 normal beats) decreased from 56 ± 47 during the placebo period to 40 ± 27 ($p$ = not significant [NS]) and 25 ± 17 ($p < 0.05$) during daily administration of digoxin, 0.25 and 0.375 mg. Digoxin had no significant effect on the qualitative occurrence of complex ventricular arrhythmia patterns (multiformity, bigeminy, couplets, ventricular tachycardia). Radionuclide left ventricular (LV) ejection fraction was measured during the placebo period. Seven patients had normal (ejection fraction >50%) and 6 abnormal global LV performance. In the normal group, the mean premature ventricular complex frequency decreased from 69 ± 58 to 20 ± 18 ($p < 0.05$) and the mean couplet frequency decreased from 0.59 ± 0.85 to 0.07 ± 0.06 ($p < 0.04$) during the placebo and 0.375 mg digoxin dosing periods, respectively. In contrast, no significant changes in either variable occurred after digoxin in subjects with depressed LV function. This study indicates that oral digoxin is moderately effective in suppressing premature ventricular complexes, and that its effects are greatest in patients with normal overall LV performance.**

The digitalis glycosides exert a variety of direct and indirect effects on myocardial cells[1–3] and are widely utilized for their inotropic and atrial antiarrhythmic properties. These agents have not, however, been generally used in the treatment of ventricular arrhythmias and, indeed, in toxic doses, are often implicated in their production.[4] In 1977, Lown et al[5] reported that intravenous administration of the digitalis-like agent acetylstrophanthidin was effective in suppressing ventricular ectopy in approximately one half of patients studied over a monitoring period of several hours.[5] That study has stimulated considerable interest in the ventricular antiarrhythmic properties of cardiac glycosides.

The present study was undertaken to determine the effects of digoxin—the most commonly used oral digitalis preparation—on the occurrence of ventricular ectopy. Long-term ambulatory electrocardiographic monitoring was used to provide a statistically adequate sampling of arrhythmia frequencies, in view of recent studies documenting the wide spontaneous variation which may occur in the frequency of premature ventricular complexes.[6,7] In addition, global left ventricular (LV) function was assessed with radionuclide angiocardiography and related to antiarrhythmic drug response.

## Methods

**Patient population:** Seventeen ambulatory outpatient men participated in the study. Subjects were selected on the basis of a random 24-hour ambulatory electrocardiographic recording demonstrating a mean premature ventricular complex frequency ≥10/1,000 normal beats. Patients in whom a history of life-threatening arrhythmia precluded temporary discontinuation of antiarrhythmic drug therapy or in whom ventricular tachycardia was noted on random Holter monitoring were excluded. Also excluded were patients with a serum creatinine level ≥1.5 mg/100 ml. In 4 subjects, the mean premature ventricular complex frequency decreased spontaneously during the placebo period (see section on Protocol) to values <2/1,000 normal beats. These patients were not included in final data analysis.

Thirteen patients aged 45 to 66 years (mean 57) completed the protocol and are the subject of data analysis. Six had definite coronary artery disease, documented by prior myocardial infarction or coronary arteriography; 1 additional patient with a classic anginal syndrome was presumed to have coronary disease. The remaining 7 patients had systemic hypertension; 1 of these also had aortic valvular stenosis. Two patients had a history of congestive heart failure; neither was in clinical heart failure at the time of study. Five patients had symptoms potentially referable to arrhythmias; 1 had palpitations and dizziness, 2 palpitations alone, and 2 dizziness alone.

**Protocol:** A single-blind placebo-controlled study design was utilized. At the initial study visit, antiarrhythmic medications were withdrawn and subjects began receiving a placebo tablet (identical in appearance to Lanoxin®, 0.25 mg) once daily. At the end of a 1-week dosing period, a 24-hour ambulatory electrocardiogram was recorded. In addition, resting left ventricular ejection fraction (LVEF) was determined using first-pass quantitative radionuclide angiocardiography. Subjects were then given oral digoxin (Lanoxin), 0.25 mg daily for a 1-week period, at the end of which ambulatory monitoring was repeated. If no signs or symptoms of digitalis intoxication were noted, the digoxin dose was increased to 0.375 mg daily and a final 24-hour electrocardiogram recorded at the end of a 1-week dosing period. (One patient in whom sinus bradycardia developed during the 0.25 mg dosing period did not receive the higher dose.) Pill counts were used to verify compliance.

**Arrhythmia detection and quantification:** Ambulatory electrocardiograms were recorded on 2-channel Avionics Model 425 Electrocorders using a bipolar $V_5$ and $V_5R$ lead system. Electrocardiographic recordings were analyzed using the YALECG research minicomputer system.[8] Currently configured on a Data General Eclipse S/130 processor, the YALECG algorithm is based on a width-sensitive peak detector for location of QRS complexes and a dual width correlation matching algorithm for waveform comparison. The system is operator-interactive and a series of on-line validity checks is used to ensure optimal program function.

The accuracy of this system in detecting premature ventricular complexes has been validated previously.[8] In a study of 20 1-hour electrocardiographic recording segments, system output was compared with a beat-by-beat hand count of the electrocardiogram. These recording segments, which were different from those used during algorithm development, contained 100,771 normal beats and 9,070 premature ventricular complexes. The true-positive rate for detection of premature ventricular complexes (sensitivity) was found to be 99.2%, the true-negative rate (specificity) 99.9%, and the false-positive rate 0.20%.

Mean heart rate and the total frequency of premature ventricular complexes (expressed per 1,000 normal beats) were determined for each electrocardiogram. The occurrence of 2 consecutive premature ventricular depolarizations was defined as a couplet, and couplet frequencies (per 1,000 normal beats) were also determined. The time of occurrence and QRS morphologic sequence of complex arrhythmic events—couplets, bigeminy, and ventricular tachycardia (defined as ≥3 consecutive premature ventricular complexes occurring at a rate of ≥100/min)—were recorded in a computer-generated remark file.

**Radionuclide angiography:** Patients were studied while they were supine in the anterior position using a computerized multicrystal scintillation camera (Baird-Atomic System-77, Bedford, Massachusetts). An 18 gauge 1.5 inch catheter was placed in an antecubital vein and high-specific activity technetium-99m pertechnetate (10 to 15 mCi) injected. LVEF was determined from first-pass quantitative radionuclide angiocardiograms using standard techniques previously reported from this laboratory.[9,10]

Left ventricular end-diastolic volume (LVEDV) was measured using planimetry of the end-diastolic images obtained.[11] LVEDV measured in this manner correlates well with that

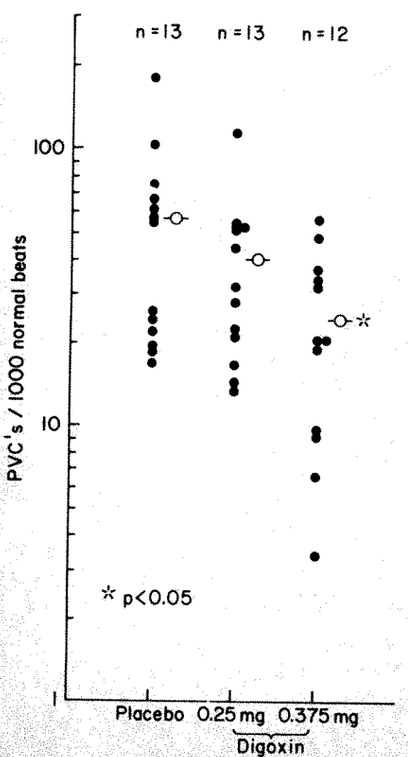

**FIGURE 1.** Effect of digoxin on the mean frequency of premature ventricular complexes (PVC's) in 13 patients.

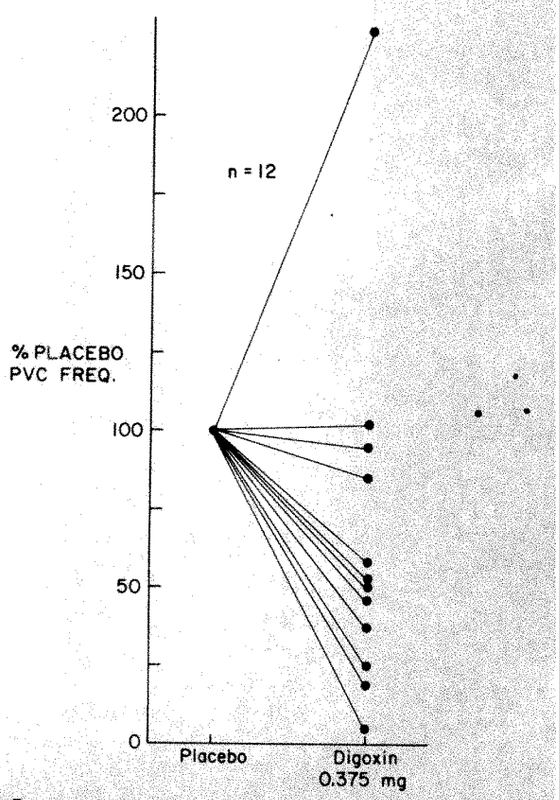

**FIGURE 2.** Percent change in the mean frequency of premature ventricular complexes (PVC FREQ.) during administration of digoxin, 0.375 mg daily.

measured by contrast angiography, and, in our laboratory, a correlation coefficient (r = 0.87) was noted in a group of 25 patients studied by both techniques. End-systolic volume (ESV) was calculated using the following formula: ESV = EDV − EDV·LVEF.

**Statistical methods:** Data are expressed as mean values ± standard deviation. Comparisons of mean heart rates and $\log_{10}$ of premature ventricular complex and couplet frequencies were made by paired (2-tailed) $t$ test. When multiple $t$ tests were performed on a data set, p values were corrected by multiplying the calculated p value by the number of tests performed, as suggested by Glantz.[12] Comparisons of the incidence of complex arrhythmia patterns were performed by the chi-square method. A p value <0.05 was considered significant.

## Results

**Electrocardiography:** Digoxin administration resulted in a modest decrease in the average heart rate. The mean heart rate declined from 84.4 ± 14.5 beats/min during the placebo period to 79.4 ± 12.4 beats/min (p <0.06) and 80.2 ± 11.5 beats/min (p <0.04) during the digoxin 0.25 mg and 0.375 mg dosage periods, respectively. The P-R interval increased from a placebo mean value of 0.164 ± 0.03 second to 0.177 ± 0.03 second (p <0.02) during the low-dose and 0.181 ± 0.04 second (p <0.002) during the high-dose digoxin treatment period. A decrease in the rate-corrected[13] Q-T interval was observed from 0.447 ± 0.05 second (placebo) to 0.429 ± 0.06 (digoxin 0.25 mg) and 0.426 ± 0.06 (digoxin 0.375 mg). These changes in the Q-$T_c$ interval did not reach statistical significance.

**Ventricular arrhythmias:** For the group as a whole, mean premature ventricular complex frequency (per 1,000 normal beats) decreased from 56.1 ± 46.6 during the placebo period to 40.0 ± 27.2 (p = NS), and 24.8 ± 17 (p <0.05) during administration of digoxin, 0.25 and 0.375 mg, respectively (Fig. 1). Changes in premature ventricular complex frequency in individual patients are depicted in Figure 2. Two subjects showed an increase and 10 of 12 (83%) a decrease in mean premature ventricular complex frequency. However, only 3 of 12 (25%) demonstrated ≥75% ectopic suppression.

The effect of digoxin on ventricular couplet frequency was also examined. Mean couplet frequency (per 1,000 normal beats) decreased from 1.13 ± 1.9 during placebo to 0.84 ± 1.5 (p = NS) and 0.36 ± 0.59 during the low- and high-dose digoxin periods. The observed reduction in couplet frequency at the 0.375 mg dose closely approached statistical significance (t = 2.5520, p <0.06).

Digoxin appeared to have little effect on the qualitative occurrence of complex ventricular ectopic patterns (Table I). During the placebo period, multiformity was present in 12 of 13 (93%) patients, bigeminy in 13 of 13 (100%), couplets in 13 of 13 (100%), and ventricular tachycardia in 2 of 13 (15%). There was no significant change in the incidence of these arrhythmia patterns during either of the digoxin dose periods.

**Left ventricular function and ventricular arrhythmia:** Resting LVEF during the placebo period ranged from 40 to 69% and averaged 51.4%. Seven patients had normal and 6 demonstrated depressed overall LV performance (ejection fraction <50%). In patients with a normal ejection fraction, end-diastolic volume averaged 144 ± 13 ml and end-systolic volume 58 ± 12 ml. Patients with an abnormal ejection fraction had significantly higher mean values for both end-diastolic volume (226 ± 44 ml, p <0.005) and end-systolic volume (131 ± 25 ml, p <0.001).

**TABLE I Effect of Digoxin on Complex Ventricular Ectopic Patterns (n = 13)**

| | Placebo | Digoxin, 0.25 mg | Digoxin, 0.375 mg |
|---|---|---|---|
| Multiformity | 12/13 (93%) | 12/13 (93%)* | 9/12 (75%)* |
| Bigeminy | 13/13 (100%) | 13/13 (100%)* | 12/12 (100%)* |
| Couplets | 13/13 (100%) | 13/13 (100%)* | 11/12 (92%)* |
| Ventricular tachycardia | 2/13 (15%) | 2/13 (15%)* | 1/12 (9%)* |

* p = NS, compared with placebo.

The effect of digoxin on premature ventricular complex frequency in these 2 subgroups is shown in Figure 3. In patients with a normal ejection fraction, the mean frequency decreased from 69.3 ± 57.9 during placebo to 20.4 ± 17.8 during the digoxin 0.375 mg dosing period (p <0.05). A significant reduction in couplet frequency was also observed, with mean values decreasing from 0.59 ± 0.85 to 0.07 ± 0.06 (p <0.04). All patients exhibiting ≥75% premature ventricular complex suppression were in the subgroup with normal LV function.

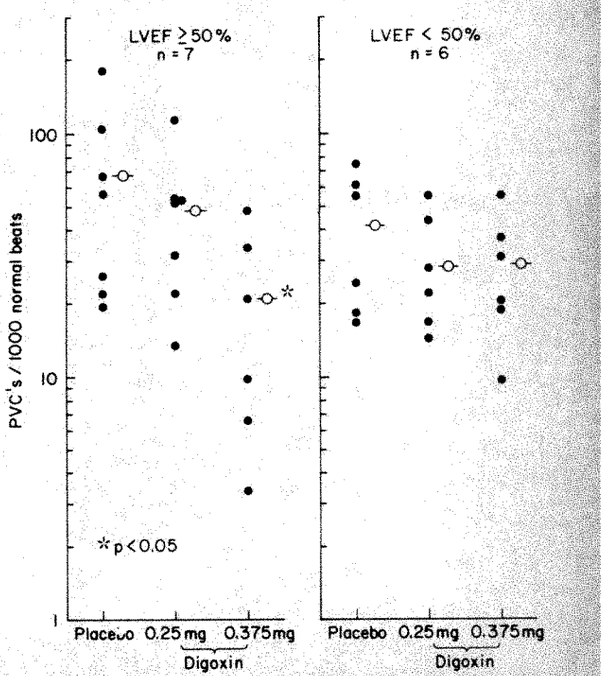

**FIGURE 3.** Effect of digoxin on the mean frequency of premature ventricular complexes (PVC's) in patients with normal (≥50%) and abnormal (≥50%) left ventricular ejection fraction (LVEF).

In the subset of patients with depressed LV function, however, no significant changes occurred either in mean premature ventricular complex or couplet frequencies after digoxin administration. Mean values for premature complex frequency were 42.0 ± 29.9 during placebo and 29.2 ± 16.5 during digoxin 0.375 mg (p = NS). Mean couplet frequency values were 0.71 ± 0.90 and 0.65 ± 0.76 (p = NS), respectively, during the same 2 dosing periods.

**Toxicity:** No study patient exhibited signs or symptoms of digitalis toxicity. One subject did show a 127% increase in premature ventricular complex frequency and had short runs of ventricular tachycardia while receiving digoxin. Whether these changes were an expression of digitalis toxicity or merely an example of spontaneous arrhythmia frequency variation is uncertain.

## Discussion

Given their propensity, at toxic doses, for producing serious and even fatal ventricular rhythm disturbances, the digitalis glycosides have not received extensive evaluation in the treatment of ventricular dysrhythmias. The notion that they may be useful in this context is not, however, new. Scherf[14] reported in 1960 that "the various digitalis glycosides abolish most atrial and ventricular extrasystoles, provided they are not caused by digitalis." Blumberg et al[15] reported that oral digitalis preparations reduced premature ventricular complex frequency by >90% in 12 of 16 patients with frequent ventricular ectopy but without other evidence of organic heart disease. More recently, Lown et al[5] performed short-term acetylstrophanthidin tolerance testing in a group of 143 patients, and reported that 46% demonstrated >50% ventricular ectopic suppression after intravenous drug administration. Furthermore, in this subgroup of "responders" it was observed that repetitive ectopic beats (couplets and ventricular tachycardia) were abolished in all but 1 of the patients exhibiting them during the control period.

The present study demonstrates that oral digoxin also possesses significant activity against ventricular ectopy, but indicates that the extent of this activity is somewhat limited. At a daily digoxin maintenance dose of 0.375 mg, total premature ventricular complex frequency decreased 56%, and there appeared to be a concurrent reduction in couplet frequency. In contrast to Blumberg's study, however, complete or near-complete premature complex suppression was rarely seen and, unlike in Lown's study, there was little observed reduction in maximal arrhythmia grade.

The apparent discrepancy between these results and those of earlier studies probably reflects differences in study design. In Blumberg's study (available only in abstract form), patients were apparently recruited on the basis of a single 10-hour electrocardiographic recording demonstrating a premature ventricular complex frequency ≥30/1,000 QRS complexes. Several studies have now documented that significant spontaneous variation regularly occurs in premature ventricular complex frequencies in many individuals.[6,7,16] The selection of subjects on the basis of a random electrocardiographic recording exhibiting a high premature complex frequency will therefore tend to result in the inclusion of many individuals at the "high tide" of their ectopic frequency pattern, while excluding patients at a low point in their ectopic occurrence. The danger of this type of recruitment process is that the results of any study in which ectopic beat frequency is used as an end point will be biased in the direction of demonstrating the efficacy of the particular treatment modality in question. In the current study, patients were chosen initially on the basis of an average premature ventricular complex frequency of >10/1,000 normal beats. Four of these original 17 patients demonstrated a >90% *spontaneous* reduction in premature complex frequency during the placebo period. Use of a placebo-controlled study design allows such patients to be recognized and excluded from data analysis and avoids exaggerating treatment efficacy.

In Lown's study, the finding that repetitive beat formation was almost completely abolished in the "responder" subset may also in part be a function of study design. It has been observed that the reproducibility of couplet occurrence over short monitoring periods is often poor[7,17] and that couplet detection is directly related to monitoring duration.[18,19] It is possible that the observation periods used in Lown's study (several hours or less) may not have been sufficient to document continued couplet occurrence. In the present study, couplet frequency could be shown to decline after drug administration, but complete abolition of repetitive beat formation was observed in only 1 subject. This probably reflects the longer (24-hour) electrocardiographic monitoring periods used in the present study.

It is of interest that digoxin was found more effective in suppressing premature ventricular complexes in patients with normal, compared to abnormal, baseline LV function. While this finding could prove to be due to small sample size, it more likely represents one aspect of the complex pathophysiologic interrelationship between ventricular arrhythmias and abnormalities of ventricular function. In patients surviving acute myocardial infarction, for example, several studies have shown that the prognostic implications of recorded ventricular arrhythmias are more adverse in the presence of significant LV dysfunction.[20,21] It is possible that ventricular arrhythmias in the setting of myocardial structural abnormalities severe enough to compromise overall LV function will prove more resistant to any attempts at pharmacologic suppression. Further study is needed to clarify this issue.

Recent experimental evidence suggests that the ventricular antiarrhythmic properties of the digitalis glycosides are mediated by way of the autonomic nervous system. It is now well-established that the effects of digitalis on the central nervous system are complex, dose-related, and probably responsible for many of the manifestations of digitalis toxicity.[3] At toxic doses, digitalis augments sympathetic neural input to the heart; this increased sympathetic activity has been correlated with the development of malignant ventricular dysrhythmias.[22] In studies performed on the anesthetized cat, Evans and Gillis[23] reported that

subtoxic doses of ouabain *decrease* sympathetic activity and prevent the development of arrhythmias produced by hypothalamic stimulation. Gillis and Quest[3] postulated that this reduction in efferent sympathetic activity, which appears to be reflexly mediated, may account for the antiarrhythmic effects of digitalis on the ventricle. Digitalis drugs also augment vagal tone and other investigators[5] have suggested that the antiarrhythmic effects of vagal stimulation[24–26] may be important in explaining the effects of these agents in suppressing ventricular arrhythmias.

Hemodynamic mechanisms may also be postulated in explaining the ventricular antiarrhythmic properties of digoxin. Previous authors have speculated that digitalis drugs might reduce ventricular arrhythmias in patients with congestive heart failure by increasing contractility, reducing LV size and wall stretch, and improving myocardial oxygen supply/demand ratio.[4] Although approximately half of our patients had depressed resting LV function at the time of study, none had clinical congestive heart failure. Furthermore, the patients found most responsive to digoxin were those with normal LV function. In this circumstance, digitalis would be expected to actually increase myocardial oxygen demand.[27,28] It thus seems unlikely that hemodynamic changes are the primary mechanism responsible for reducing ventricular ectopy in the present study.

**Conclusion:** This study indicates that oral digoxin is a moderately effective agent for suppressing premature ventricular complexes. Its inability to effectively treat the complex ventricular arrhythmias (multiformity, bigeminy, couplets, and ventricular tachycardia) which have been shown in some patient populations to be harbingers of sudden death[20,29–32] is disturbing, and may limit the utility of this class of drugs as ventricular antiarrhythmic agents. Further studies, such as those designed to evaluate the effect of digoxin on ventricular tachycardia inducibility in the electrophysiology laboratory, may be of particular value in determining the place of the digitalis glycosides in the armamentarium of ventricular antiarrhythmic agents.

**Acknowledgment:** We thank Burroughs-Wellcome, Research Triangle Park, North Carolina, for providing the placebo tablets used in the study, Linda Leon for expert assistance in statistical analysis, and Rebecca McKeen for skilled manuscript preparation.

# Cardiac Electrophysiologic Effects of Flecainide Acetate For Paroxysmal Reentrant Junctional Tachycardias

KEVIN J. HELLESTRAND, MB, FRACP, ANTHONY W. NATHAN, MB, MRCP, RODNEY S. BEXTON, MA, MRCP, ROWORTH A. J. SPURRELL, MD, BSc, FRCP, and A. JOHN CAMM, MD, BSc, MRCP

**Intravenous flecainide acetate was administered to 33 patients undergoing routine electrophysiologic study: 18 patients had a direct accessory atrioventricular (AV) pathway and 15 patients had functional longitudinal A-H dissocciation (dual A-H pathways). Flecainide was given to 14 patients during sustained AV reentrant tachycardia and to 9 patients during sustained intra-AV nodal reentrant tachycardia.**

**AV reentrant tachycardia was successfully terminated in 12 of 14 patients. Tachycardia termination was due to retrograde accessory pathway block in 11 patients and AV nodal block in 1. During flecainide administration, tachycardia cycle lengths increased (327 ± 55 to 426 ± 84 ms) principally because of retrograde conduction delay in the accessory pathway (127 ± 34 to 197 ± 67 ms). After flecainide administration, tachycardia reinitiation was not possible in 6 patients. In all 18 patients with accessory AV pathway conduction, flecainide significantly increased both anterograde and retrograde accessory pathway effective refractory periods, with anterograde accessory pathway block in 3 patients and retrograde accessory pathway block in 8.**

**Intra-AV nodal reentrant tachycardia was successfully terminated in 8 of 9 patients. Tachycardia termination was due to retrograde "fast" A-H pathway block in 7 patients and anterograde "slow" A-H pathway block in 1 patient. During flecainide administration, tachycardia cycle lengths increased (326 ± 50 to 433 ± 64 ms) due to both anterograde, A-H and H-V (AV 242 ± 97 to 343 ± 75 ms), and retrograde, earliest ventricular to earliest atrial (51 ± 14 to 70 ± 23 ms) conduction delay. After flecainide administration, reinitiation of intra-AV nodal reentrant tachycardia was not possible in 4 patients. In all 15 patients with dual A-H pathways, flecainide selectively prolonged the retrograde effective refractory period of the fast A-H pathway, having little effect on anterograde fast A-H pathway refractoriness or on anterograde and retrograde slow A-H pathway refractoriness. Anterograde fast A-H pathway block occurred in 1 patient and retrograde fast A-H pathway block occurred in 6 patients. No serious adverse effects were encountered during the study.**

**Flecainide acetate is an effective agent for the acute termination of both orthodromic AV and intra-AV nodal reentrant tachycardias. This antiarrhythmic action appears to be mediated through a predominant effect on either accessory AV pathway or retrograde fast A-H pathway refractoriness.**

Flecainide acetate (Riker Laboratories, St. Paul, Minnesota) is a membrane-stabilizing antiarrhythmic agent[1] with proven efficacy in the termination of some experimentally induced arrhythmias.[2–4] Favorable pharmacokinetic properties[5,6] and preliminary clinical studies demonstrating its effectiveness against a wide spectrum of arrhythmias[7–9] indicate that flecainide may be a valuable addition to presently available antiarrhythmic agents. Recent electrophysiologic studies have shown that flecainide prolongs all cardiac conduction intervals with particularly marked effects on His-Purkinje and ventricular myocardial conduction.[10] On the basis of its pronounced effect on cardiac conduction but its relatively minor effect on the duration of repolarization, flecainide has been described as a class IC antiarrhythmic drug.[11] Although flecainide appears to have little effect on refractoriness of normal cardiac tissue, it significantly prolongs the refractoriness of accessory

pathways.[10] This drug may therefore be particularly valuable in the management of reentrant tachycardias which utilize such tissues. The present study was undertaken to investigate this antiarrhythmic potential.

## Methods

**Patient group:** In 33 consecutive patients (18 male and 15 female) aged 22 to 73 years (mean 40) electrophysiologic studies were performed for the investigation of recurrent paroxysmal "junctional" tachycardias. Eighteen patients had a direct accessory atrioventricular (AV) pathway, 15 of whom had provocable AV reentrant (orthodromic) tachycardia utilizing the accessory pathway as the retrograde limb of the tachycardia circuit. Accessory pathway conduction was bidirectional, with ventricular preexcitation during sinus rhythm (Wolff-Parkinson-White syndrome) in 9 patients and retrograde only (electrophysiologically concealed AV accessory pathway conduction) in the remaining 9 patients. The other 15 patients had functional longitudinal A-H dissociation; 9 of these had inducible intra-AV nodal reentrant tachycardia.[12-16]

**Electrophysiologic study:** All patients were studied after absorption in nonsedated state after giving informed written consent. All antiarrhythmic drugs were discontinued at least 3 drug elimination half-lives before electrophysiologic study.

Under local anesthesia (10 to 15 ml of 1% lidocaine) and by means of fluoroscopic guidance, 4 pacing electrodes were introduced into the heart. By way of the left subclavian vein, the tip of a hexapolar electrode was positioned at the right ventricular apex. The 2 distal poles were used for right ventricular pacing and 2 of the 4 proximal poles were selected to obtain the best possible bipolar recording from the lateral wall of the right atrium. A quadripolar electrode was introduced from the same subclavian vein and positioned in the coronary sinus for both stimulating and recording. Two bipolar electrodes were introduced by way of a femoral vein. One electrode was advanced into the high right atrium for pacing and the other electrode was positioned against the septal leaflet of the tricuspid valve to record distinct low right atrial, His bundle, and proximal right ventricular electrograms. Intracardiac signals were filtered between 50 and 500 Hz and recorded on a 16-channel Mingograf inkjet recorder (Siemens-Elema, Stockholm, Sweden) simultaneously with surface electrocardiographic leads I, aVF, $V_1$, and $V_6$. Paper speeds of 100 and 250 mm/s were used. Intracardiac stimulation was achieved with a Devices-type 4279 "programmable" stimulator (Digitimer, Welwyn, Hertfordshire, England) using pulse amplitudes at twice diastolic threshold and pulse durations of 1.5 to 2.5 ms.

Intracardiac conduction intervals were measured during sustained AV reentrant tachycardia (14 patients) and sustained intra-AV nodal reentrant tachycardia (9 patients). Refractory periods of accessory AV (18 patients) and dual A-H pathways (15 patients) were determined during basic atrial and ventricular pacing using the extrastimulus technique.[17,18]

Tachycardia initiation windows were determined in each patient during basic atrial or ventricular pacing followed by the introduction of a single atrial or ventricular extrastimulus, respectively. The tachycardia initiation window is defined as the difference, in milliseconds, between the longest and shortest atrial or ventricular extrastimulus coupling intervals which result in the initiation of 2 or more beats of reentrant tachycardia.

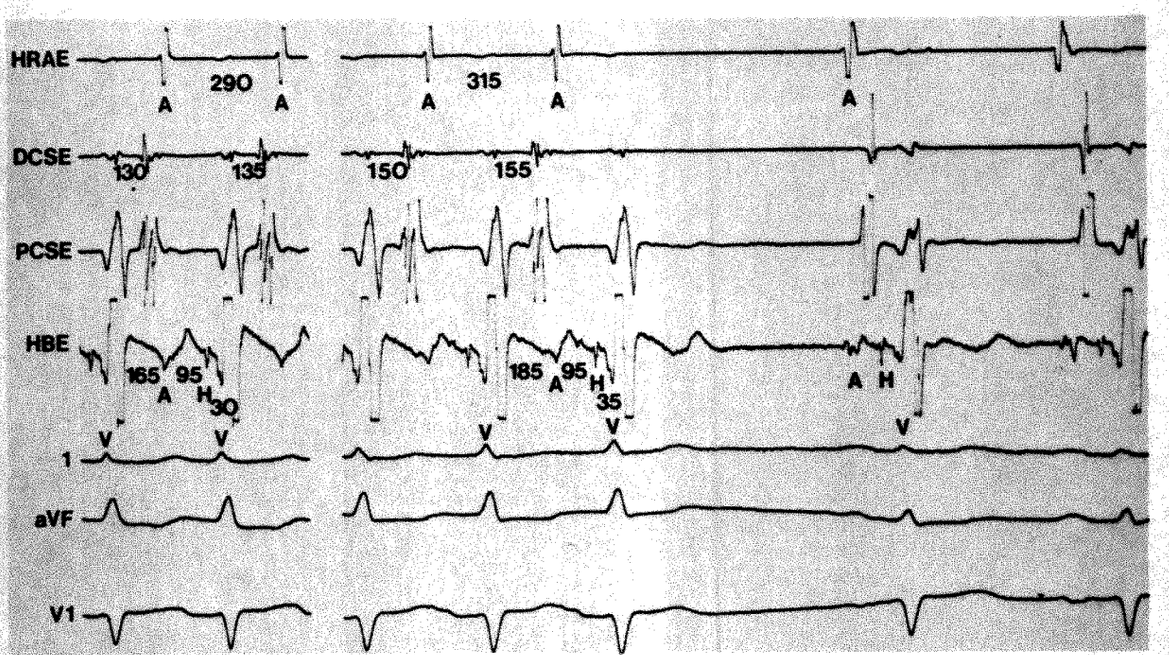

**FIGURE 1.** In this patient with a left free wall accessory AV pathway, tachycardia termination occurred 45 seconds after flecainide administration began, that is, after 14 mg of a total dose of 88 mg had been given. Tachycardia termination resulted from retrograde block in the accessory pathway, the last electrical event in tachycardia being ventricular depolarization. Before termination, the tachycardia cycle length increased from 290 to 315 ms due to delay in ventricular to atrial conduction. A small increase in the HV interval was also observed. A = intracardiac atrial electrogram; DCSE = distal coronary sinus electrogram; H = intracardiac His bundle deflection; HBE = His bundle electrogram; HRAE = high right atrial electrogram; PCSE = proximal coronary sinus electrogram; L1, aVF, $V_1$, and $V_6$ = surface electrocardiographic leads; V = ventricular depolarization. All measurements in milliseconds.

All measurements were made to the nearest 5 ms. For comparison, identical basic atrial and ventricular cycle lengths were used before and after flecainide administration. Conduction intervals and refractory periods were determined as previously described.[10]

**Flecainide administration:** After baseline electrophysiologic evaluation, a dose of flecainide acetate (2 mg/kg of body weight) was administered intravenously over 5 minutes. Flecainide was given during reentrant tachycardia to 23 patients (14 with AV reentrant tachycardia and 9 with intra-AV nodal reentrant tachycardia) in whom tachycardia had been initiated and sustained for at least 10 minutes before injection. Flecainide was given to the remaining 10 patients during sinus rhythm. The complete dose of flecainide was administered whether termination of tachycardia occurred or not. Electrophysiologic assessment after drug administration began 15 minutes after commencing drug infusion and was completed within 45 minutes of drug administration. Before beginning electrophysiologic evaluation after drug administration, pacing thresholds were readjusted to twice diastolic threshold.

Flecainide acetate doses in all 33 patients ranged from 88 to 175 mg (mean 134).

**Statistics:** Statistical data were analyzed using Student's 2-tailed $t$ test for paired data.

## Results

**Orthodromic AV reentrant tachycardia (Tables I and II):** Flecainide acetate successfully terminated AV reentrant tachycardia in 12 patients an average of 3 minutes (range 45 seconds to 8 minutes) after beginning administration. Tachycardia termination was due to block in the retrograde limb of the tachycardia circuit in 11 patients and block in the anterograde (A-H) limb in the remaining patient. A typical example of tachycardia termination is illustrated in Figure 1.

After starting flecainide administration, tachycardia cycle lengths increased in all patients (Fig. 2) due principally to an increase in retrograde conduction time (Table I). Anterograde conduction intervals during

AVERP = anterograde effective refractory period; VAERP = retrograde effective refractory period; AVRT = orthodromic AV reentrant tachycardia; Before = before flecainide administration; After = after flecainide administration.
All measurements in milliseconds.

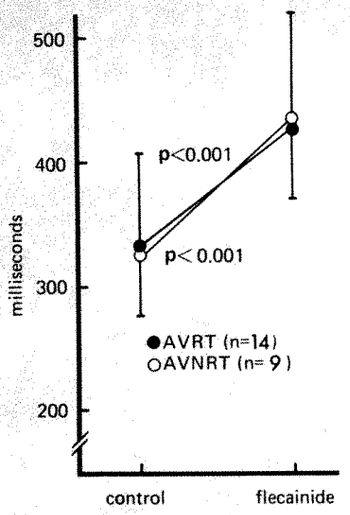

**FIGURE 2.** Comparison of tachycardia cycle lengths before flecainide administration and immediately before tachycardia termination. AVNRT = intra-AV nodal reentrant tachycardia; AVRT = orthodromic AV reentrant tachycardia.

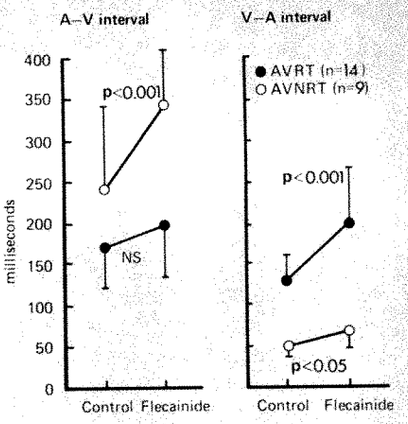

**FIGURE 3.** Comparison of anterograde and retrograde conduction intervals during reentrant "junctional" tachycardia before flecainide administration and immediately before tachycardia termination. A-V interval = A-H + H-V conduction times; V-A interval = earliest ventricular to earliest atrial conduction time.

tachycardia increased only slightly, due almost entirely to increased H-V conduction time (Fig. 3).

Tachycardia was reinitiated in 9 patients (6 with overt preexcitation and 3 with concealed accessory pathway conduction) during the course of the electrophysiologic assessment after drug infusion. A single atrial extrastimulus was able to initiate reentrant tachycardia in 15 patients during the control study but sustained tachycardia was possible in only 14. In these 15 patients this tachycardia initiation window was significantly reduced and in 6 patients was completely abolished by flecainide infusion. A single ventricular extrastimulus initiated tachycardia in only 3 of the 18 patients before flecainide administration. No orthodromic AV reentrant tachycardia initiation windows to a single ventricular extrastimulus were present after flecainide. However 1 patient (Table I, Case 6) had antidromic AV reentrant tachycardia during ventricular extrastimulation after flecainide. In this patient, ventricular extrastimuli with coupling intervals shorter than the retrograde effective refractory period of the accessory pathway (280 ms) conducted retrogradely through the AV node and then anterogradely through the accessory pathway, resulting in antidromic reentrant tachycardia at a cycle length of 370 ms.

Flecainide administration resulted in anterograde accessory pathway block in 3 patients, all of whom had long refractory periods during the control study (300, 440, and 480 ms). In the remaining 6 patients with overt

AVERP = anterograde effective refractory period; VAERP = retrograde effective refractory period; AVNRT = intra-AV nodal reentrant tachycardia; Before = before flecainide administration; After = after flecainide administration.
All measurements in milliseconds.

preexcitation where accessory pathway anterograde refractoriness was ≤265 ms during the control study, refractoriness increased insignificantly in 4 and showed a relative increase in the remaining 2 patients. By comparison, effective refractory periods of the atrial myocardium in these 9 patients changed insignificantly (191 ± 24 to 197 ± 30 ms).

Accessory pathway retrograde refractoriness was more markedly increased by flecainide administration. Retrograde accessory pathway block persisted in 8 patients, 7 of whom had accessory pathway retrograde refractory periods of ≥300 ms during the control study. In the 10 remaining patients, retrograde refractoriness (<300 ms in all cases during the control study) was increased in 5, unchanged in 1 (268 ± 24 to 322 ± 71 ms, difference not significant [NS]), relatively shortened in 1, and relatively increased in the remaining 3 patients. Right ventricular myocardial refractoriness in these 18 patients demonstrated a slight change from 217 ± 22 to 226 ± 24 ms ($p < 0.05$).

**Intra-AV nodal reentrant tachycardia (Tables I and III):** All patients with intra-AV nodal tachycardia had the typical variety of reentry comprising anterograde slow A-H pathway conduction and retrograde fast A-H pathway conduction with virtually simultaneous atrial and ventricular activation. Flecainide acetate successfully terminated intra-AV nodal reentrant tachycardia in 8 patients an average of 5 minutes (range 1 to 15) after administration began.

Tachycardia termination resulted from block in the retrograde limb of the tachycardia circuit in 7 patients and block in the anterograde (A-H) limb in the remaining patient. A typical example of tachycardia termination is illustrated in Figure 4. Flecainide increased intra-AV nodal reentrant tachycardia cycle lengths in all patients due to an increase in both AV and VA times (Fig. 2, Table I). However VA time was measurable in only 5 patients, the low right atrial deflection on the His bundle electrogram occurring simultaneously with and thus indistinguishable from the right ventricular deflection in the remaining 4 patients.

In 5 patients, intra-AV nodal reentrant tachycardia could be reinitiated during the post-drug study. In 3 of the 4 remaining patients, retrograde block of the fast A-H pathway persisted. After flecainide administration, the tachycardia initiation window using a single atrial extrastimulus decreased insignificantly. A single ventricular extrastimulus initiated tachycardia in 4 patients only during the control study and not after flecainide administration.

Flecainide markedly increased retrograde refractoriness of the fast A-H pathway, retrograde block persisting in 6 patients, remaining markedly prolonged in 7 patients, and unchanged in 2 (see Table III). The magnitude of this increase was not, however, related to the effective refractory period measured during the control study. Anterograde fast A-H pathway refractoriness (350 ± 52 to 355 ± 45 ms) was not significantly affected by flecainide. Similarly, refractoriness of the slow A-H pathway in both the anterograde and retrograde directions was not significantly affected by flecainide. The change in myocardial refractoriness of both the right atrium (200 ± 31 to 210 ± 30 ms) and right ventricle (225 ± 23 to 222 ± 21 ms) after flecainide administration in these 15 patients with functional A-H duality was not statistically significant.

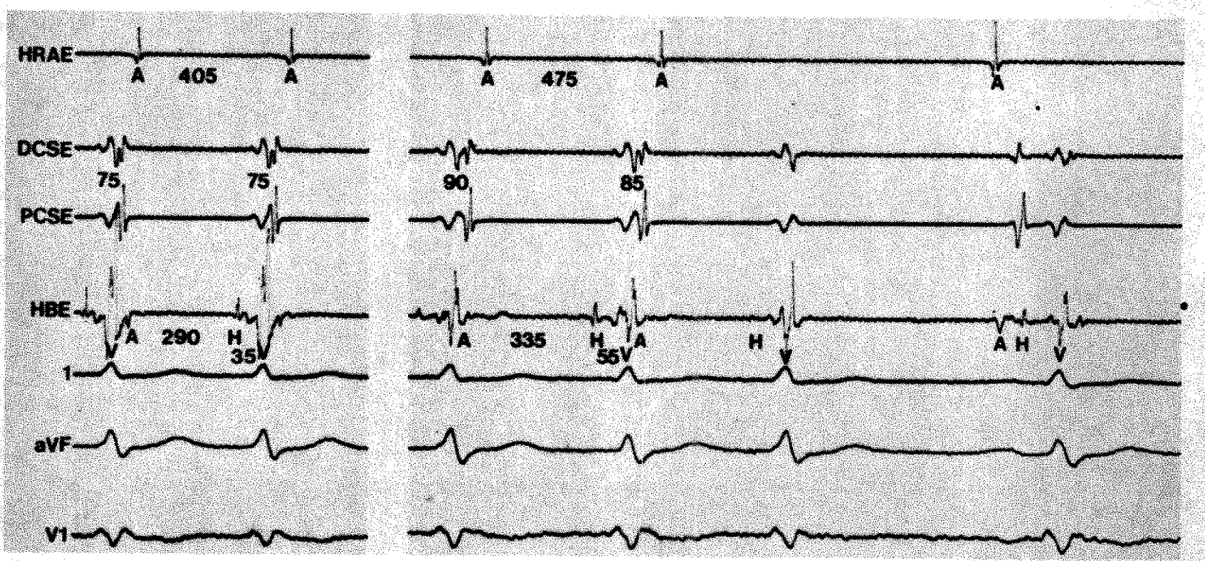

**FIGURE 4.** In this patient tachycardia termination occurred 85 seconds after flecainide administration began, that is, after 40 mg of a total dose of 140 mg had been given. Tachycardia termination occurred as a result of block in the retrograde limb (fast A-H pathway) of the tachycardia circuit, the last electrical event during tachycardia being ventricular depolarization. Before termination, the tachycardia cycle length increased from 405 to 475 ms due to conduction delay in both the anterograde and retrograde limbs of the tachycardia circuit. A = intracardiac atrial electrogram; DCSE = distal coronary sinus electrogram; H = intracardiac His bundle deflection; HBE = His bundle electrogram; HRAE = high right atrial electrogram; PCSE = proximal coronary sinus electrogram; L1, aVF, $V_1$, and $V_6$ = surface electrocardiographic leads; V = ventricular depolarization. All measurements in milliseconds.

**Adverse effects:** Two patients experienced major adverse effects. Antidromic AV reentrant tachycardia was initiated in 1 patient in whom it was only possible to initiate orthodromic AV reentrant tachycardia during the control study. In another patient, a single ventricular extrastimulus reproducibly initiated ventricular flutter and fibrillation only after flecainide administration. Minor adverse effects included numbness and paresthesia of the buccal mucosa in 28 patients, transient drowsiness or dizziness in 5 patients, and discomfort at the injection site in 3 patients.

## Discussion

The maintenance of reentrant "junctional" tachycardia depends upon tachycardia cycle length exceeding the refractory period of any 1 of the components of the reentry circuit. Hence, any pharmacologic agent which increases refractoriness within the reentry circuit beyond the cycle length of the tachycardia will prevent induction and maintenance of reentrant tachycardia. Ideally such an antiarrhythmic agent would selectively increase refractoriness within the anomalous pathways (fast A-H pathway or accessory AV pathway) without affecting conduction or refractoriness within the normal conduction system of the heart.

Many reports have described the efficacy of Vaughan Williams[19] class I and III antiarrhythmic agents in the management of the Wolff-Parkinson-White syndrome.[20–22] Disopyramide was shown to significantly increase both anterograde and retrograde accessory pathway refractoriness to a similar extent and to effectively terminate orthodromic AV reentrant tachycardia by blocking the retrograde limb of the circuit; however, conduction time through the accessory pathway was probably also increased.[23,24] Wellens et al[25,26] found that procainamide, quinidine, ajmaline and amiodarone had marked effects on anterograde refractoriness of accessory pathways with a lesser effect on retrograde refractoriness. The magnitude of the effects of these drugs on anterograde accessory pathway refractoriness was related to initial accessory pathway anterograde effective refractory period before drug administration,[27] a more marked lengthening of refractoriness occurring if the initial refractoriness was ≥270 ms. No such drug effect was observed with regard to retrograde refractoriness of accessory pathways in the same group of patients.

In our study, flecainide had a marked effect on both anterograde and retrograde accessory pathway refractoriness, its effects on retrograde refractoriness apparently being more marked. The response of accessory pathway anterograde refractoriness to flecainide also appears related to its resting value with short (<270 ms) refractory periods showing only modest lengthening after flecainide and longer (>270 ms) refractory periods showing more marked lengthening or anterograde conduction block (in all 3 of our patients with accessory pathway anterograde refractory periods of ≥300 ms anterograde conduction block developed). A similar response of accessory pathway retrograde refractoriness to flecainide was observed. When initial retrograde refractoriness was ≥300 ms, marked prolongation occurred (all 7 of our patients had accessory pathway retrograde block after flecainide administration), whereas the response to flecainide was much less marked when retrograde refractoriness was <300 ms. The more marked effect of many antiarrhythmic agents, including flecainide acetate, on accessory pathway refractoriness compared with their reduced effect on either atrial or ventricular refractoriness suggests that accessory pathways, although histologically similar to ventricular muscle,[28,29] have quite distinct electrophysiological characteristics.

Similarly, procainamide[30] and quinidine[31] were shown to selectively depress retrograde fast A-H pathway conduction in patients with intra-AV nodal reentrant tachycardia, with little or no effect on anterograde fast A-H pathway conduction and no significant effect on either anterograde or retrograde slow A-H pathway conduction.

This study has shown that flecainide effectively terminates intra-AV nodal reentrant tachycardias by selectively prolonging retrograde fast A-H pathway refractoriness. Its selective depressant effect on fast A-H pathway refractoriness with a negligible effect on either atrial or ventricular refractoriness in the same group of patients are findings which are strikingly similar to the effects observed with procainamide and quinidine and in agreement with the suggestion by Gomes,[32,33] Platt,[34] and their co-workers that the fast A-H pathway is electrophysiologically dissimilar to either the slow A-H pathway or the normal AV node and more characteristic of accessory or anomalous pathway tissue. In 6 of our patients, retrograde duality of AV nodal conduction only became evident after flecainide administration (Table II), presumably due to the selective impairment of retrograde fast A-H pathway conduction by flecainide.

Although slow pathway refractoriness was unaffected by flecainide, the A-H interval during intra-AV nodal reentry was prolonged markedly. Previous studies have shown that flecainide depresses conduction through the normal AV node.[10] Despite this the A-H interval during AV reentry remained unchanged, presumably a result of concomitant slowing of the tachycardia rate. The different response of the slow pathway may be related to an increased sensitivity to flecainide. Also this A-H interval is not a linear conduction time and is not directly comparable to the A-H interval during sinus rhythm or during AV reentry.

The significant depressant effect of flecainide on normal cardiac conduction pathways as well as anomalous pathways may theoretically tend to favor continuation of reentrant tachycardias, although at a slower rate. However, the disproportionate influence of flecainide on abnormal pathway refractoriness assured tachycardia termination in 20 of the 23 patients. Since flecainide appears to have relatively minor negative inotropic effects in both experimental models[1] and the normal human heart,[35] slowing the tachycardia rate should improve the clinical and hemodynamic state of patients with reentrant tachycardias.

In this study, flecainide acetate proved to be an extremely effective agent for the acute management of

reentrant junctional tachycardias which utilize either accessory AV pathways or dual A-H pathways. The usual mode of tachycardia termination in response to flecainide was marked prolongation of the retrograde effective refractory periods of these pathways such that refractoriness exceeded the increase in tachycardia cycle length. It is unlikely that tachycardia termination was spontaneous and coincidental with flecainide administration as all patients had previous histories of long and sustained episodes of tachycardia, tachycardia was well established in each patient before flecainide administration, and tachycardia termination was due to retrograde block in the anomalous pathway in all except 2 patients.

# Cardiac Effects of Treatment With Quinidine and Digoxin, Alone and in Combination

KARIN SCHENCK-GUSTAFSSON, MD, TOMAS JOGESTRAND, MD, LARS-ÅKE BRODIN, MD, ROLF NORDLANDER, MD, and RUNE DAHLQVIST, MD

**Systolic time intervals ($QS_2$-I and LVET-I) and echocardiographically determined ejection fraction and velocity of circumferential fiber shortening were recorded in 10 healthy volunteers as measures of inotropic effect during maintenance treatment with 4 consecutive drug regimens: (1) quinidine, 1,200 mg/day; (2) digoxin, average dose 0.31 mg/day; (3) the combination of (1) and (2); and (4) digoxin alone (average dose 0.65 mg/day) to provide the same steady-state serum concentration of digoxin as during the period with combination of digoxin and quinidine. The steady-state serum concentration of digoxin during the low-dose regimen increased from 0.72 ± 0.15 (mean ± standard deviation [SD]) to 1.63 ± 0.28 nmol/liter when quinidine was added. With the high dose of digoxin alone, the serum digoxin level reached 1.68 ± 0.50 nmol/liter. Skeletal muscle digoxin concentrations during these periods were 27.7 ± 8.3, 48.7 ± 16.2, and 51.6 ± 23.6 nmol/kg of dry weight, respectively. The skeletal muscle to serum concentration ratio of digoxin decreased significantly during quinidine treatment.**

**Systolic time intervals were significantly prolonged by quinidine alone and shortened by digoxin alone, the latter effect being dose-dependent. Subtracting the effect of quinidine itself, the induced increase in digoxin level caused a significant increase in inotropic effect. When these corrected values were compared with those attained during the period with the same steady-state digoxin concentration but in the absence of quinidine, no significant differences were found. Echocardiographically measured ejection fraction and velocity of circumferential fiber shortening showed trends for similar drug effects, as did the systolic time intervals.**

**This study, performed under steady-state conditions, demonstrates that the quinidine-induced increase in steady-state serum digoxin concentration will, with due consideration to quinidine's own pharmacodynamic properties, be accompanied by increased cardiac effects. This indicates that quinidine is not interfering with active receptor sites in the heart for digoxin.**

Recent studies have documented that the steady-state concentration of digoxin in plasma/serum increases markedly during co-medication with quinidine[1–3] due to reduced renal[4–6] and nonrenal digoxin clearance.[5,7] The cardiac effects of the increased serum digoxin concentrations are not fully clarified. Clinical reports indicate that cardiac as well as extracardiac adverse effects of digoxin occur as a result of the interaction with quinidine.[2,6,8–10] In 2 experimental studies in man, a reduced inotropic effect of single doses of digoxin was reported during treatment with quinidine.[11,12] The present study was undertaken to evaluate the cardiac effects of digoxin in volunteers during quinidine treatment employing conditions of drug therapy approaching those of the clinical situation.

## Methods

**Subjects and procedures:** Ten healthy male volunteers (mean age 31 years, range 24 to 38) gave informed consent to participate in the study (most of them were colleagues). (The Ethical Committee of the Karolinska Hospital approved the investigation.) Results of physical examination, routine blood study, including electrolytes, serum creatinine, blood count, and sedimentation rate, electrocardiograms, blood pressure, systolic time intervals, and echocardiograms were normal.

The subjects were investigated on 6 occasions (Fig. 1): before intake of quinidine and digoxin (control I); after 4 days' intake of quinidine, 1,200 mg/day (Quinidine Durules®, Hässle-Astra, Sweden); after 2 to 3 weeks' intake of digoxin in a low dose (0.31 ± 0.07 [mean ± SD] mg/day) to produce a steady-state serum level of 0.6 to 1.0 nmol/liter; and after a

4-day period with the same low digoxin dose combined with 1,200 mg/day of quinidine. (It has been documented that the steady state of digoxin is reached after approximately 4 days of combination treatment.[6,8,13]) The final period consisted of 2 to 3 weeks with a higher dose of digoxin alone (0.65 ± 0.14 mg/day), monitored to give the same serum digoxin concentration as that attained during the combination treatment. At least 6 weeks after discontinuing digoxin treatment a second control investigation without medication was performed (control II).

Blood samples, skeletal muscle biopsies, blood pressure, electrograms, systolic time intervals, and echocardiographic measurements were all taken after at least 45 minutes of rest with the patient in the supine position and approximately 24 hours after the last dose of digoxin. The 3 biopsy samples were taken from the quadriceps femoris muscle (vastus lateralis) with the percutaneous needle biopsy technique of Bergström.[14] The needle was inserted into the muscle through a small incision made in locally anesthetized skin.

During the first 24 hours of the combination treatment all subjects were in hospital and monitored with electrocardiography. There was close contact between the investigators and the subjects during the different test periods to monitor potential untoward reactions.

**Determination of skeletal muscle and serum digoxin concentrations:** The skeletal muscle samples were freeze-dried and carefully freed from connective tissue and fat. Two pieces from each biopsy sample were weighed and homogenized in phosphate buffer; afterwards, digoxin was extracted from the tissue with dichloromethane. After evaporation of the dichloromethane phase, the residue was redissolved in human serum, and the digoxin concentration was measured by radioimmunoassay with a commercial iodine-125 radioimmunoassay kit (New England Nuclear, Boston, Massachusetts). The method has previously been described in detail.[15,16] The serum digoxin concentration was measured with the iodine-125 radioimmunoassay kit without any extraction procedure. The coefficients of variation for duplicate analyses of skeletal muscle and serum digoxin were 11 and 6, respectively. The skeletal muscle and serum concentrations given are the mean values of duplicate determinations. The digoxin concentrations in skeletal muscle were obtained from 9 volunteers as the muscle biopsy samples from the 10th subject were lost.

**Quinidine analyses:** The quinidine concentrations in plasma were determined by the method of Cramér and Isaksson.[17]

**Electrocardiograms:** The electrocardiograms were recorded at a paper speed of 100 mm/s with a Mingograph 62 (Siemens-Elema). Heart rate, P-Q interval, QRS duration and Q-T interval corrected for heart rate ($QT_c$) according to Bazett[18] were measured in 10 consecutive beats in lead II and the same complexes were included in the calculation of the systolic time intervals. The electrocardiographic measurements were done by 1 of the investigators without knowledge of the corresponding drug regimen. There were no significant differences in measurements performed by an independent observer who, also blindly, reviewed random tracings.

**Systolic time intervals of the left ventricle:** The systolic time intervals were measured from simultaneous records of the lead II electrocardiogram, phonocardiogram, and external carotid arterial pulse. A piezoelectric crystal microphone (EMT 25B, Siemens-Elema) was used to record the heart sounds. The carotid pulse was recorded using an airborne system with a funnel shaped pick-up attached by polyethylene tubing to a piezoelectric pressure transducer (EMT 510C, Siemens-Elema). The tracings were made at a paper speed of 100 mm/s with a Mingograph 62. The total electromechanical systole ($QS_2$) and left ventricular ejection time (LVET) were calculated from the mean values of 10 consecutive heart beats, corrected for heart rate according to Weissler et al[19,20] and presented as systolic time interval indexes ($QS_2$-I, LVET-I.[21]) Systolic time intervals were analyzed by the same investigator without knowledge of the drug period at hand. No significant differences in measurements by an independent, also blinded, investigator were observed.

**Echocardiography:** The echocardiograms were performed with an ATL (Seattle, Washington) Mark 3 ultrasonoscope utilizing a 3.0 MHz transducer with optimal focus between 3 and 8 cm. The printouts were recorded on a Honeywell LS fiberoptic recorder with a paper speed of 50 mm/s. The subjects were examined while in the partial left lateral decubitus position. The transducer was placed in the third, fourth, or fifth intercostal space parasternally. Each examination was preceded by a 2-dimensional study for general survey of the left ventricle. The left ventricular view was taken at or just below the tips of the mitral leaflets. Throughout the study, care was taken to reestablish the identical position of the patient and the transducer. The left ventricular echocardiographic dimensions were measured from the endocardial echo of the posterior wall to that of the left side of the septum. Measurements at end-diastole were made at the peak of the R-wave; measurements at end-systole were made at the point of the smallest distance separating septum from posterior wall.

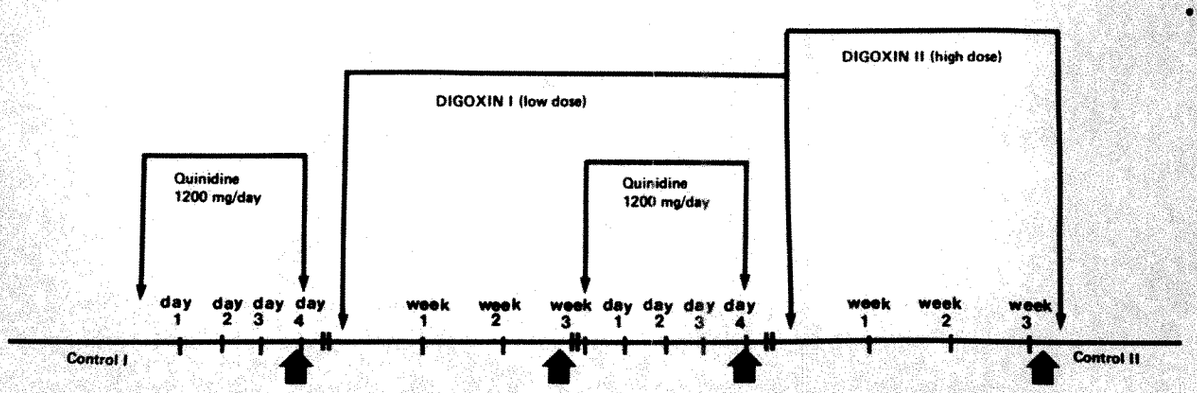

**FIGURE 1.** Study design. Cardiac effects in 10 healthy volunteers during treatment with quinidine and digoxin. **Heavy arrows** indicate the times cardiac effects and drug concentrations were measured.

The mean rates of circumferential fiber shortening and left ventricular ejection fraction were calculated by conventional techniques.[22] All the calculations were made using the average obtained from 5 consecutive cardiac cycles.

**Statistical analyses:** Values are given as the mean ± SD. Two-tailed Student's *t* test for paired observations was used to evaluate the statistical significance of differences between treatments. P values >0.05 were considered nonsignificant (NS).

## Results

**Adverse reactions:** The 2 different doses of digoxin were tolerated well without significant adverse effects by all 10 subjects. Quinidine treatment caused a light to modest tiredness in several volunteers and in a few cases minor anticholinergic reactions. No differences in these regards were noted during the quinidine-digoxin combination period compared with treatment with quinidine alone. No ventricular arrhythmias were recorded and no changes in blood pressure were registered during the treatment periods.

**Serum digoxin concentration:** When quinidine was added to the low digoxin dose, the mean serum digoxin concentration increased from 0.72 ± 0.15 nmol/liter to 1.63 ± 0.28 nmol/liter (126% increase, p <0.001) (Table I). With the high digoxin dosage the mean serum digoxin concentration was 1.68 ± 0.40 nmol/liter (Table I), which was not significantly different from that reached during combined treatment with quinidine and the low digoxin dose.

**Skeletal muscle digoxin concentration:** The steady-state digoxin concentration in skeletal muscle was 27.7 ± 8.3 nmol/kg of dry weight during the period with the lower digoxin dose. Skeletal muscle digoxin increased to 48.7 ± 16.2 nmol/kg of dry weight (76% increase, p <0.001) during the combination therapy with quinidine. This was not significantly different from the value attained (51.6 ± 23.6 nmol/kg of dry weight) during the period with digoxin alone in the higher dose (Table I).

**TABLE I Serum and Skeletal Muscle Concentrations of Digoxin at Steady State During the Different Test Periods (Mean ± SD, n = 10)**

| | Digoxin I | Digoxin I + Quinidine | Digoxin II |
|---|---|---|---|
| Digoxin dose (mg/day) | 0.31 ± 0.07 | 0.31 ± 0.07 | 0.65 ± 0.14 |
| Serum digoxin (concentration (nmol/liter) | 0.72 ± 0.15 | 1.63 ± 0.28† | 1.68 ± 0.40† |
| | | NS | |
| Skeletal muscle digoxin concentration* (nmol/kg dry weight) | 27.7 ± 8.3 | 48.7 ± 16.2‡ | 51.6 ± 23.6‡ |
| | | NS | |

* n = 9.
† Significantly different from digoxin I, p <0.001.
‡ Significantly different from digoxin I, p <0.005.
Digoxin I = low digoxin dose; Digoxin II = high digoxin dose.

The mean *ratio* of the digoxin concentration in skeletal muscle to that in serum decreased from 39.1 ± 12.0 to 30.7 ± 13.4 (22% decrease, p <0.02) when quinidine was added to the lower digoxin dose. During period of the high digoxin dose this ratio was 31.1 ± 18.1, which was not significantly different from either of the other 2 periods.

**Quinidine concentration:** The mean predose quinidine concentration in plasma was 4.9 ± 1.5 μmol/liter during treatment with quinidine alone in a daily dose of 1,200 mg, and 4.8 ± 1.2 μmol/liter during the combination with digoxin with the same quinidine dose.

**Cardiac effects:** *Control periods:* The mean values of the systolic time intervals and echocardiographic measurements from the 2 control periods did not differ significantly, nor did the values for their standard deviations. The individual values were within the normal ranges.[18–21]

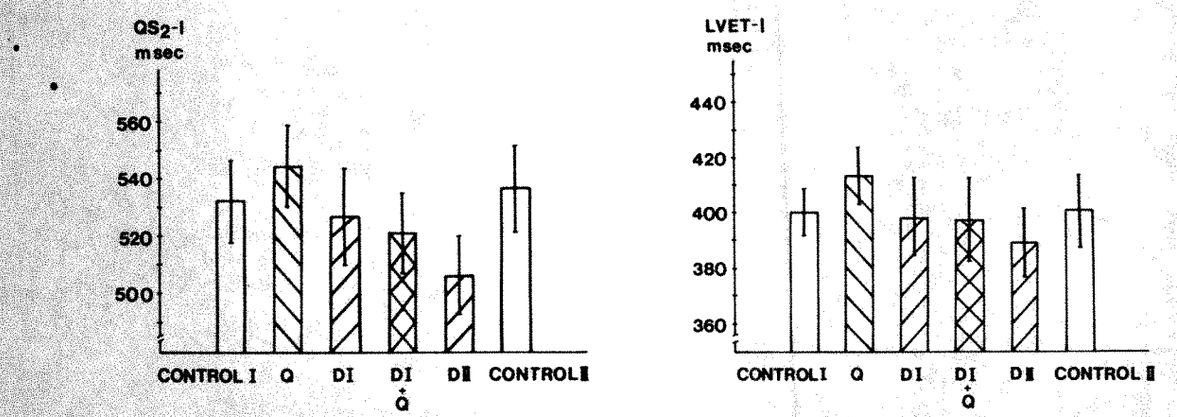

**FIGURE 2.** Heart rate-corrected electromechanical systole ($QS_2$-I) **(left panel)** and left ventricular ejection time (LVET-I) **(right panel)** in 10 volunteers during the following test periods: control periods before (control I) and after (control II) drug administration; Q, maintenance treatment with quinidine 1,200 mg/day; DI, maintenance treatment with the low digoxin dose; DI + Q, maintenance treatment with the low digoxin dose in combination with quinidine; and DII, maintenance treatment with the high digoxin dose. During the periods DI + Q and DII the digoxin concentrations were similar. Values are means ± SD.

**TABLE II Electrocardiographic, Systolic Time Intervals, and Echocardiographic Measurements at Steady State During the Different Test Periods (Mean ± SD, n = 10)**

| | Control I | Quinidine | Digoxin I | Digoxin I + Quinidine | Digoxin II | Control II |
|---|---|---|---|---|---|---|
| Heart rate | 61 ± 10 | 59 ± 9 | 57 ± 9 | 59 ± 8 | 53 ± 7* | 57 ± 8 |
| $QT_c$ (ms) | 37 ± 2 | 42 ± 3* | 36 ± 1 | 40 ± 3†† | 34 ± 1 | 37 ± 2 |
| $QS_2$-I (ms) | 533 ± 15 | 545 ± 14† | 527 ± 17†† | 521 ± 14† | 516 ± 13* | 537 ± 15 |
| | | | p <0.05 | | | |
| LVET I (ms) | 400 ± 9 | 413 ± 10* | 398 ± 14 | 397 ± 15 | 389 ± 12† | 401 ± 13 |
| | | | NS | | | |
| Vcf (circ/s) | 1.2 ± 0.1 | 1.1 ± 0.1†† | 1.2 ± 0.1 | 1.2 ± 0.1 | 1.2 ± 0.1 | 1.1 ± 0.1 |
| EF (%) | 72 ± 4 | 70 ± 4 | 73 ± 4 | 75 ± 3 | 74 ± 3 | 72 ± 5 |

* Statistically significant from control period, p <0.001.
† Statistically significant from control period, p <0.01.
†† Statistically significant from control period, p <0.05.
Digoxin I = low digoxin dose; Digoxin II = high digoxin dose; EF = ejection fraction; Vcf = circumferential fiber shortening.

*Electrocardiographic measurements:* The heart rate did not change significantly during the different test periods except for a decrease with the high digoxin dose (Table II). $QT_c$ was significantly prolonged compared with the control period during treatment with quinidine alone and also with quinidine in combination with the low digoxin dose. The high digoxin dose was associated with a shortening of $QT_c$ (Table II). The P-Q interval and the QRS duration were not significantly altered during any treatment period.

*Systolic time intervals:* Heart rate corrected $QS_2$ and LVET ($QS_2$-I and LVET-I) are presented in Table II and Figure 2. During the quinidine period the systolic time intervals were significantly longer than during the control periods. In contrast, when quinidine was added during digoxin treatment, a slight shortening of $QS_2$-I was recorded (p <0.05), whereas LVET-I was not significantly changed compared with the low digoxin dose alone period.

The low digoxin dose caused a shortening of $QS_2$-I (p <0.05), but no statistically significant decrease in LVET-I. This inotropic effect was more marked with the higher digoxin dose ($QS_2$-I, p <0.001; LVET-I, p <0.002). Compared with the effect of quinidine alone, the addition of digoxin significantly shortened both $QS_2$-I and LVET-I (p <0.001).

During 2 treatment periods (combination low digoxin dose and quinidine, and high digoxin dose), serum as well as skeletal muscle digoxin concentrations were similar. After individual correction for the effect of quinidine, the effects of digoxin on the systolic time intervals were similar. This is illustrated for $QS_2$-I in Figure 3.

*Echocardiographic measurements:* During quinidine treatment there was a slight but significant reduction (p <0.05) in the mean velocity of circumferential fiber shortening, whereas the ejection fraction was not significantly changed (Table II, Fig. 4). During the combined treatment with quinidine and digoxin there was a significant increase in both mean velocity of circumferential fiber shortening and ejection fraction compared with treatment with quinidine alone (p <0.01). Digoxin alone did not induce any statistically significant change in velocity of circumferential fiber shortening or ejection fraction, although a tendency for values to increase was observed with both doses compared with the control period.

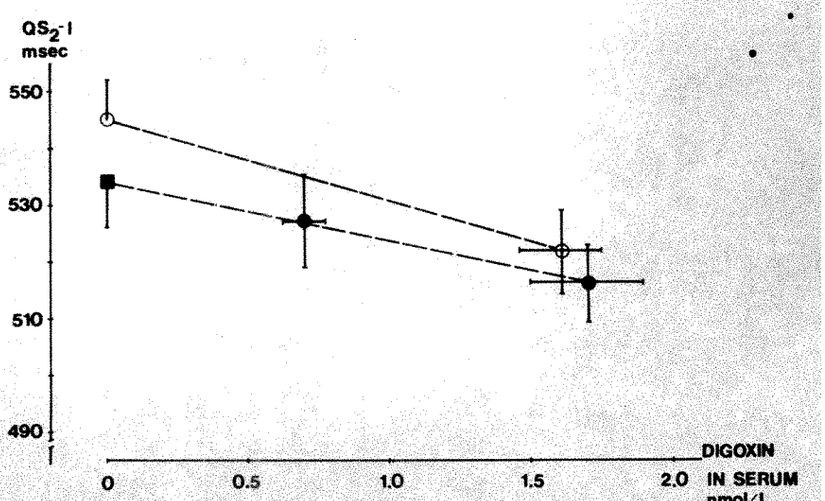

**FIGURE 3.** Electromechanical systole ($QS_2$-I) related to the steady-state serum digoxin concentration. **Solid square,** control period without drugs; **open circles,** quinidine treatment; **closed circles,** no quinidine treatment. Values are means ± SD.

End-diastolic diameters were not changed during the different drug periods.

## Discussion

In the present study, left ventricular performance has been measured noninvasively during treatment with digoxin and quinidine, alone and in combination, in healthy volunteers. The design involved maintenance treatment with normal therapeutic doses of the drugs to mimic the clinical situation. A treatment period with digoxin alone, monitored to yield the same steady-state serum digoxin concentration as during the combination of quinidine and digoxin, enabled us to assess the responsiveness of the heart to a given concentration of digoxin in the absence and in the presence of quinidine.

In accordance with previous studies, quinidine treatment approximately doubled the steady-state concentration of digoxin in serum,[1–3,6,7] and caused a lesser increase in skeletal muscle.[23] The ratio of the digoxin concentration in skeletal muscle to that in serum therefore decreased by about 22% confirming our previous findings with a decreased ratio of 23%.[23] However, this decrease in the ratio does not mean a reduced tissue digoxin concentration. On the contrary, because of the quinidine-induced increase in the total body load of digoxin, the digoxin concentration in skeletal muscle was increased by approximately 75%.

Left ventricular performance is mainly dependent upon preload, afterload, and contractility (inotropy). Preload and afterload—measured as left ventricular end-diastolic diameter and systemic blood pressure, respectively—were unchanged during the study; therefore, drug effects on the noninvasive variables may be considered changes in contractility of the left ventricle. Heart rates did not change during the different test periods except for during the period with a high digoxin dose, where a significantly decreased heart rate was recorded in comparison with the control period.

As previously known, quinidine decreased and digoxin increased contractility measured as changes in systolic time intervals.

When quinidine was administered to the subjects during maintenance digoxin treatment, contractility measured as shortening of $QS_2$-I was slightly enhanced, whereas LVET-I and the echocardiographic measures were not significantly changed. Thus, since the negative effect of quinidine on contractility was of the same magnitude as the positive effect of the induced increase in digoxin level, the effects cancel out and net contractility remains essentially unchanged. Quinidine therefore causes a shift to the right of the serum concentration-effect curve for digoxin with regard to contractility (Fig. 3). Such a shift may, however, not occur for adverse effects of digoxin. The net effect of the combination treatment therefore could be a decrease in the therapeutic index of digoxin.

Subtracting the negative inotropic effects of quinidine alone, the quinidine-induced increase in digoxin in the body caused a significant improvement in contractility measured as changes in systolic time intervals

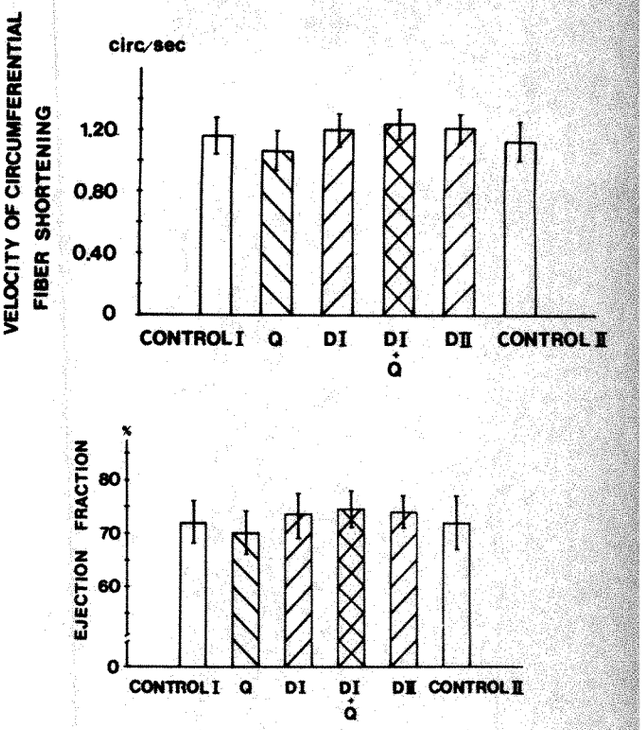

**FIGURE 4.** Echocardiographic measurements in 10 healthy volunteers during test periods, as in Figure 2. **Top panel,** velocity of circumferential fiber shortening (circ/s). **Bottom panel,** ejection fraction. Values are means ± SD.

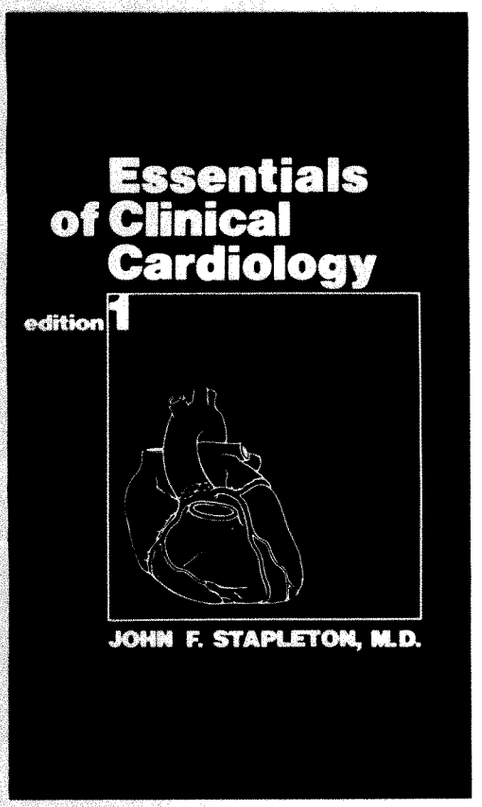
compared with the control period. When these values are compared with those attained during the period with the same steady-state digoxin level but in the absence of quinidine, no significant differences appear. Therefore, the contractile responsiveness of the heart to a given steady-state serum concentration of digoxin is probably not affected by quinidine. This would exclude a major and clinically significant interference of quinidine with the binding and action of digoxin at active sites in the heart, supporting recent in vitro studies.[24–27] These results may seem to contradict the reported decrease in the ratio of the digoxin concentration in skeletal muscle to that in serum. However, the decrease in the ratio was very moderate (about 20%). Furthermore, it is not known whether the decrease in total digoxin binding to skeletal muscle is accompanied by a decreased binding to active sites in the heart.



Concerning the inotropic effects of digoxin and quinidine, results similar to ours were recently presented by Belz et al[28] in a preliminary report, whereas partly contradictory conclusions were reached in 2 other experimental studies in man.[11,12] However, the conclusions from the present study and that by Belz et al[28] are strengthened by their experimental design measuring effects at steady state and distribution equilibrium and by their use of more rigorous crossover control periods.

# *Announcing—A Major New Review Text*

## ESSENTIALS OF CLINICAL CARDIOLOGY

This new brief textbook in the F. A. Davis **Essentials of Medical Education Series** is a concise clinical review of cardiology and cardiovascular pathophysiology. Believing that more puzzles are solved by taking a second history than by doing all the tests — emphasis is on history, physical signs and symptoms.

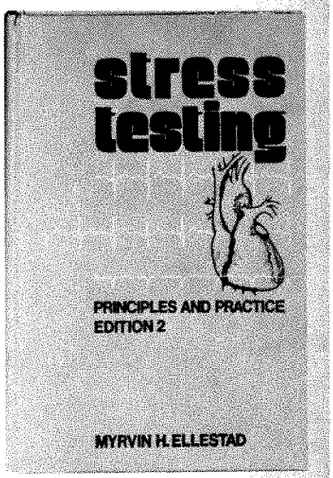
It's ideal for use by 3rd and 4th year medical students during their clinical rotations. Family practice and internal medicine residents will also find Stapleton's **Essentials of Clinical Cardiology** to be a useful review book.

Excellent illustrations depict diagnostic methods and findings. *Review questions, complete with answers, and a selected bibliography are provided for each chapter* — adding immeasurably to this book's value.

By **John F. Stapleton,** MD, Associate Dean and Professor of Medicine, Georgetown University School of Medicine, Medical Director, Georgetown University Hospital, Washington, D.C. About 490 pp., 140 ill. Soft cover. About $19.95. Ready April 1983.

**Contents:** Cardiac Function • The Initial Examination • Electrocardiography • Graphic Methods of Study • Echocardiography • Radiology • Cardiovascular Nuclear Medicine • Cardiac Catheterization • Congestive Heart Failure • (Acyanotic) Congenital Heart Disease • Cyanotic Congenital Heart Disease • Cardiomyopathy • Cor Pulmonale • Systemic Arterial Hypertension • Infective Endocarditis • Ischemic Heart Disease • Aortic Regurgitation • Mitral Valve Disease • Tricuspid Valve Disease • Rheumatic Fever • Neoplastic Heart Disease • Diseases of the Pericardium • Cardiac Pharmacology • Pulmonary Embolism • Disorders of Conduction and Rhythm • Other Aspects of Heart Disease.

The Editor-in-Chief of the **Essentials of Medical Education Series** is **David T. Lowenthal,** MD, FACP, FACC, Professor of Medicine and Pharmacology Director, Clinical Pharmacology and Cardiac Fitness Center, Likoff Cardiovascular Institute, Hahnemann University, Philadelphia, Pa.



*The extensively revised second edition continues to be the leading "how-to" guide to stress testing*

**STRESS TESTING: Principles and Practice,** 2nd Edition

By **Myrvin H. Ellestad,** MD, Chief, Section of Cardiology, Director, Division of Clinical Physiology, Memorial Hospital Medical Center, Long Beach, California; Clinical Professor of Medicine, University of California at Irvine. 424 pp., 217 ill. Aug. 1980. $38.00.

"Numerous illustrations and ECG reproductions serve to emphasize descriptive comments and highlight pertinent findings. Exercise technicians, physiologists, and physicians engaged in exercise testing will find this a good follow-up to the first edition, one of the best textbooks on exercise testing."

The Physician and Sportsmedicine, April 1981.

I would like to receive the indicated books on 30-day approval.

- ☐ #8097 Stapleton: **Essentials of Clinical Cardiology.** About $19.95. Ready April 1983.

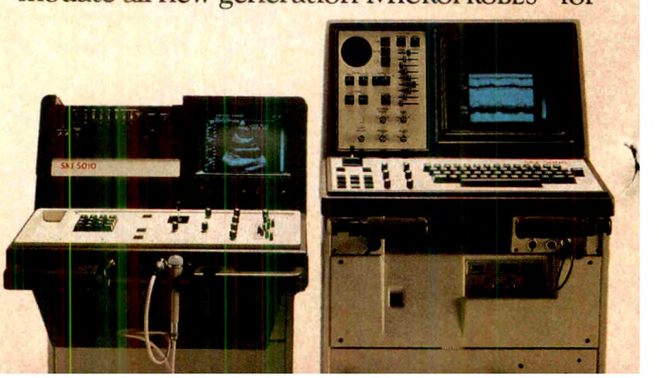
# EkoLine introduces

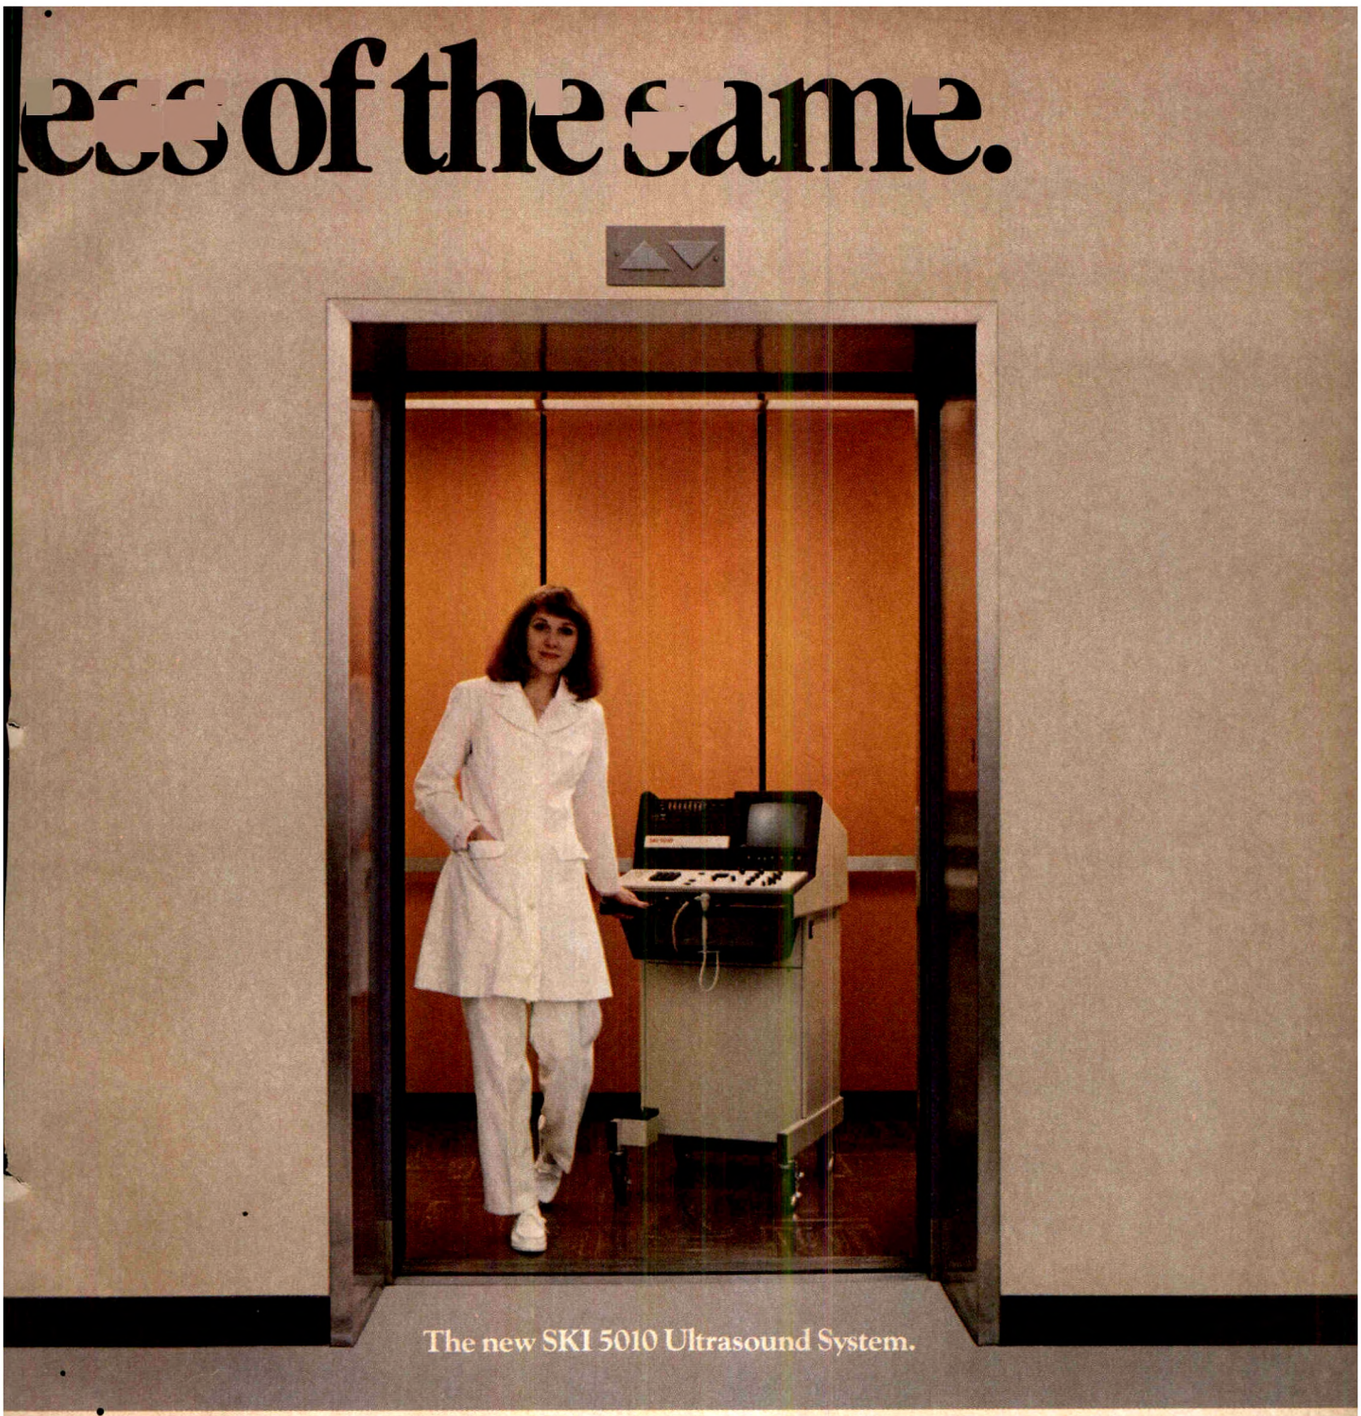
The SKI 5000 Ultrasound System.

The new super-portable SKI 5010 has the same advanced sector image as the SKI 5000 - and less.



Less size.

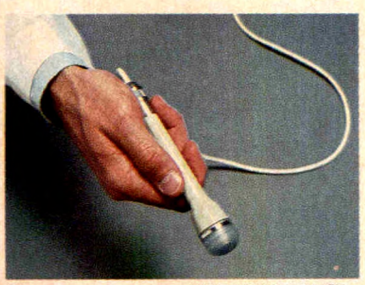
Less weight.



Less cost.

Of course, it has a few less features than the SKI 5000. But it still has the same superior M-mode, manual TGC with nine separate slide controls, and a video tape recorder that produces compatible tapes with other recorders like the one in the SKI 5000.

In addition, the SKI 5010 will accommodate all new generation MICROPROBES™ for



# ecs of the same.

The new SKI 5010 Ultrasound System.

M-mode or sector imaging. For more information about the new SKI 5010 or the SKI 5000, send coupon today. Or call toll-free (800) 538-1556. In California, (408) 732-6010. EkoLine, Inc., 880 West Maude Avenue, Sunnyvale, CA 94086.

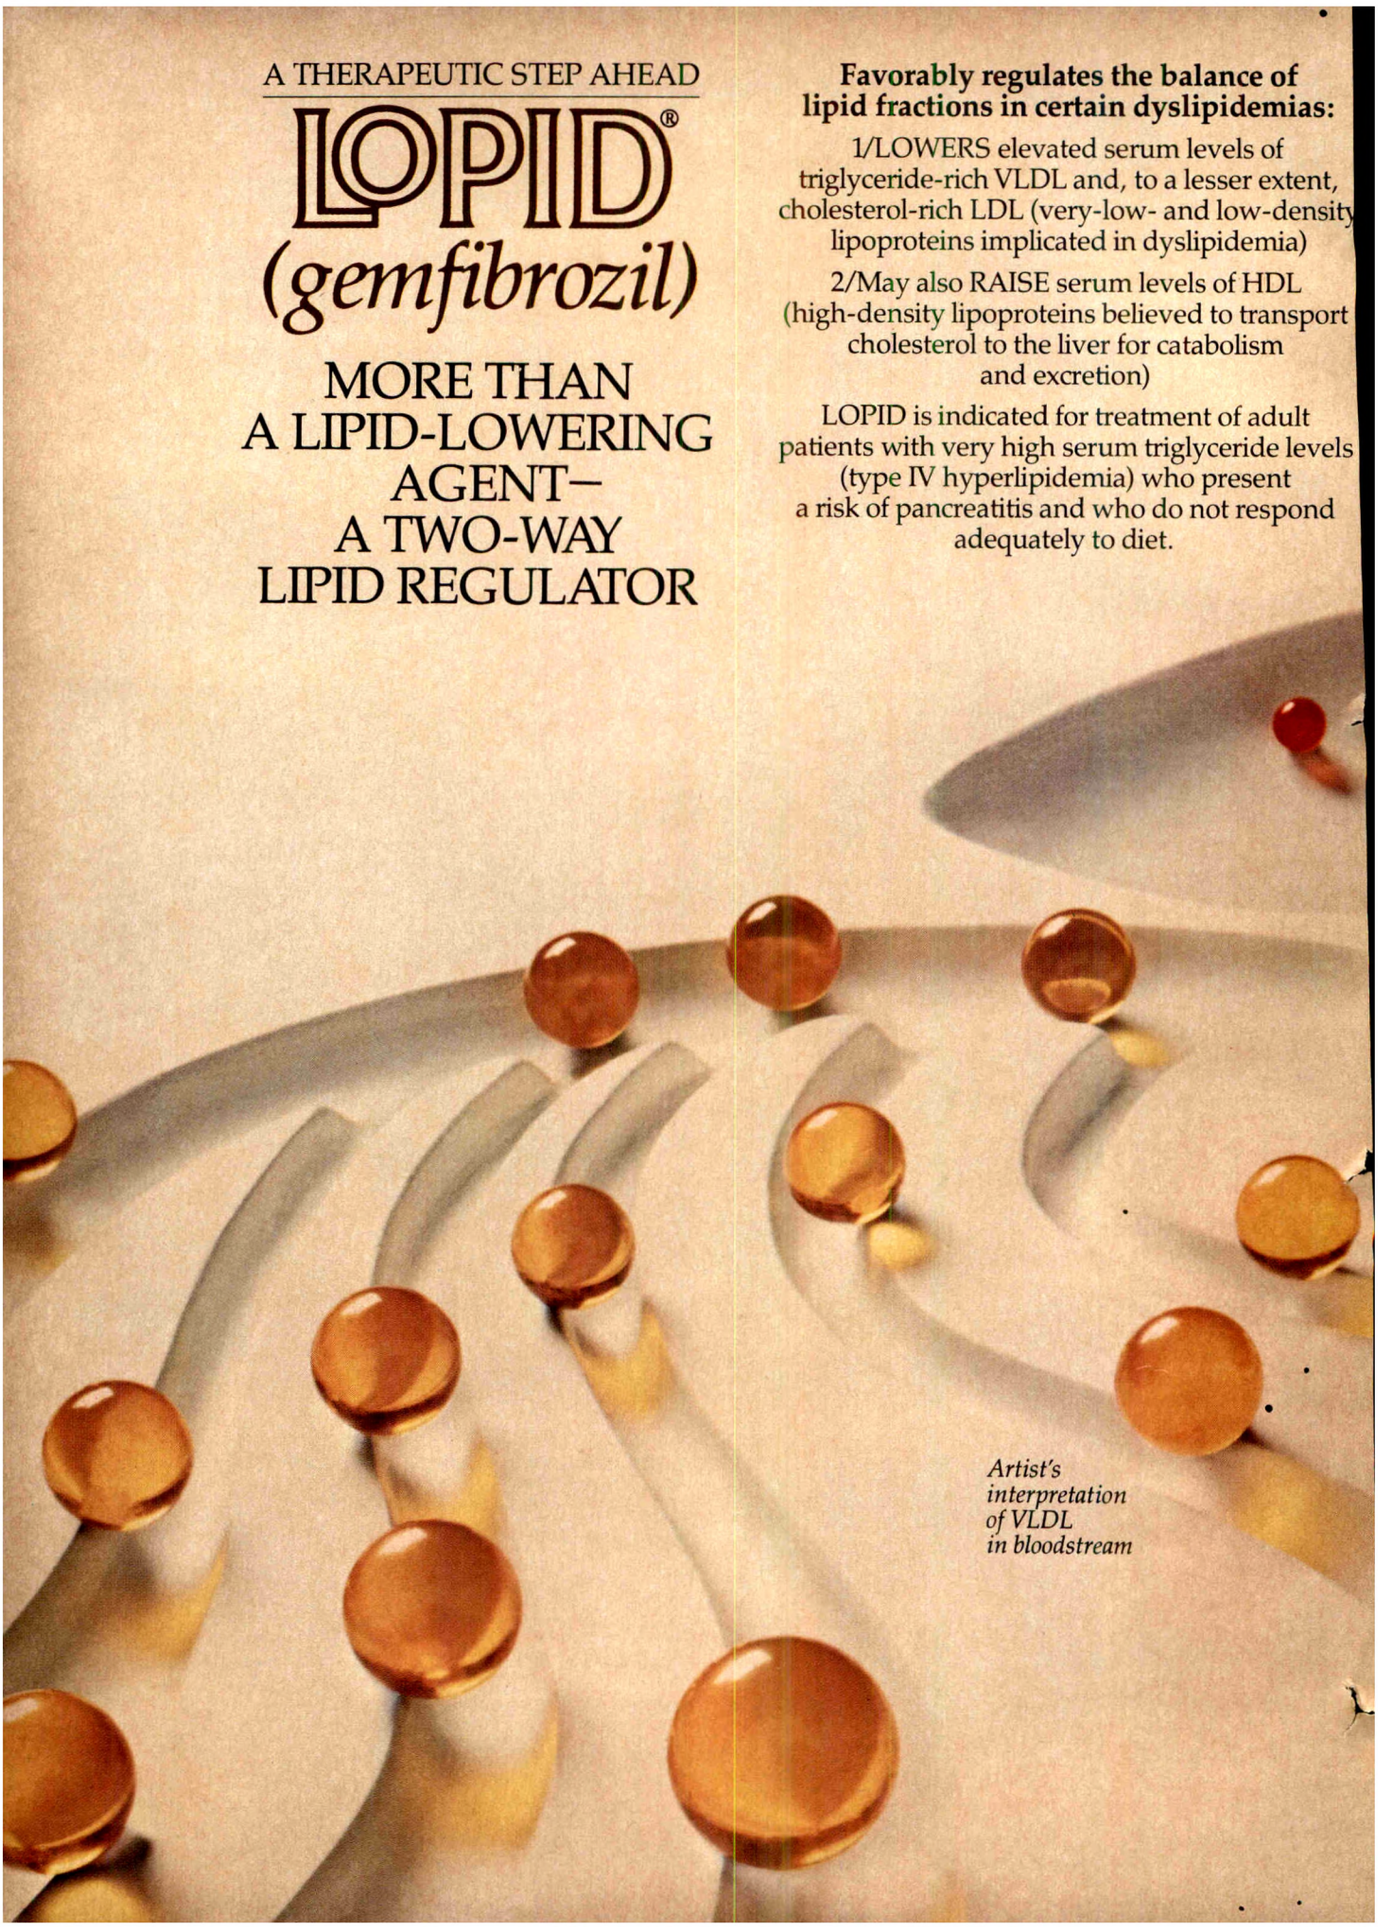
A THERAPEUTIC STEP AHEAD

# LOPID®
# *(gemfibrozil)*



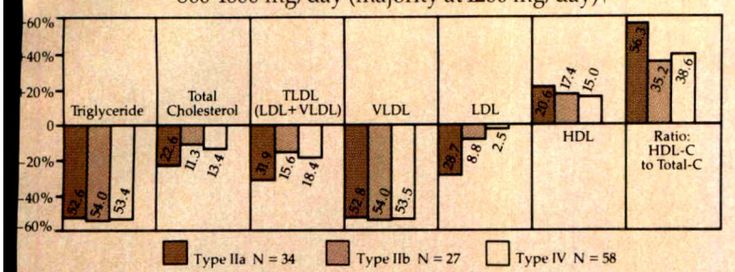
## MORE THAN A LIPID-LOWERING AGENT— A TWO-WAY LIPID REGULATOR

**Favorably regulates the balance of lipid fractions in certain dyslipidemias:**

1/LOWERS elevated serum levels of triglyceride-rich VLDL and, to a lesser extent, cholesterol-rich LDL (very-low- and low-density lipoproteins implicated in dyslipidemia)

2/May also RAISE serum levels of HDL (high-density lipoproteins believed to transport cholesterol to the liver for catabolism and excretion)

LOPID is indicated for treatment of adult patients with very high serum triglyceride levels (type IV hyperlipidemia) who present a risk of pancreatitis and who do not respond adequately to diet.



*Artist's interpretation of VLDL in bloodstream*

## Lipid-regulating efficacy demonstrated in 1,437 patients with dyslipidemia[1]

Results of open-label phase of US multicenter study (119 patients) at end of 12 lunar months*

Average % change from baseline at doses ranging from 800-1600 mg/day (majority at 1200 mg/day)†

*Visit every 4 weeks during long-term use of LOPID.
†Data cited on this graph reflect clinical experience based on the multicenter trial. They do not imply an indication for Types IIa and IIb dyslipidemias.

## Well tolerated, well accepted in clinical trials[1]

Profile of side effects similar to that of placebo.

No significant abnormalities seen in clinical and laboratory evaluations.

Less than 1% patient dropout in largest US study.

## Convenient BID dosage

*Diet, exercise, and weight loss are the first choice in therapy of lipid disorders.*

*(gemfibrozil)*

**PARKE-DAVIS**

Please see following pages for brief summary of prescribing information.

© 1983 Warner-Lambert Company

# LOPID®
## (gemfibrozil)
## A LIPID REGULATOR

**LOPID® (gemfibrozil) Capsules**

**Before prescribing, please see full prescribing information.**
**A Brief Summary follows:**

**CLINICAL PHARMACOLOGY.** LOPID is a lipid regulating agent which lowers elevated serum lipids primarily by decreasing serum triglyceride with a variable reduction in total serum cholesterol. These decreases occur primarily in the very low density lipoprotein (VLDL) fraction and less frequently in the low density lipoprotein (LDL) fraction. In addition, LOPID may increase the high density lipoprotein (HDL) cholesterol fraction, an action considered of possible benefit to inhibition of the atherosclerotic process.

The mechanism of action has not been definitively established. In man, LOPID has been shown to inhibit peripheral lipolysis and to decrease the hepatic extraction of free fatty acids, thus reducing hepatic triglyceride production. LOPID also inhibits synthesis of VLDL carrier apoprotein, leading to a decrease in VLDL production.

Animal studies suggest that LOPID may, in addition to elevating HDL cholesterol, reduce incorporation of long-chain fatty acids into newly formed triglycerides, accelerate turnover and removal of cholesterol from the liver, and increase excretion of cholesterol in the feces.

LOPID is well absorbed from the gastrointestinal tract after oral administration. Peak plasma levels occur in one to two hours with a plasma half-life of 1.5 hours following single doses and 1.3 hours following multiple doses. Plasma levels appear proportional to dose and do not demonstrate accumulation across time following multiple doses.

LOPID mainly undergoes oxidation of a ring methyl group to successively form a hydroxymethyl and a carboxyl metabolite. Approximately seventy percent of the administered human dose is excreted in the urine, primarily as unchanged gemfibrozil. Six percent of the dose is accounted for in the feces.

In a large, controlled multicenter trial of 427 patients, lipid and lipoprotein changes from average baseline (%) by hyperlipoproteinemic (HLP) type are summarized below for those patients receiving gemfibrozil, 1200 mg/day, at the end of 12 weeks.

| HLP Type | TRIGLYCERIDE | CHOLESTEROL | | | | RATIO |
|---|---|---|---|---|---|---|
| | | Total | VLDL | LDL | HDL | HDL Cholesterol / Total Cholesterol |
| IIa | −44% | −4.2% | −44.3% | −5.8% | +24.6% | +33% |
| IIb | −45% | −8.6% | −45.0% | −6.4% | +19.5% | +34% |
| IV | −40% | −1.8% | −40.8% | +14.6% | +17.4% | +23% |

**INDICATIONS AND USAGE.** Drug therapy should not be used for the routine treatment of elevated blood lipids for the prevention of coronary heart disease. Dietary therapy specific for the type of hyperlipidemia is the initial treatment of choice. Excess body weight and excess alcoholic intake may be important factors in hypertriglyceridemia and should be addressed prior to any drug therapy. Physical exercise can be an important ancillary measure. Contributory diseases such as hypothyroidism or diabetes mellitus should be looked for and adequately treated. The use of drugs should be considered only when reasonable attempts have been made to obtain satisfactory results with nondrug methods. If the decision is to use drugs, the patient should be instructed that this does not reduce the importance of adhering to diet.

Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, and the adverse findings with clofibrate in two large clinical studies (see Warnings), use of gemfibrozil should be restricted to the following indications.

LOPID may be considered for the treatment of adult patients with very high serum triglyceride levels (type IV hyperlipidemia) who present a risk of abdominal pain and pancreatitis and who do not respond adequately to a determined dietary effort to control them. Patients with triglyceride levels in excess of 750 mg per deciliter are likely to present such risk.

LOPID (gemfibrozil) has little effect on elevated cholesterol levels in most subjects. A minority of subjects show a more pronounced response. However, it must be understood that there is no evidence that use of any lipid-altering drug will be beneficial in preventing death from coronary heart disease (See WARNINGS). Therefore, the physician should be very selective and confine gemfibrozil treatment to patients with clearly defined risk due to severe hypercholesterolemia (eg, individuals with familial hypercholesterolemia starting in childhood) who inadequately respond to appropriate diet and more effective cholesterol-lowering drugs.

LOPID is not useful for the hypertriglyceridemia of Type I hyperlipidemia.

The biochemical response to gemfibrozil is variable, and it is not always possible to predict from the lipoprotein type or other factors which patients will obtain favorable results. It is essential that lipid levels be assessed and that the drug be discontinued after three months in any patient in whom lipids do not show significant improvement.

The effect of drug-induced reduction of serum cholesterol or triglyceride levels or elevation of HDL cholesterol levels on morbidity or mortality due to coronary heart disease has not been established. Several years may be required before ongoing long-term investigations will resolve this question.

**CONTRAINDICATIONS.** 1. Hepatic or severe renal dysfunction, including primary biliary cirrhosis.

2. Preexisting gallbladder disease. (See Warnings).

3. Hypersensitivity to gemfibrozil.

**WARNINGS.** 1. Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, the adverse findings with clofibrate in two large clinical studies may also apply to gemfibrozil. In the first of those studies, the Coronary Drug Project, 1000 subjects with previous myocardial infarction were treated for five years with clofibrate. There was no difference in mortality between the clofibrate-treated subjects and 3000 placebo-treated subjects, but twice as many clofibrate-treated subjects developed cholelithiasis and cholecystitis requiring surgery. In the other study, conducted by the World Health Organization, 5000 subjects without known coronary heart disease were treated with clofibrate for five years and followed one year beyond. There was a statistically significant 36% higher total mortality in the clofibrate-treated than in a comparable placebo-treated control group. The excess mortality was due to noncardiovascular causes, including malignancy, postcholecystectomy complications, and pancreatitis. The higher risk of clofibrate-treated subjects for gallbladder disease was confirmed.

2. Long-Term Toxicity and Animal Tumorigenicity Studies: Long-term studies have been conducted in rats and mice at one and ten times the human dose. The incidence of benign liver nodules and liver carcinomas was significantly increased in high dose male rats. The incidence of liver carcinomas increased also in low dose males, but this increase was not statistically significant ($p$ greater than 0.05). There were no statistically significant differences from controls in the incidence of liver tumors in female rats, and in male and female mice.

Electron microscopy studies have demonstrated a florid hepatic peroxisome proliferation following LOPID administration to the male rat. Similar changes have not been found in the human liver.

Male rats had a dose-related increase of benign Leydig cell tumors. Subcapsular bilateral cataracts occurred in 10%, and unilateral in 6.3% of the high dose males.

3. Since a reduction of mortality from coronary artery disease has not been demonstrated and liver and interstitial cell testicular tumors were increased in male rats, LOPID should be administered only to those patients described in the Indications and Usage Section. If a significant serum lipid response is not obtained, LOPID should be discontinued.

4. Cholelithiasis — LOPID may increase cholesterol excretion into the bile leading to cholelithiasis. If cholelithiasis is suspected gallbladder studies are indicated. LOPID therapy should be discontinued if gallstones are found.

5. Concomitant Anticoagulants — Caution should be exercised when anticoagulants are given in conjunction with LOPID. The dosage of the anticoagulant should be reduced to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has stabilized.

**PRECAUTIONS.** 1. **Initial Therapy** — Before instituting LOPID (gemfibrozil) therapy, every attempt should be made to control serum lipids with appropriate diet, exercise, weight loss in obese patients, and other medical problems such as diabetes mellitus and hypothyroidism.

2. **Continued Therapy** — Pretreatment laboratory studies should be performed to ensure that patients have abnormal levels of serum lipids. Periodic determinations of serum lipids should be obtained during LOPID administration. The drug should be withdrawn after three months if the lipid response is inadequate.

3. **Seasonal Variation of Lipid Levels** — LOPID is not expected to alter seasonal variations of higher serum lipid values in mid-winter and late summer or the lower values in fall and spring.

4. **Impairment of Fertility** — Administration of approximately three and ten times the human dose to male rats for 10 weeks resulted in a dose-related decrease of fertility. Subsequent studies demonstrated that this effect was reversed after a drug-free period of about eight weeks, and it was not transmitted to their offspring.

5. **Pregnancy Category B** — Reproduction studies have been performed in the rat at doses 3 and 9 times the human dose, and in the rabbit at 2 and 6.7 times the human dose. These studies have revealed no evidence of impaired fertility in females or harm to the fetus due to LOPID. Minor fetotoxicity was manifested by reduced birth rates observed at the high dose levels. No significant malformations were found among almost 400 offspring from 36 litters of rats and 100 fetuses from 22 litters of rabbits.

There are no studies in pregnant women. In view of the fact that LOPID is tumorigenic in male rats, the use of LOPID in pregnancy should be reserved for those patients where the benefit clearly outweighs the possible risk to the patient or fetus.

6. **Nursing Mothers** — Because of the potential for tumorigenicity shown for gemfibrozil in male rats, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

7. **Hematologic Changes** — Mild hemoglobin, hematocrit and white blood cell decreases have been observed in occasional patients following initiation of LOPID therapy. However, these levels stabilize during long-term administration. Therefore, periodic blood counts are recommended during the first 12 months of LOPID administration.

8. **Liver Function** — Abnormal liver function tests have been observed occasionally during LOPID administration, including elevations of SGOT, SGPT, LDH, and alkaline phosphatase. These are usually reversible when LOPID is discontinued. Therefore periodic liver function studies are recommended and LOPID therapy should be terminated if abnormalities persist.

9. **Cardiac Arrhythmias** — Although no clinically significant abnormalities occurred that could be attributed to LOPID, the possibility exists that such abnormalities may occur.

10. **Use in Children** — Safety and efficacy in children have not been established.

**ADVERSE REACTIONS.** In controlled clinical trials of 805 patients, including 245 who received LOPID for at least one year, the most frequently reported adverse reactions associated with LOPID involved the gastrointestinal system. In decreasing order of frequency, these were abdominal pain (6.0%), epigastric pain (4.9%), diarrhea (4.8%), nausea (4.0%), vomiting (1.6%), and flatulence (1.1%). Other adverse reactions where the probability of a causal relationship to LOPID therapy exists are listed by system.

**Integumentary:** rash, dermatitis, pruritus, urticaria
**Central Nervous System:** headache, dizziness, blurred vision
**Musculoskeletal:** painful extremities
**Hematopoietic:** anemia, eosinophilia, leukopenia

Other reactions have been reported under conditions where a causal relationship is difficult to establish, thus the physician should be alert to these occurrences. Reports of viral and bacterial infections (common cold, cough, and urinary tract infections) were more common in gemfibrozil than in placebo-treated patients.

**Other reactions were:**

**Gastrointestinal:** dry mouth, constipation, anorexia, gas pain, dyspepsia
**Musculoskeletal:** back pain, arthralgia, muscle cramps, myalgia, swollen joints
**Central Nervous System:** vertigo, insomnia, paresthesia, tinnitus
**Clinical Laboratory:** hypokalemia, liver function abnormalities (increased SGOT, SGPT, LDH, CPK, alkaline phosphatase)
**Miscellaneous:** fatigue, malaise, syncope

**DOSAGE AND ADMINISTRATION.** The recommended dose for adults is 1200 mg administered in two divided doses 30 minutes before the morning and evening meal. Some patients will experience therapeutic effects on 900 mg/day; a few may require 1500 mg/day for satisfactory results.

**DRUG INTERACTIONS.** CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH LOPID (GEMFIBROZIL). THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS STABILIZED.

**MANAGEMENT OF OVERDOSAGE.** While there has been no reported case of overdosage, symptomatic supportive measures should be taken should it occur.

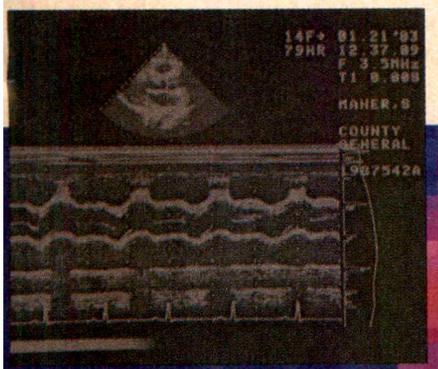
## Toshiba SSH-40A Ultrasound Scanner
## The Complete Cardiac Lab.

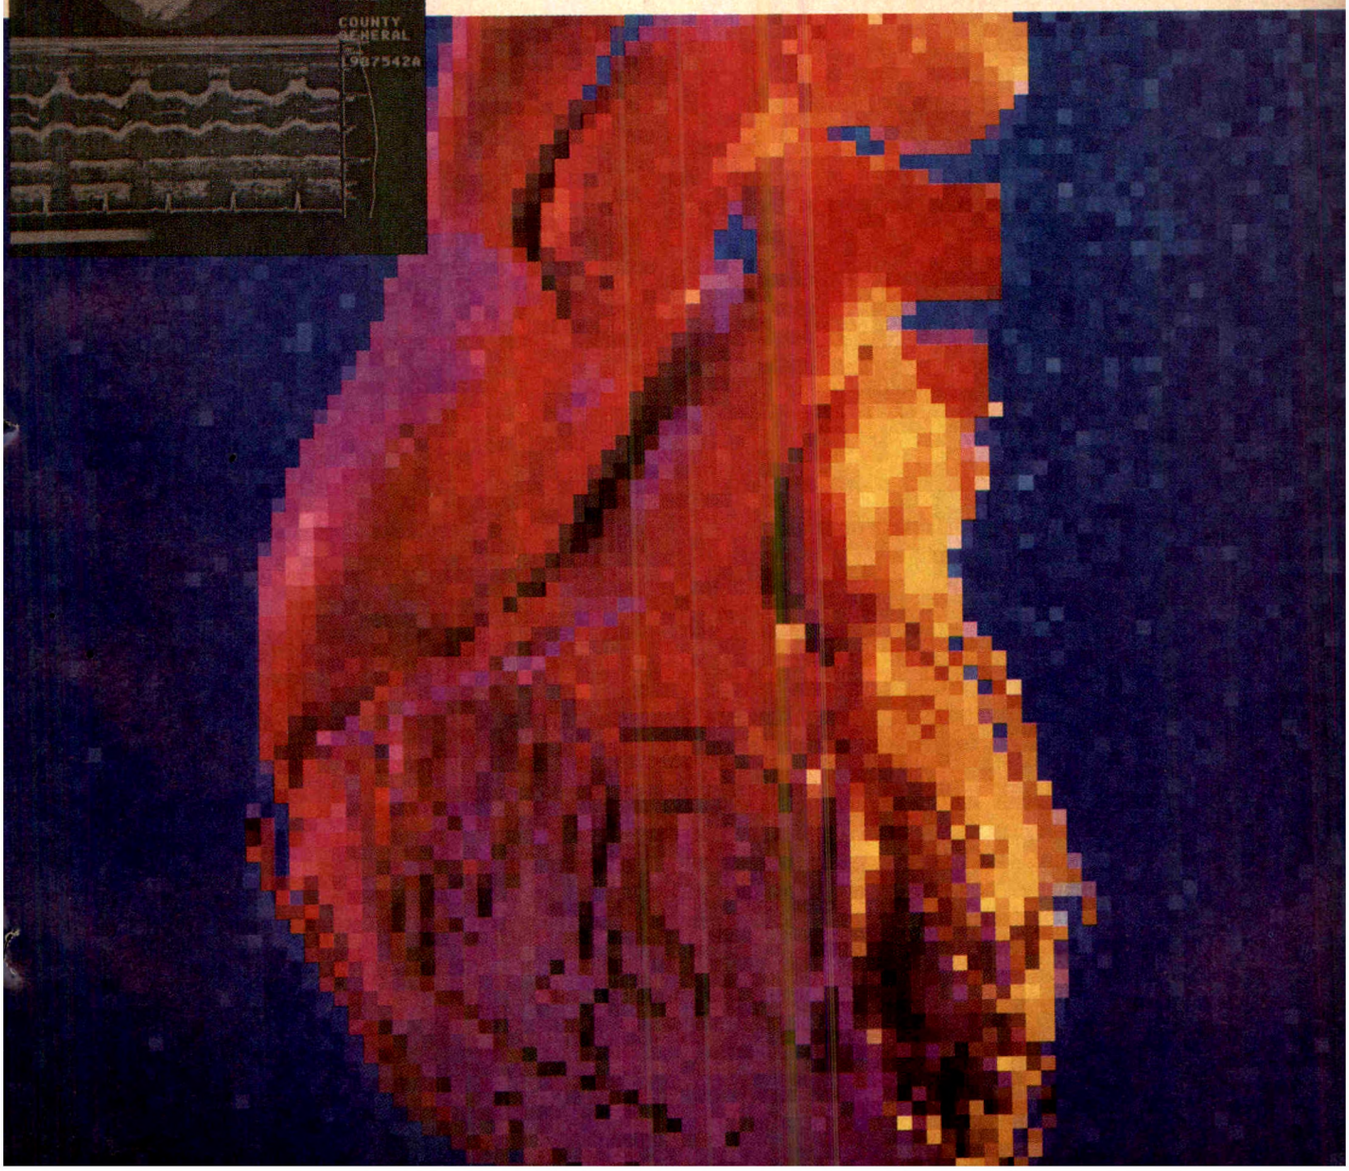
How do you measure commitment? With words? Toshiba prefers to have the products make the point. Newest proof: the Toshiba SSH-40A Cardiac Ultrasound Laboratory, a vivid example of our commitment to echocardiographic diagnostics.



Clinical versatility is the watchword for the SSH-40A. It means independent or simultaneous display of 2-D echocardiograms, M-Mode and Doppler images for faster, more complete diagnosis. It means you can scan with various probes for the best image quality in all patient sizes and specialized procedures. Perform two dimensional, multi-gate array Doppler flow studies and perform all cardiac function computations instantly.

Image quality? Startling. Low level echoes contain the most significant diagnostic information. The SSH-40A captures and displays them with a unique, low-noise digital system: dual microprocessors and more memory than any ultrasound instrument. Plus the powerful Digital Scan Processor provides optimum control over image quality.

Such insights, frankly, defy words. That's why we're eager to provide you with a demonstration of the SSH-40A's powerful capabilities. Then you can complete the picture yourself.



Please see the reverse side for further information.

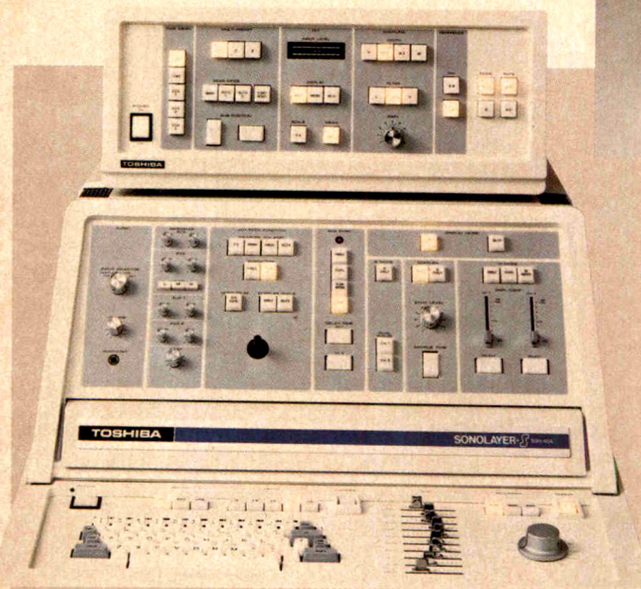
## TOSHIBA SSH-40A CARDIAC ULTRASOUND LABORATORY.



The Toshiba SSH-40A is a complete cardiac ultrasound laboratory that combines clinical versatility, superior image quality and powerful digital scan processing to provide a host of features for new insights into cardiac diagnoses.

The SSH-40A is available with a standard 3.5 MHz probe and optional 5 MHz linear scan probe and 2.4 MHz sector scan probe to enable accurate examinations of all patients, from neonates to adults. All pertinent image and exam data, including results from computations, can be displayed. And the unique two dimensional multigate array Doppler capability enables the operator to perform flow studies, to display frequency spectrum from the digital FFT analyzer and to compute flow rate, velocity and other cardiac function data. Extensive computational algorithms are on-line to ensure fast, accurate analyses.

Superb image quality results from the advanced scanning technology incorporated in the SSH-40A. A new receiver design and a new digital scan processor provide optimized image quality with clearly defined edge differentiation and excellent tissue differentiations. A faithful display of low level echoes provides excellent gray scale resolution.

The SSH-40A delivers the image processing functions cardiologists require. Echo enhancement, post processing and other echo processing operations, synchronous freezing of two phases of a cardiac cycle, slow motion display and measurement of distances and areas on frozen images are all well within the range of this remarkable system's capabilities.

- Simultaneous 2-D imaging and dual M-Mode or Doppler operation ensures more exact correlation, faster diagnosis and state-of-the-art performance.
- Cardiac function (SV, EF, FS, CO and others), area, circumference, slope and distance can be computed at the touch of a keyboard, thanks to a selection of stored algorithms.
- Simultaneous display of two images, strobed from two selected points on the ECG cycle, allows detection of abnormal wall motion.
- Comprehensive exam data display permits date, time, frequency and patient data and image annotation to be included for more complete patient records.

For further information on the SSH-40A electronic sector scanner, or other Toshiba Medical Systems' products, please call toll free 800-421-1968, in California call (714) 730-5000 or write Toshiba Medical Systems, 2441 Michelle Drive, Tustin, CA 92680.

# Immediate Hemodynamic Effects of a New Calcium-Channel Blocking Agent (Nitrendipine) in Essential Hypertension

HECTOR O. VENTURA, MD, FRANZ H. MESSERLI, MD, WILLIE OIGMAN, MD, FRANCIS G. DUNN, MD, EFRAIN REISIN, MD, and EDWARD D. FROHLICH, MD

**The immediate hemodynamic effects of a new calcium-channel blocking agent nitrendipine were studied in 12 patients with mild established essential hypertension. According to the response to mean arterial pressure, patients were classified into responders (decrease >10 mm Hg, 7 patients) and nonresponders (≤10 mm Hg, 5 patients). The decrease in arterial pressure in responders was associated with a significant ($p < 0.01$) decrease in total peripheral resistance and a significant ($p < 0.05$) increase in heart rate, cardiac index, and left ventricular ejection rate. The plasma norepinephrine level was significantly ($p < 0.05$) increased in the responders. The response to upright tilt was qualitatively similar to pretreatment values. Thus, nitrendipine lowered arterial pressure as a result of arteriolar dilatation associated with a reflexive increase in heart rate and cardiac index. These hemodynamic properties make the drug particularly apt for use in combination with beta-adrenergic blockade for the treatment of arterial hypertension.**

The place of calcium-channel blocking agents in the medical management of coronary heart disease has been well established over the last few years.[1–6] These agents act by inhibiting calcium ion entrance into the vascular smooth muscle cell,[7,8] thereby promoting vasodilation.[9] Since essential hypertension is hemodynamically characterized by an increased vascular resistance, it is not surprising that calcium-channel blocking agents have also been used with success in the treatment of systemic hypertension.[10–12] For example, nifedipine has been shown to be an effective form of therapy both in hypertensive emergencies[13] and in less severe forms of hypertension.[14,15]

However, various calcium-channel blocking agents seem to have disparate effects on cardiac contractility and electrophysiology. Accordingly, the hemodynamic response to these compounds is not uniform.[16] The present study was designed to evaluate the immediate effects of a new calcium-channel blocking agent, nitrendipine, a compound that is structurally similar to nifedipine.

From the Department of Internal Medicine, Division of Hypertensive Diseases, Ochsner Clinic, and the Research Division, Alton Ochsner Medical Foundation, New Orleans, Louisiana. Manuscript received September 15, 1982; revised manuscript received December 3, 1982, accepted December 6, 1982.

Address for reprints: Franz H. Messerli, MD, Ochsner Clinic, 1514 Jefferson Highway, New Orleans, Louisiana 70121.

## Methods

Twelve patients (10 men and 2 women) with mild established essential hypertension were included in the present study. Each subject provided informed consent to a protocol previously approved by our institution's review committee. All subjects were evaluated to exclude secondary forms of hypertension[17] and other concomitant disorders. Patients were enrolled if, after discontinuation of all medications for at least 3 weeks, the diastolic pressure (Phase V of Korotkoff sounds) in the supine and standing positions was 90 to 114 mm Hg.

As previously described in detail,[17] systemic hemodynamics were determined before and then 60 and 120 minutes after oral administration of nitrendipine (20 mg). Intraarterial and venous pressures were monitored continuously and supine cardiac output was determined in triplicate using indocyanine green dye (5 mg) in the postabsorptive state.[17]

Plasma volume was determined with radioactive iodine-125 human serum albumin.[17] Blood samples were withdrawn for determination of plasma renin activity[18] and catecholamine (epinephrine, norepinephrine, and dopamine) concentrations[19] 1 hour after insertion of the intravascular catheters, and 60 and 120 minutes after the administration of the agent. In addition, M-mode echocardiography[20] was performed before and 60 and 120 minutes after nitrendipine administration. Response to upright tilt (45°) for 5 minutes was also studied in eight patients. Cuff blood pressures were recorded in all patients for an additional 3 hours after completion of the hemodynamic study. Statistical evaluation was done by analysis of variance with repetitive measurements and a subsequent Tukey's honestly significant difference test.[21]

**TABLE I Clinical Characteristics of the Patients**

| | Responders | Nonresponders |
|---|---|---|
| Number | 7 | 5 |
| Age (yr) | 45 ± 7 | 43 ± 18 |
| Sex (male:female) | 6:1 | 4:1 |
| Race (white:black) | 5:2 | 3:2 |
| Height (cm) | 172 ± 8 | 178 ± 8 |
| Weight (kg) | 84 ± 1 | 91 ± 2 |
| BSA ($m^2$) | 1.96 ± 0.1 | 2.08 ± 0.3 |
| SAP | 158 ± 7 | 147 ± 5 |
| DAP | 101 ± 3 | 93 ± 1 |
| MAP | 120 ± 4 | 111 ± 1 |

BSA = body surface area; DAP = diastolic arterial pressure; MAP = mean arterial pressure; SAP = systolic arterial pressure.

## Results

According to the response of mean arterial pressure 2 hours after the drug administration, patients were classified into responders (decrease ≥10 mm Hg in mean arterial pressure, average −14 ± 2, 7 patients) or nonresponders (≤10 mm Hg decrease in mean arterial pressure, average +4 ± 3, 5 patients). Clinical characteristics of the 2 groups are detailed in Table I. Except for a somewhat lower arterial pressure in the nonresponding patients, no significant pretreatment differences between the 2 groups were found. The mean arterial pressure decrease in the responding patients was accompanied by an increase in heart rate, cardiac output, and a decrease in total peripheral resistance (Fig. 1). Arterial distensibility as measured by pulse pressure divided by stroke volume[22] also changed after nitrendipine administration. The velocity of circumferential fiber shortening and the ejection fraction remained unchanged during the 2-hour study, although the left ventricular ejection rate increased (Table II).

The responses of circulating humoral substances to nitrendipine (Table III) primarily reflected a significant ($p < 0.05$ after 2 hours) increase in plasma norepinephrine level; there was no change in plasma epinephrine, dopamine, or renin activity. Arterial pressure remained at a low level in responding patients throughout the 3-hour period of observation after completion of the hemodynamic assessment.

The response to upright tilt (Table IV) was qualitatively unchanged (except for mean arterial pressure) with nitrendipine when compared with pretreatment values. Comparison between responding and nonresponding patients was not appropriate in view of the small number involved.

## Discussion

The present data show that the immediate antihypertensive effect of an oral dose of 20 mg of nitrendipine was associated with a significant decrease in total peripheral resistance and an increase in cardiac output, heart rate, and left ventricular ejection rate in the responding group. These findings are in agreement with reports of other calcium-channel inhibiting agents,[14,23,24] indicating that the decrease in arterial pressure is due to a decreased vascular resistance produced by predominantly arteriolar dilatation. Since postural hypotension was not produced during upright tilt, significant peripheral venodilation seemed unlikely.

The increase in heart rate and cardiac output associated with the decrease in arterial pressure that occurred in our study has also been observed with nifedipine administration.[14,23,24] Although both nifedipine and nitrendipine increase cardiac output, the increase is produced by an elevation of heart rate only with the latter, whereas both heart rate and stroke volume become elevated with nifedipine. Since calcium-channel blockers exert negative direct chronotropic and inotropic[25] effects under in vitro conditions, it is fair to conclude that the cardioacceleration (and the increase in cardiac output) occurred secondary to augumented sympathetic or decreased baroreceptor mediated vagal activity. Indeed, the observed increase in norepinephrine of >50% above pretreatment levels lends support to this concept.

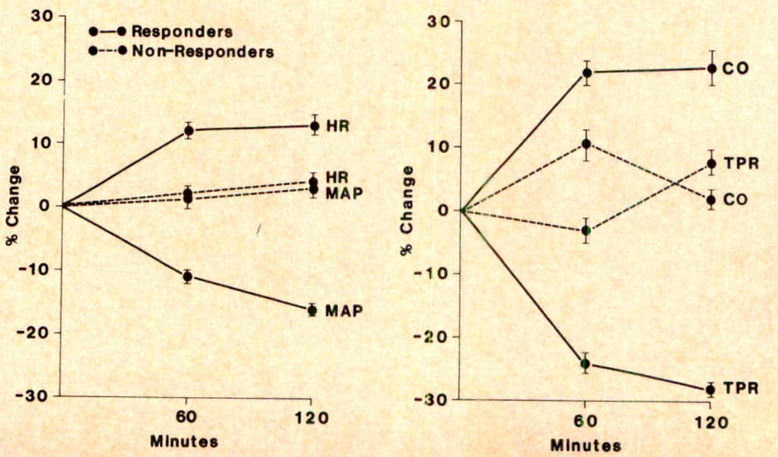

**FIGURE 1.** Immediate hemodynamic effect of oral administration of nitrendipine (20 mg) on (**left**) mean arterial pressure (MAP) and heart rate (HR), and (**right**) cardiac output (CO) and total peripheral resistance (TPR).

**TABLE IV Head-Up Tilt**

| | Responders | | | | Nonresponders | | | |
|---|---|---|---|---|---|---|---|---|
| | Before | | After | | Before | | After | |
| | Supine | Tilt | Supine | Tilt | Supine | Tilt | Supine | Tilt |
| MAP (mm Hg) | 113 ± 5 | 116 ± 8 | 99 ± 4 | 92 ± 7 | 104 ± 3 | 110 ± 5 | 108 ± 6 | 114 ± 5 |
| CI (liters/min/m$^2$) | 2.79 ± 0.2 | 2.32 ± 0.1 | 3.63 ± 0.1 | 2.80 ± 0.2 | 2.90 ± 0.2 | 2.56 ± 0.2 | 2.90 ± 0.2 | 2.66 ± 0.1 |
| HR (beats/min) | 72 ± 5 | 80 ± 7 | 83 ± 6 | 98 ± 9 | 65 ± 3 | 70 ± 4 | 67 ± 4 | 73 ± 5 |
| TPRI (units) | 43 ± 2 | 48 ± 3 | 27 ± 2 | 34 ± 2 | 36 ± 3 | 44 ± 3 | 38 ± 3 | 43 ± 3 |

CI = cardiac index; HR = heart rate; MAP = mean arterial pressure; TPRI = total peripheral resistance index.

The response of cardiac output, heart rate, and total peripheral resistance to upright tilt was qualitatively similar during nitrendipine when compared with the pretreatment period. However, although mean arterial pressure showed a slight decrease under nitrendipine no orthostatic hypotension was observed, indicating that the venous return to the heart remained unchanged after nitrendipine administration. Thus, the compound seems to predominantly affect the arteriolar vascular bed. Indeed, Olivari et al,[11] measuring pressures in the right side of the heart during nifedipine administration, were unable to document any significant drug effects.

Since we did not measure the drug concentration in the plasma, the reason for the lack of effect in the nonresponding patients remains speculative. Conceivably, they might not have absorbed the drug, or the receptor concentration of the compound might not have been high enough to produce vasodilatation.

*In conclusion*, the antihypertensive effect of nitrendipine is related to an arteriolar dilation associated with a reflexive increase in heart rate and cardiac index. Accordingly, its combination with beta-blocking agents would be beneficial in the treatment of arterial hypertension.

# Predictability of Blood Pressure Response to Isometric Stress

ROBERT H. CHANEY, MD and STEPHAN ARNDT, PhD

**Isometric exercise causes transient systemic hypertension, but with individual differences. An attempt was made to delineate predictors of those differences by analyzing the blood pressure (BP) response in terms of variables readily measured in clinical practice. For each of 270 office patients, we determined blood pressure, heart rate (HR), electrocardiographic findings, and symptoms in response to maximal isometric and maximal dynamic exercise. For systolic BP response as the predicted measure, 4 predictor variables in combination, including age, sex, resting systolic BP, and maximal treadmill systolic BP, yielded 70% predictability. For diastolic BP, 5 predictors in combination, including handgrip strength, resting diastolic BP, treadmill HR, systolic BP, and diastolic BP, allowed 66% prediction. Not predictive of either were resting HR, abnormality of treadmill test, presence of heart disease, and certain other medical diagnoses.**

Since Alam and Smirk[1] 4 decades ago described the increase in systemic blood pressure (BP) during exercise of muscle groups with compromised circulation, there has been increasing interest in the cardiovascular response to isometric stress. While Alam and Smirk[1] restricted circulation in contracting muscles by overwork or vascular occlusion, others[2–4] have demonstrated that isometric exercise itself restricts blood flow in the contracting muscles and causes transient systemic arterial hypertension. However, Alam and Smirk[1] also described individual variation in BP response to isometric stress, and this has received much less interest. Yet some individuals develop extreme transient hypertension with isometric exercise, such as that frequently performed in occupational and recreational activities. In observing BP during maximal handgrip contraction, we found great individual differences. We therefore attempted to determine whether the responses were related to, and predicted by, any or a combination of readily measured variables. It has been stated that an increase in BP with isometric exercise is a predictable function of the intensity of the stress.[2,5] Other factors, usually tested singly, also have been reported to influence this response, including age,[4,6–8] sex,[9] systemic hypertension,[10–12] body fat content,[13] and heart disease.[14] We therefore determined the association of BP response in isometric stress with several noninvasive clinical factors in combination and singly.

From the Social Science Training and Research Laboratory and the Department of Psychology, University of Notre Dame, Notre Dame, Indiana. Manuscript received July 27, 1982; revised manuscript received October 18, 1982, accepted October 26, 1982.

Address for reprints: Robert H. Chaney, MD, 1846 North Garey Avenue, Pomona, California 91767.

## Methods

Each of 270 office patients was subjected once to 1 minute of maximal isometric handgrip stress. They included 194 men (72%) and 76 women (28%) aged 20 to 79 years (mean 52, standard deviation 10.07). A Kolmogorov-Smirnov test[15] was used to ensure the normalcy of the age distribution and demonstrated that this distribution did not depart significantly from the normal curve ($D = 0.042$, $p < 0.15$). Of the 270 patients, 33% had arteriosclerotic coronary heart disease, 17% had had myocardial infarcts, 22% had controlled hypertension, and 19% were receiving digitalis and antihypertensive or antiarrhythmic agents (including beta-adrenergic blocking agents). However, none had severe hypertension, serious arrhythmia, myocardial infarction within 2 months, crescendo angina, or active cerebrovascular disease. Other precautions included informed consent, continuous electrocardiographic monitoring, and presence of a crash cart and personnel trained in basic life support.

After baseline measurements of heart rate (HR) and BP and electrocardiography, each patient, standing with a hand dynamometer (Smedley, Stoelting, Chicago) adjusted to the right hand, squeezed for 2 or 3 seconds, 3 different times, to obtain a maximal reading. The patient was then instructed to sustain maximal exertion for 60 seconds, at the same time relaxing all other muscle groups and breathing normally. At 30 and 50 seconds he was again urged to do his best and was told the remaining time. Blood pressure usually increased through the minute of sustained contraction. Although fatigue

**TABLE I Blood Pressure Response to Isometric Handgrip Exercise (n = 270)**

| | Resting (mm Hg) | | Maximal on HG (mm Hg) | | Absolute Increase (mm Hg) | | % of Resting | |
|---|---|---|---|---|---|---|---|---|
| BP | Range | Mean | Range | Mean | Range | Mean | Range | Mean |
| Systolic | 68–200 (SD 19.36) | 123 | 90–260 (SD 26.26) | 166 | 0–90 (SD 16.76) | 43 | 100–180 (SD 14.56) | 136 |

BP = blood pressure; HG = handgrip; SD = standard deviation.

caused a decrease in actual handgrip pressure over the minute, we were concerned only that the effort was maximal for each subject. During this minute, BP was repeatedly measured and the highest reading toward the end of the static effort was recorded. The patient and the oscilloscope were watched for evidence of complications, and in the last 5 seconds an assistant obtained a 4-lead electrocardiographic write-out. The method was reproducible. Intrasubject reliability was demonstrated by retesting 74 of the subjects approximately 1 year later. The correlations for systolic BP and diastolic BP were 0.673 and 0.664, respectively (both p values <0.001). The dynamic exercise was a graded, interrupted, multistage, maximal treadmill test, with HR, BP, and 4-lead electrocardiogram recorded each minute of exercise and rest.

Analysis of the data was made by 2 stepwise multiple regression analyses. One regression used systolic BP response to isometric stress as the predicted variable and the other analysis involved diastolic BP reaction. For both analyses the following variables were included as potential predictors: resting HR, resting systolic BP, resting diastolic BP, maximal HR and systolic BP and diastolic BP on the treadmill test, handgrip strength, age, sex, presence or absence of heart disease, whether or not the treadmill test was abnormal, presence or absence of hypertension, normal/abnormal resting electrocardiographic results, and cardiovascular medication. Other medical diagnoses were also considered, including diabetes mellitus (n = 15), chronic obstructive pulmonary disease (n = 10), hyperuremia (n = 11), hyperlipidemia (n = 18), and peptic ulcer (n = 35). Effects coding[16] was used for all of these diagnostic categories so that they could be tested as a group and then, if significant, inspected individually. This procedure is frequently useful to control for excessively liberal interpretation of the statistical tests.

**TABLE II Measures of Importance for Significant Variables in Predicting Systolic BP and Diastolic BP Response to Isometric Stress (n = 270)**

| Variable | Beta Weight | Change in $R^2$ | Simple r | B Coefficient |
|---|---|---|---|---|
| **Systolic BP Response** | | | | |
| Age | 0.105* | 0.011† | 0.227† | 0.27 |

## Results

The BP response to isometric stress varied greatly among individual patients, as seen in Table I. For instance, diastolic BP reaction ranged from a decrease in 1 patient to a 2-fold increase in another. It is noteworthy that individual variability of the systolic BP response to isometric exertion (standard deviation 26.21) was significantly greater than the sample's variability of resting systolic BP (standard deviation 19.33; $t(268) = 7.94$; $p < 0.001$). This difference was also true for diastolic BP (standard deviation 15.28 and 11.97 for reactions to isometric stress and resting values, respectively; $t(268) = 5.94$; $p < 0.001$).

In order to predict both systolic BP and diastolic BP during isometric stress, 2 stepwise multiple regressions were performed. As predictor variables (for example, resting diastolic BP and age) were stepped into the regression, the improvement in $R^2$ (an index of predictability)[16] was tested for significance. This procedure continued only as long as adding a new variable increased prediction significantly. The presence or absence of other medical diagnoses was treated as a single group of variables during this phase of the analysis. This resulted in the best set of variables which could be used to determine the maximal blood pressure response to the isometric stress.

The multiple R with systolic response as the dependent measure proved highly significant ($R = 0.837$; $F(4,265) = 155.04$; $p < 0.001$; SDe = 14.45) with 4 independent variables which included age, sex, systolic BP at rest, and systolic BP on maximal treadmill exercise. Indeed, the analysis was able to account for 70% of the individual variation in systolic BP response. The 4 variables are listed in Table II along with alternate measures of the variables' relative importance in prediction.

Neither HR nor diastolic BP during rest or during treadmill exercise was predictive of systolic BP reaction. No other variable was significant. For example, neither strength, the presence or absence of heart disease, abnormality of treadmill exercise, nor the presence of other medical diagnoses added to the prediction of systolic BP during the isometric stress. In interpretation of the beta weights, the individual who is likely to have high systolic BP during isometric stress can be described as having high systolic BP while at standing rest as well as high systolic BP on the maximal treadmill test. Age and sex were also significantly descriptive, although to a lesser extent, with older patients and male patients reaching higher systolic BP levels.

The results with diastolic BP response also showed predictability. The multiple R for the diastolic BP was 0.814 ($F[5,264] = 103.45$; $p < 0.001$; SDe = 8.97) and included 5 predictor variables (Table II). These predictors were handgrip strength, resting diastolic BP, treadmill HR, systolic BP, and diastolic BP. In this analysis, 66% of the patient variability in diastolic BP reaction to isometric stress was explained.

In predicting systolic BP reaction to isometric stress, the best predictor was the resting systolic BP. Similarly, the best estimate of diastolic BP reaction was afforded by the resting diastolic BP level. As with systolic BP response, a description can be made of individuals expected to have a high diastolic BP response. Such persons had a high diastolic BP while resting as well as a high diastolic and systolic BP during the treadmill test. Furthermore, these persons had a lower maximal heart rate on the treadmill test and tended to have stronger handgrip. As with systolic BP, the presence or absence of heart disease, abnormality of the treadmill exercise, and other medical diagnoses were not associated with the diastolic BP reaction. In contrast, however, neither age, sex, nor resting systolic BP contributed to diastolic BP prediction.

Based on the first order correlation, sex was a significant predictor of diastolic BP response. However, after the strength variable entered the regression, sex ceased being significantly related. This suggests that although generally men have higher diastolic BP responses, this is because they are also stronger, with strength being the deciding factor.

The last column in Table II, labeled "B coefficient," presents the basis for formulating the prediction of both systolic and diastolic BP during isometric stress. A predicted score can be calculated by multiplying the value of each variable by the appropriate B coefficient, then summing, and adding the constant. For instance, a 50-year-old woman with a resting systolic BP of 123 mm Hg and a maximal systolic BP of 175 mm Hg would have a predicted maximal systolic BP during handgrip stress as follows: Predicted systolic BP = 50(0.27) + 2(−6.59) + 123(0.62) + 175(0.36) + 21.99 = 162 mm Hg.

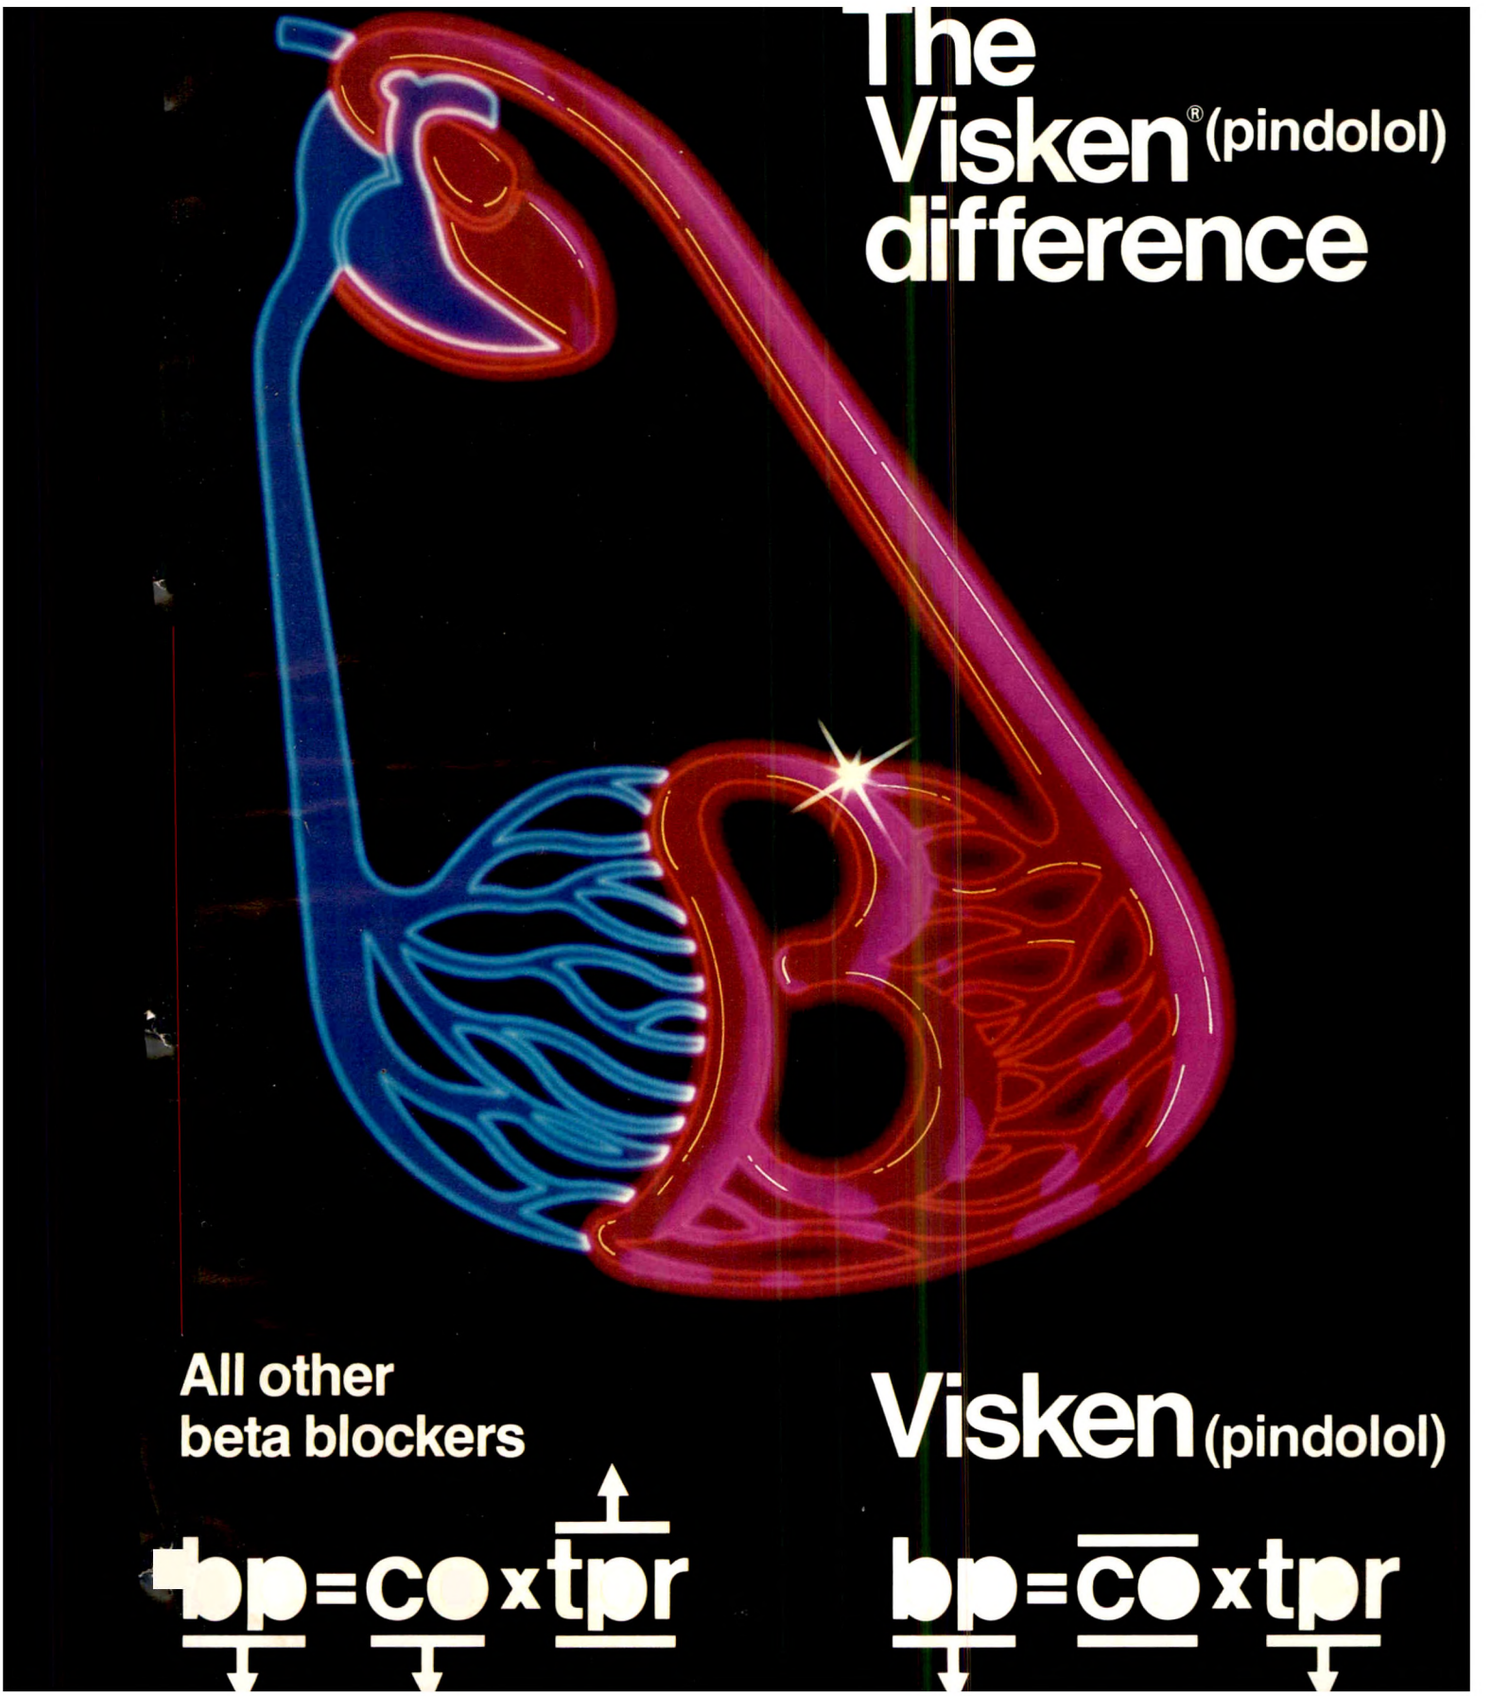
B coefficients will vary with different samples of persons, and these formulas will not be totally generalizable. They do, however, predict well for subjects in our sample, and should predict for similar subjects.

## Discussion

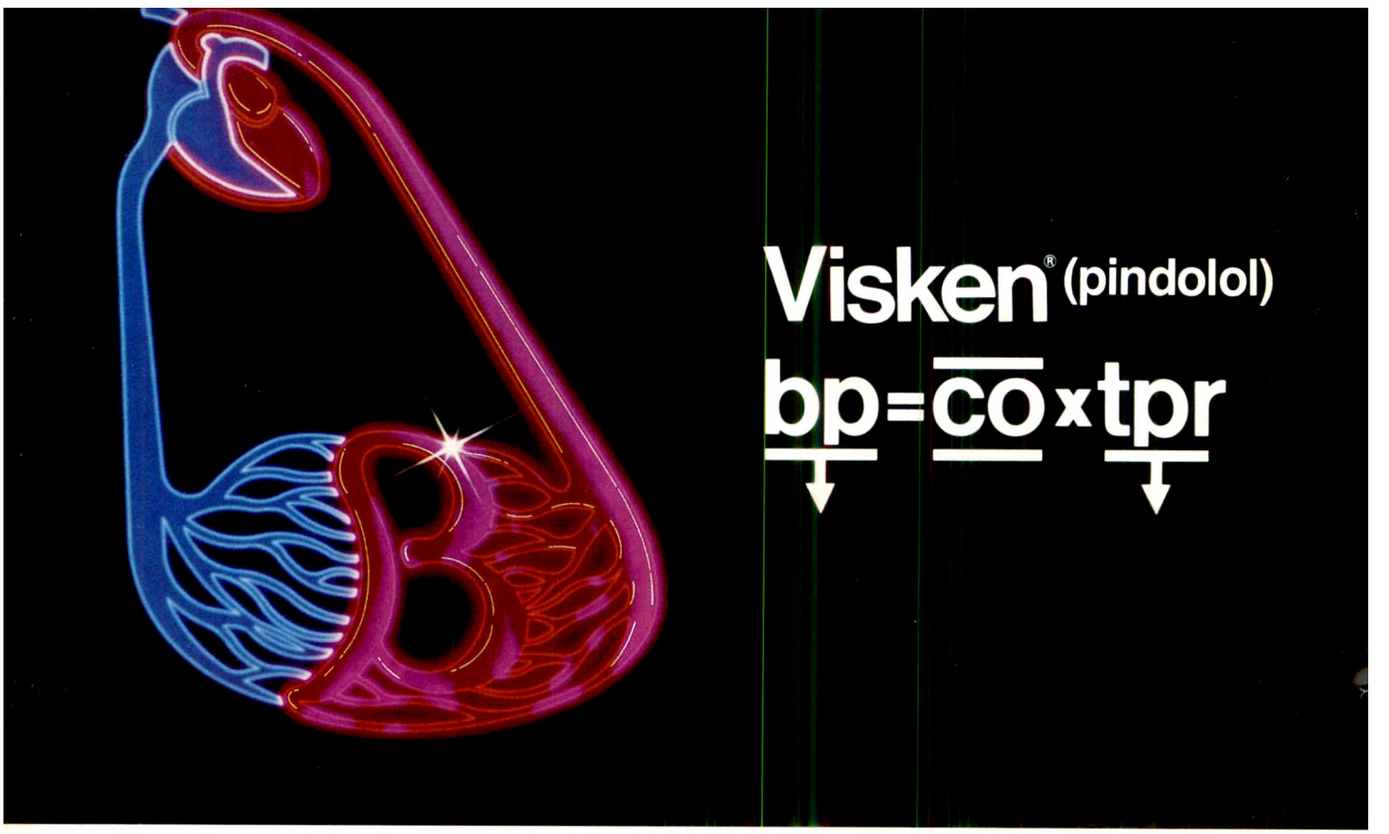
The stimulus for this study was the observation of marked individual variation in blood pressure response to isometric stress. The major question was whether or not the response could be predicted by basic clinical information. The answer to our question is yes in that BP reactions could be predicted with 70% of systolic BP and 66% of diastolic BP variation accounted for. Different sets of variables are required for predicting systolic and diastolic BP reactions, and there are patterns that are important to prediction. The most important information for predicting systolic BP reaction is systolic BP with the subject at standing rest. Likewise, resting diastolic BP is the strongest predictor of diastolic BP response. The patients' maximal BP reactions on the treadmill contribute additional information. Maximal systolic BP on the treadmill is useful for estimating the systolic BP reaction to isometric stress, whereas both the systolic BP and the diastolic BP, as well as HR, on the treadmill are important for predicting the diastolic BP. However, we found an inverse relation between HR on the treadmill and diastolic BP during handgrip; lower HR is associated with higher diastolic BP reactions.

While sex and age are relevant only to systolic BP response, strength is only involved in predicting diastolic BP response. The weak relation of age with systolic BP and the lack of relation to diastolic BP during isometric stress is interesting since previous reports[4,6–8] have indicated as association in subjects of comparable age. Further caution in predicting is indicated by our finding that although strength related well to diastolic BP, several patients with weakest strength had the greatest BP increase relative to resting levels, and some with greatest strength had the smallest increase.

Of importance was the nonsignificance of the presence or absence of heart disease to either systolic BP or diastolic BP reaction in our series. Heart disease tended to predispose to higher systolic BP response with handgrip exercise, but without statistical significance. This is consistent with the findings of Kino et al,[7] who reported no difference between BP response in older normal persons and that in older patients with heart disease. Fisher et al,[14] on the other hand, found a greater increase in BP in persons with normal left ventricular function than in those with abnormal function. Our results agree with those of others[10,11] in that hypertensive patients had greater increases in BP with isometric stress than nonhypertensive patients. Strong et al[12] found in youngsters aged 7 to 14 years an inverse relation between resting BP and *percent* change with exercise.



Although it has become popular to emphasize the dangers of isometric exercise,[3,17–19] we found infrequent S-T depressions, no significant arrhythmia, and no angina or other notable symptoms in our patients. Other workers have also spoken to the safety of isometric testing.[20–22] While isometric stress does increase myocardial oxygen consumption,[22] coronary flow has been shown to increase,[3,23] presumably meeting[3] or even



exceeding[24] the increased myocardial oxygen consumption. We have found isometric stress, as we have employed it, monitored for electrocardiogram and symptoms as well as BP, a safe and practical noninvasive test. It appears, then, that such testing is neglected at times when it might be useful. Many variables affect BP increase with this type of exertion; we found that patterns of readily obtained clinical variables can account for two thirds of the variation in BP response.

The Visken® (pindolol) difference
All other beta blockers
bp=co×tpr
Visken (pindolol)
bp=co×tpr

# Makes hemodynamic sense in the treatment of hypertension

## Reduces blood pressure

It's as effective as propranolol in normalizing blood pressure (dbp ≤ 90 mmHg) when used alone. It's also effective when used in combination with a diuretic.[1]

## Has little effect on resting cardiac output

Unlike other beta blockers, Visken (pindolol) maintains resting cardiac output during long-term therapy. The clinical significance of this has not been evaluated.

## Reduces total peripheral resistance*

Visken (pindolol) reduces one of the recognized components of hypertension: increased peripheral resistance.* Studies of 178 patients treated with Visken (pindolol) for at least two weeks have shown that Visken therapy reduces total peripheral resistance.[1]

## Reduces exercise-induced tachycardia

Like other beta blockers, Visken (pindolol) blocks stimulation by catecholamines to reduce exercise-induced increases in systolic blood pressure and heart rate.

© 1983 Sandoz, Inc.

*The clinical significance has not been evaluated. See clinical significance statement on facing page of this advertisement.

# the only beta blocker that reduces blood pressure and total peripheral resistance*

## Has little effect on resting heart rate

Visken® (pindolol) produces minimal changes in resting heart rate. Average reduction: 4-8 beats/minute.

## The clinical significance has not been evaluated

The clinical significance of maintaining resting cardiac output, resting heart rate and reduced total peripheral resistance has not been evaluated and there is no evidence or reason to believe that exercise cardiac output is less affected by Visken (pindolol) than other beta blockers.

## Maintains renal blood flow

Visken (pindolol) reduces supine and standing blood pressure while maintaining effective renal plasma flow and glomerular filtration rates.[2]

## Favorable side effect profile

## Low incidence of bradycardia

## Low incidence of cold extremities

Visken (pindolol) is contraindicated in:

1) bronchial asthma
2) overt cardiac failure
3) cardiogenic shock
4) second- and third-degree heart block
5) severe bradycardia

*See clinical significance statement.

Please see next page of this advertisement for brief summary of prescribing information.

# Visken® (pindolol)

## Available in 5 mg and 10 mg tablets

## Convenient bid dosage

Dosage should be titrated on an individual basis.
Many patients respond to 10-30 mg a day in divided doses.

*Before prescribing or administering, see package circular for full product information. The following is a brief summary.*

**INDICATIONS AND USAGE**
Visken (pindolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide type diuretic.

**CONTRAINDICATIONS**
Visken (pindolol) is contraindicated in: 1) bronchial asthma; 2) overt cardiac failure; 3) cardiogenic shock; 4) second and third degree heart block; 5) severe bradycardia; (see Warnings).

**WARNINGS**
**Cardiac Failure:** Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, Visken (pindolol) can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

**In Patients Without A History of Cardiac Failure:** In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Visken (pindolol) therapy should be withdrawn (gradually if possible).

**Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal:** Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered Visken (pindolol), particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Visken (pindolol) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Visken (pindolol) therapy abruptly even in patients treated only for hypertension.

**Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—Patients with Bronchospastic Diseases Should in General Not Receive Beta-Blockers:** Visken (pindolol) should be administered with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

**Major Surgery:** Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase the risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, beta-blockers should be withdrawn well before surgery takes place. In the event of emergency surgery, the anesthesiologist should be informed that the patient is on beta-blocker therapy. The effects of Visken® (pindolol) can be reversed by administration of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

**Diabetes and Hypoglycemia:** Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust the dose of antidiabetic drugs.

**Thyrotoxicosis:** Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta-blockade which might precipitate a thyroid crisis.

**PRECAUTIONS**
**Impaired Renal or Hepatic Function:** Beta-blocking agents should be used with caution in patients with impaired hepatic or renal function. Poor renal function has only minor effects on Visken (pindolol) clearance, but poor hepatic function may cause blood levels of Visken (pindolol) to increase substantially.

**Information for Patients:** Patients, especially those with evidence of coronary artery insufficiency, should be warned against interruption or discontinuation of Visken (pindolol) therapy without the physician's advice. Although cardiac failure rarely occurs in properly selected patients, patients being treated with beta-adrenergic blocking agents should be advised to consult the physician at the first sign or symptom of impending failure.

**Drug Interactions:** Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients receiving Visken (pindolol) plus a catecholamine depleting agent should, therefore, be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Visken (pindolol) has been used with a variety of antihypertensive agents, including hydrochlorothiazide, hydralazine, and guanethidine without unexpected adverse interactions.

**Carcinogenesis, Mutagenesis, Impairment of Fertility:** In chronic oral toxicologic studies (one to two years) in mice, rats, and dogs, Visken (pindolol) did not produce any significant toxic effects. In two-year oral carcinogenicity studies in rats and mice in doses as high as 59 mg/kg/day and 124 mg/kg/day (50 and 100 times the maximum recommended human dose), respectively, Visken (pindolol) did not produce any neoplastic, preneoplastic, or nonneoplastic pathologic lesions. In fertility and general reproductive performance studies in rats, Visken (pindolol) caused no adverse effects at a dose of 10 mg/kg.

In the male fertility and general reproductive performance test in rats, definite toxicity characterized by mortality and decreased weight gain was observed in the group given 100 mg/kg/day. At 30 mg/kg/day, decreased mating was associated with testicular atrophy and/or decreased spermatogenesis. This response is not clearly drug related, however, as there was no dose response relationship within this experiment and no similar effect on testes of rats administered Visken (pindolol) as a dietary admixture for 104 weeks. There appeared to be an increase in prenatal mortality in males given 100 mg/kg but development of offspring was not impaired.

In females administered Visken (pindolol) prior to mating through day 21 of lactation, mating behavior was decreased at 100 mg/kg and 30 mg/kg. At these dosages there also was increased mortality of offspring. Prenatal mortality was increased at 10 mg/kg but there was not a clear dose response relationship in this experiment. There was an increased resorption rate at 100 mg/kg observed in females necropsied on the 15th day of gestation.

**Pregnancy—Category B:** Studies in rats and rabbits exceeding 100 times the maximum recommended human doses, revealed no embryotoxicity or teratogenicity. Since there are no adequate and well-controlled studies in pregnant women, and since animal reproduction studies are not always predictive of human response, Visken (pindolol), as with any drug, should be employed during pregnancy only if the potential benefit justifies the potential risk to the fetus.

**Nursing Mothers:** Since Visken (pindolol) is secreted in human milk, nursing should not be undertaken by mothers receiving the drug.

**Pediatric Use:** Safety and effectiveness in children have not been established.

**CLINICAL LABORATORY**
Minor persistent elevations in serum transaminases (SGOT, SGPT) have been noted in 7% of patients during Visken (pindolol) administration, but progressive elevations were not observed and liver injury has not been reported in the medical literature over a ten (10) year period of marketing. Alkaline phosphatase, lactic acid dehydrogenase (LDH) and uric acid are also elevated on rare occasions. The significance of these findings is unknown.

**ADVERSE REACTIONS**
Most adverse reactions have been mild. The incidences listed in the following table are derived from 12 week comparative double-blind, parallel design trials in hypertensive patients given Visken (pindolol) as monotherapy, given various active control drugs as monotherapy, or given placebo. Data for Visken (pindolol) and the positive controls were pooled from several trials because no striking differences were seen in the individual studies, with one exception. The frequency of edema was noticeably higher in positive control trials (16% Visken (pindolol) vs 9% positive control) than in placebo controlled trials (6% Visken (pindolol) vs 3% placebo). The table includes adverse reactions reported in greater than 2% of Visken (pindolol) patients and other selected important reactions.

| Body System/ Adverse Reaction | Total (Volunteered and Elicited) Visken (pindolol) (N = 322) % | Active Controls* (N = 188) % | Plac (N = % |

*Active Controls: Patients received either propranolol, ∝-methyldopa or a diuretic (hydrochlorothiazide or chlorthalidone).

The following selected (potentially important) adverse reactio were seen in 2% or fewer patients and their relationship to Visken (pindolol) is uncertain. AUTONOMIC NERVOUS SYSTEM: hyperhidrosis; CARDIOVASCULAR: bradycardia, claudication, cold extremities, heart block, hypotension, syncope, tachycardia; GASTROINTESTINAL: diarrhea, vomiting; RESPIRATORY: wheezing; UROGENITAL: impotence, pollakiuria; MISCELLANEOUS: eye discomfort or burning eyes.

**POTENTIAL ADVERSE EFFECTS**
In addition, other adverse effects not listed above have been r ported with other beta-adrenergic blocking agents and should be considered potential adverse effects of Visken (pindolol).

**Central Nervous System:** Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

**Cardiovascular:** Intensification of AV block. See CONTRAINDICATIONS.

**Allergic:** Erythematous rash; fever combined with aching and sore throat; laryngospasm; respiratory distress.

**Hematologic:** Agranulocytosis; thrombocytopenic and nonthrombocytopenic purpura.

**Gastrointestinal:** Mesenteric arterial thrombosis; ischemic colitis.

**Miscellaneous:** Reversible alopecia; Peyronie's disease.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with Visken (pindolol) during investigational use and extensive foreign experience amounting to over 4 million patient-years.

**OVERDOSAGE**
No specific information on emergency treatment of overdosage is available. Therefore, on the basis of the pharmacologic actions of Visken (pindolol), the following general measures should be employed as appropriate in addition to gastric lavage:

**Excessive Bradycardia:** administer atropine; if there is no response to vagal blockade, administer isoproterenol cautiously.

**Cardiac Failure:** digitalize the patient and/or administer diuretic. It has been reported that glucagon may be useful in this situation.

**Hypotension:** administer vasopressors, e.g., epinephrine or levarterenol, with serial monitoring of blood pressure. (There is evidence that epinephrine may be the drug of choice.)

**Bronchospasm:** administer a $beta_2$ stimulating agent such as isoproterenol and/or a theophylline derivative.

A case of an acute overdosage has been reported with an intake of 500 mg of Visken (pindolol) by a hypertensive patient. Blood pressure increased and heart rate was ⩾80 beat/min. Recovery was uneventful. In another case 250 mg of Visken (pindolol) was taken with 150 mg diazepam and 50 mg nitrazepam, producing coma and hypotension. The patient recovered in 24 hours.

**DOSAGE AND ADMINISTRATION**
The dosage of Visken (pindolol) should be individualized. The recommended initial dose of Visken (pindolol) is 10 mg b.i.d. alone or in combination with other antihypertensive agents. Many patients will respond to 15 mg per day (5 mg t.i.d.). The antihypertensive response usually occurs within the first week of treatment. If a satisfactory reduction in blood pressure does not occur within 2-3 weeks, the dose may be adjusted in increments of 10 mg per day at 2-3 week intervals up to a maximum of 60 mg per day.

**HOW SUPPLIED**
White, round, scored tablets: 5 mg and 10 mg, packages of 100. 5 mg tablets embossed "VISKEN 5" on one side, and "78-111" and scored on other side (NDC 0078-0111-05). 10 mg tablets embossed "VISKEN 10" on one side, and "78-73" and scored on other side (NDC 0078-0073-05). [VIS-Z2 9/1/82]

# Clonidine in Congestive Heart Failure: A Vasodilator With Negative Inotropic Effects

JAMES B. HERMILLER, MD, RAYMOND D. MAGORIEN, MD, MARK E. LEITHE, MD, DONALD V. UNVERFERTH, MD, and CARL V. LEIER, MD

**Fourteen patients with moderately severe congestive heart failure (CHF) were given clonidine orally (0.2 and 0.4 mg doses) to determine the hemodynamic effects of a typical centrally acting vasodilator. The 0.2 mg dose significantly reduced mean systemic (15%) and mean pulmonary artery (20%) pressure; the corresponding reductions in vascular resistance were not as great because of a diminished cardiac output. Pulmonary capillary wedge pressure decreased significantly (27%). Heart rate decreased 11% and stroke volume remained unchanged. At a higher dose (0.4 mg), clonidine augmented these reductions but increased stroke volume modestly (15%). Isovolumic developed pressure/duration of isovolumic contraction and the duration of the preejection period were used as indexes of inotropy. After both doses, isovolumic developed pressure/duration of isovolumic contraction decreased dramatically (≥33%) and the preejection period increased substantially (≥18%) (both $p < 0.05$).**

**Compared with currently employed vasodilating agents, the centrally acting agent clonidine appears unique in that the drug-induced systemic and pulmonary arterial vasodilation are not accompanied by a commensurate improvement in ventricular systolic function. This lack of improvement appears to be a result of negative inotropic effects.**

Peripherally acting vasodilators are now commonly used in the management of congestive heart failure (CHF). Many classes of agents (adrenergic blockers, nonspecific vasodilators, and angiotensin-converting enzyme inhibitors) have been extensively examined over the past decade. Numerous studies have demonstrated that these agents augment stroke volume and cardiac output, primarily by reducing ventricular afterload.[1,2]

In contrast to the peripheral class of compounds, centrally acting vasodilators have received little attention in the setting of low output CHF. One typical centrally acting agent is clonidine. Clonidine is used predominantly in hypertensive patients, in whom it effectively reduces systemic blood pressure, systemic vascular resistance, and heart rate.[3-5] It induces its antihypertensive effect by attenuating sympathetic outflow by way of a complex interaction with the central alpha-adrenergic system.[6,7]

We postulated that clonidine may be an effective vasodilator since it does reduce sympathetic activity, a major cause of the elevated ventricular afterload accompanying CHF. This study was designed to determine the acute hemodynamic properties of oral clonidine in patients with chronic CHF.

## Methods

**Patient population:** Fourteen patients with moderately severe CHF were studied. The mean age was 53 years (range 19 to 73); 2 patients were women. The diagnosis of dilated cardiomyopathy was confirmed by cardiac catheterization performed in each patient within 2 months before the onset of study. Thirteen patients had dilated cardiomyopathy and 1 patient had severe occlusive atherosclerotic coronary artery disease with ischemic cardiomyopathy. Twelve patients were categorized as functional class III and 2 patients as functional class IV (New York Heart Association). All those studied were receiving a digitalis preparation (daily digoxin dose of 0.25 mg in 6 patients, 0.125 mg in 7 patients, and digitoxin 0.1 mg in 1 patient) and furosemide (daily dose range 40 to 120 mg). Several patients had previously received vasodilators (isosorbide dinitrate 20 mg every 6 hours in 5 patients and hydralazine 75 mg every 8 hours in 3 patients). All vasodilators were discontinued at least 48 hours before study. The digitalis and diuretics were continued throughout the study with afternoon doses to avoid peak effect.

**Measurements:** On the first study day, a triple-lumen flow-directed catheter was introduced percutaneously into the subclavian vein and placed in the pulmonary artery for the measurement of pulmonary artery pressure, pulmonary

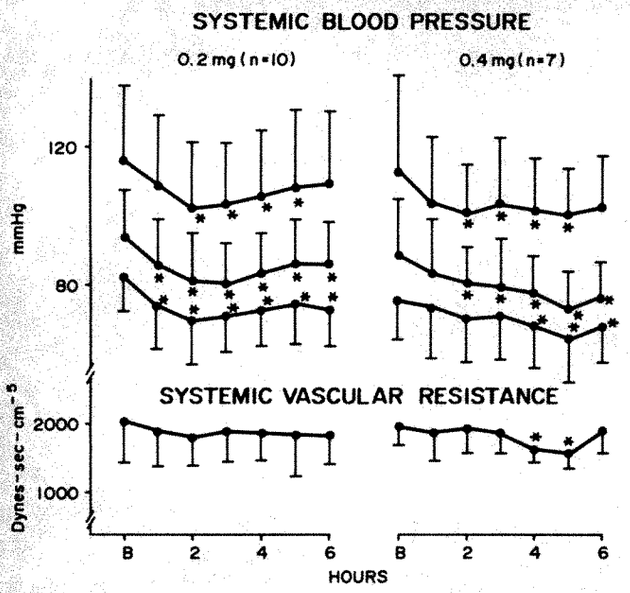

**FIGURE 1.** Both doses of clonidine significantly lowered systolic, mean, and diastolic systemic blood pressures. Only the 0.4 mg dose reduced vascular resistance. Data are presented as mean ± 1 standard deviation. * $p < 0.05$; B = baseline control.

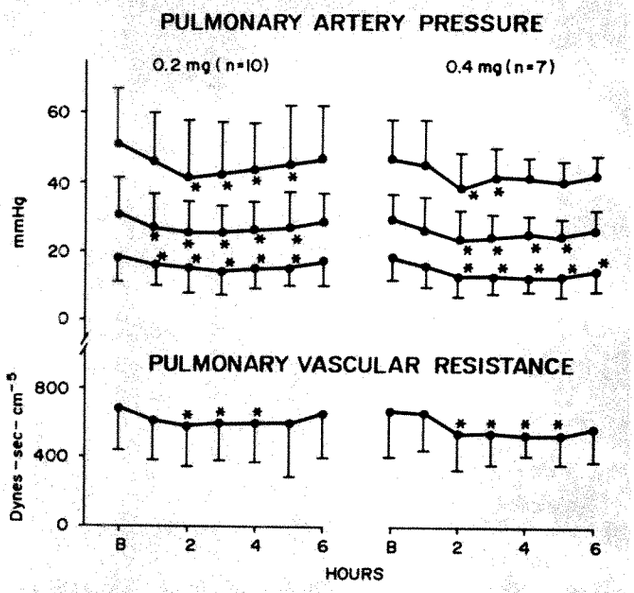

**FIGURE 2.** Pulmonary arterial pressure decreased significantly after clonidine administration. Pulmonary vascular resistance decreased as well. Data are presented as mean ± 1 standard deviation. * $p < 0.05$; B = baseline control.

capillary wedge pressure, and cardiac output (thermodilution technique). The pulmonary artery and capillary wedge pressures were measured with Becton-Dickinson Electrodyne PR-18A pressure amplifiers and ST-149 and WR-4D recording systems. The cardiac outputs were computed with an Instrumentation Laboratory computer unit 601 and recorder unit 602, and were obtained in triplicate (5 measurements were made if variation exceeded 10%). Systemic blood pressure was measured by a cuff and a mercury column sphygmomanometer. Heart rate was obtained from continuous electrocardiographic monitoring. Systolic time intervals, derived from the simultaneous recording of a carotid pulse tracing, a precordial phonocardiogram, and an electrocardiogram, were obtained with an Electronics for Medicine Echo IV unit using specifications previously outlined.[8] Standard formulas were used to determine vascular resistances. Additional calculated variables included the following: diastolic time = R-R interval minus total electromechanical systole ($QS_2$)[9]; preejection period index (milliseconds) = preejection period index corrected for heart rate[8]; and isovolumic developed pressure/duration of isovolumic contraction,[10–12] where developed pressure during isovolumic contraction = systemic diastolic blood pressure minus pulmonary capillary wedge pressure, and isovolumic contraction time = preejection period minus electromechanical delay (Q wave of the electrocardiogram to upstroke of left ventricular impulse on the apexcardiogram). The preejection period index and the isovolumic developed pressure/duration of isovolumic contraction were used as indexes of inotropy.[10–12]

**Protocol:** The patients were studied over 3 days. Day 1 was utilized for catheter placement and served as an equilibration period. On Day 2, 0.2 mg of clonidine was administered, and on Day 3, the patients received 0.4 mg. Clonidine was administered orally in the postabsorptive state. In 10 patients, hemodynamic variables (cardiac output, heart rate, pulmonary capillary wedge pressure, systemic blood pressure, and pulmonary artery pressure) were obtained before and at hourly (×6) intervals after each clonidine dose. Two of these 10 patients and 4 additional ones also underwent hemodynamic, preejection period index, and isovolumic developed pressure/duration of isovolumic contraction measurements at baseline control and 3 hours after clonidine administration.

**Statistical analysis:** The hemodynamic data were compared with control values for each dose with analyses of variance for repeated measures. The 3-hour isovolumic developed pressure/duration of isovolumic contraction and systolic time interval data were compared with control values using the *t* test for paired data.

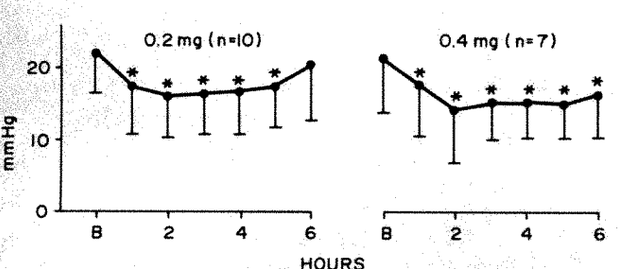

**FIGURE 3.** Pulmonary capillary wedge pressure was significantly reduced by clonidine. Data are presented as mean ± 1 standard deviation. * $p < 0.05$; B = baseline control.

## Results

The results of the hemodynamic studies are presented in Figures 1 through 5. There was no significant difference between any of the baseline control measurements of the 2 doses. After both doses there was a substantial reduction of systolic, mean, and diastolic systemic blood pressures (Fig. 1). All 10 patients who participated in the 6-hour protocol received the 0.2 mg dose, while only 7 were given 0.4 mg because hypotension (systolic blood pressure ≤90 mm Hg) developed in

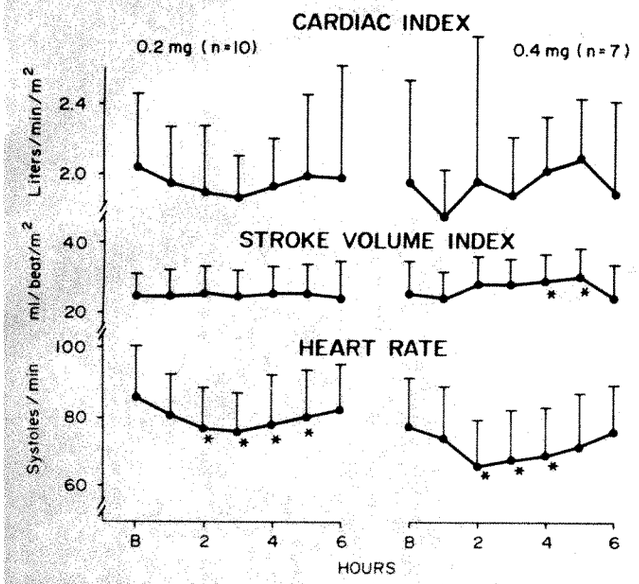

**FIGURE 4.** Clonidine did not alter cardiac index. Stroke volume increased slightly after the 0.4 mg dose, at 4 and 5 hours after drug administration. Both doses significantly lowered heart rate. Data are presented as mean ± 1 standard deviation. * $p < 0.05$; B = baseline control.

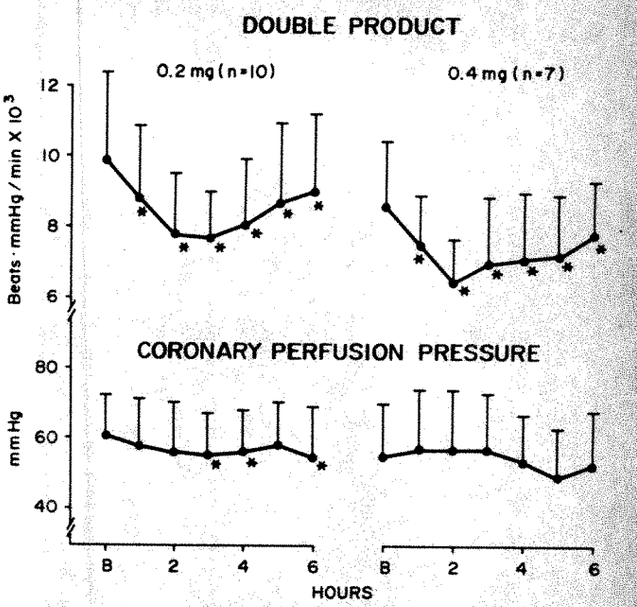

**FIGURE 5.** Double product, a calculated estimation of myocardial oxygen consumption, decreased substantially. Coronary perfusion pressure (diastolic blood pressure − pulmonary capillary wedge pressure) decreased slightly after 0.2 mg and was not altered by the higher dose. Data are presented as mean ± 1 standard deviation. *p $< 0.05$; B = baseline control.

3 patients after the lower dose. The decrease in systemic blood pressure was not accompanied by a comparable reduction of systemic vascular resistance. Pulmonary artery pressure decreased after clonidine administration; moreover, pulmonary vascular resistance decreased after both doses (Fig. 2). Pulmonary capillary wedge pressure decreased substantially (Fig. 3). Clonidine also evoked a significant negative chronotropic response; heart rate decreased 11 and 15% after the respective 0.2 and 0.4 mg doses (Fig. 4). Cardiac index was not significantly altered, and stroke volume increased only modestly 3 and 4 hours after the 0.4 mg dose. Since heart rate and systolic blood pressure both decreased, the double product, an estimate of myocardial oxygen consumption, decreased (Fig. 5). Coronary perfusion pressure (diastolic blood pressure minus pulmonary capillary wedge pressure) was slightly reduced with 0.2 mg, and was not altered by the higher dose. Diastolic perfusion time increased significantly after both doses (Table I). Isovolumic developed pressure/duration of isovolumic contraction and systolic time intervals were obtained in 6 patients. There was a dramatic reduction in isovolumic developed pressure/duration of isovolumic contraction for each patient after both doses (Fig. 6). Although the isovolumic developed pressure did not change significantly, duration of isovolumic contraction was prolonged substantially (Table I). The preejection period index lengthened significantly in each patient (Fig. 6). The ratio of the preejection period to left ventricular ejection time increased significantly after clonidine administration (Table I); this increase was secondary to a consistent prolongation of the preejection period and some shortening of the left ventricular ejection time (Table I).

All patients had somnolence after both doses of clonidine. Four patients noted dry mouths. Three patients has systemic hypotension; 1 of these patients had

| Δt (ms) | 91 ± 14 | 117* ± 21 | 89 ± 14 | 128* ± 18 |

Values are presented as mean ± 1 standard deviation.
LVETI = left ventricular ejection time index; PEP/LVET = preejection period/left ventricular ejection time; $QS_2I$ = duration of electromechanical systole index.

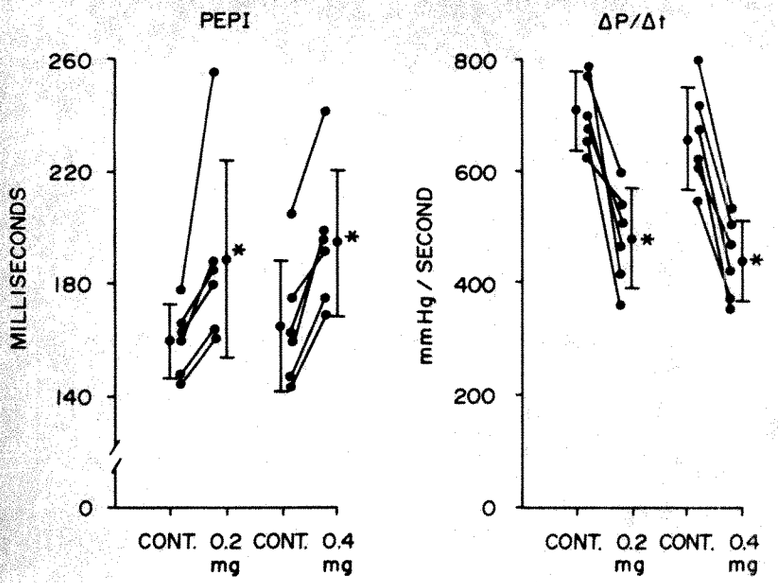

**FIGURE 6.** The preejection period index (PEPI) decreased substantially while the developed pressure during isovolumic contraction/isovolumic contraction time ($\Delta P/\Delta t$) decreased dramatically after clonidine. These changes in inotropic indexes occurred in each patient after both doses. Individual data (n = 6) are presented with brackets indicating ± 1 standard deviation and * $p < 0.05$; CONT. = control.

symptoms of postural hypotension. Intermittent right bundle branch block and first degree atrioventricular block was noted in 3 patients.

## Discussion

Clonidine evoked significant hemodynamic effects in these patients with CHF. This centrally acting vasodilator reduced systemic blood pressure, pulmonary artery pressure, and pulmonary capillary wedge pressure. Heart rate decreased significantly after clonidine administration. Cardiac and stroke volume indexes did not change substantially. Clonidine appeared to favorably affect the myocardial oxygen supply-demand ratio by minimally altering coronary perfusion pressure, increasing diastolic perfusion time, and reducing the double product and inotropic state of the ventricle.

Since stroke volume changed little after clonidine administration, the decrease in systemic blood pressure was probably secondary to systemic arteriolar vasodilatation. The systemic arteriolar vasodilatation after clonidine administration was not reflected in changes in calculated systemic vascular resistance since cardiac output either did not change or tended to decrease. Systemic vascular resistance, the major contributing factor to the state of ventricular afterload, is generally used as an approximation of afterload. Ventricular wall tension during systole, formulated by the Laplace equation as ventricular systolic pressure × ventricular volume (at the designated pressure) ÷ wall thickness, is another expression (and probably a more precise one) of ventricular afterload. Clonidine substantially decreased systolic pressure. Its effects on ventricular volume were not measured; however, since ventricular systolic and diastolic pressures decreased, ventricular volume probably either decreased or remained unaltered. Therefore, using the ventricular wall tension formulation for afterload, clonidine probably elicited a reduction in ventricular afterload despite minimal to no changes in calculated systemic vascular resistance. Certainly, clonidine effected systemic arteriolar dilatation.

The inability of the failing ventricle to increase stroke volume in response to systemic arteriolar vasodilatation (or afterload reduction) may be caused by 1 or more factors, such as, excessive preload reduction, end-stage ventricular dysfunction, provocation of ventricular ischemia, or drug-related negative inotropic effects. The degree of preload reduction (approximated by the decrease in pulmonary capillary wedge pressure) was not excessive in this population, but quite similar to the reduction effected by some of the peripheral vasodilators.[12-14] None of the patients demonstrated end-stage ventricular dysfunction and, when subsequently tested, most responded favorably (augmentation of stroke volume and cardiac index) to various peripheral vasodilators. None of the patients demonstrated clinical evidence of "rebound" after discontinuation of their vasodilator therapy (≥48 hours prestudy), although more subtle hemodynamic changes cannot be excluded. It is unlikely that a mild "rebound" effect would account for the lack of augmentation of ventricular function; in this setting, the response to clonidine might be even more favorable. It is unlikely that clonidine elicited myocardial ischemia, since all but 1 of the subjects had angiographically normal coronary anatomy and, as previously indicated, clonidine tended to favorably alter the determinants of myocardial oxygen supply-demand. Clonidine did, however, decrease isovolumic developed pressure/duration of isovolumic contraction and increase the preejection period and preejection period/left ventricular ejection time in all subjects tested at both doses indicating that this compound evoked negative inotropic effects.

The decrease in isovolumic developed pressure/duration of isovolumic contraction with clonidine was secondary to lengthening of the isovolumic contraction time. The isovolumic contraction time and the pre-

ejection period by themselves correlate well with other indexes of inotropy, although independent changes of ventricular filling and systemic pressure can profoundly alter these variables.[8,10–12,15–17] That is, without a change in contractility, an isolated reduction of ventricular filling pressure can increase the preejection period and the isovolumic contraction time, and an isolated reduction of diastolic blood pressure would shorten them. While ventricular filling pressure did decrease with clonidine administration, this drug effected a parallel reduction in systemic diastolic pressure; the resultant isovolumic developed pressure remained unchanged. Therefore, the increase in preejection period and isovolumic contraction time and the consequent decrease in isovolumic developed pressure/duration of isovolumic contraction noted after clonidine administration indicates that this drug elicited a negative inotropic effect.

Clonidine's central site of action[6,7,18,19] probably accounts for most of the differences between the hemodynamic effects of this drug and those of the peripheral vasodilating agents. Clonidine's central effects elicit an overall reduction in sympathetic nervous system outflow to cardiovascular target organs including vascular smooth muscle (generalized vasodilation), specialized conduction tissue (negative chronotropy), and myocardium (resultant negative inotropy). Clonidine has been shown to reduce circulating cathecholamines and also retard renin release (resultant decrease in angiotensin activity).[20,21] The vasodilation is not likely to be a consequence of direct peripheral action, because its peripheral effects are predominantly vasopressor.[22] The negative chronotropic effects may be partly related to heightened parasympathetic activity, since clonidine appears to exert some parasympathomimetic effects.[23] The negative inotropic effects are, in large part, mediated indirectly through reduced myocardial adrenergic tone; clonidine itself does not directly reduce inotropy.[24]

Elevated sympathetic activity is an important compensatory mechanism in maintaining adequate cardiac function in moderate to severe CHF.[25] Although norepinephrine levels of neurons innervating the heart are reduced and the number and sensitivity of $beta_1$-adrenergic receptors are attenuated, cardiac function remains quite dependent on heightened sympathetic support.[25–27] Unlike clonidine, the peripheral vasodilators act primarily at vascular or peripheral vascular innervation sites and, therefore, do not elicit myocardial depression; for example, hydralazine induces vasodilation by acting directly on arterioles, and prazosin, an $alpha_1$-antagonist, postsynaptically blocks norepinephrine at vascular innervation sites. It is possible that clonidine's overall hemodynamic effects may be more favorable in patients with heart failure of lesser severity and with less dependence on sympathetic nervous system support.

The clinical role of clonidine in CHF is likely to be restricted because of its inability to improve ventricular systolic function. Since it reduces double product, inotropy, and pulmonary capillary wedge pressure and increases diastolic perfusion time, it may be useful in patients with ischemic cardiomyopathy who have high ventricular filling pressure with mild ventricular systolic dysfunction. While its role in the treatment of CHF is probably limited, clonidine is an unusual vasodilator which has provided valuable insights into the role of the central sympathetic nervous system in human CHF.

# In Vivo Quantitation of Platelet Deposition on Human Peripheral Arterial Bypass Grafts Using Indium-111–Labeled Platelets

## Effect of Dipyridamole and Aspirin

CHARLES W. PUMPHREY, DM, MRCP, JAMES H. CHESEBRO, MD, MRINAL K. DEWANJEE, PhD, HEINZ W. WAHNER, MD, LARRY H. HOLLIER, MD, PETER C. PAIROLERO, MD, and VALENTIN FUSTER, MD

**Indium-111–labeled autologous platelets, injected 48 hours after operation, were used to evaluate the thrombogenicity of prosthetic material and the effect of platelet inhibitor therapy in vivo. Dacron® double-velour (Microvel®) aortofemoral artery bifurcation grafts were placed in 16 patients and unilateral polytetrafluoroethylene femoropopliteal grafts were placed in 10 patients. Half the patients in each group received platelet inhibitors before operation (dipyridamole, 100 mg 4 times a day) and after operation (dipyridamole, 75 mg, and acetylsalicylic acid, 325 mg 3 times a day); the rest of the patients served as control subjects. Five-minute scintigrams of the graft region were taken with a gamma camera interfaced with a computer 48, 72, and 96 hours after injection of the labeled platelets. Platelet deposition was estimated from the radioactivities of the grafts and expressed as counts per 100 pixels per microcurie injected.**

**Dipyridamole and aspirin therapy significantly reduced the number of platelets deposited on Dacron grafts and prevented platelet accumulation over 3 days. With the small amount of platelet deposition on polytetrafluoroethylene femoropopliteal artery grafts even in control patients, platelet inhibitor therapy had no demonstrable effect on platelet deposition on these grafts.**

**It is concluded that (1) platelet deposition on vascular grafts in vivo can be quantitated by noninvasive methods, and (2) dipyridamole and aspirin therapy reduced platelet deposition on Dacron aortofemoral artery grafts.**

The success of vascular surgery is limited by the substantial number of arterial grafts in which the development of thrombosis results in occlusion.[1] Studies showing accelerated consumption of platelets in patients with vascular prostheses provide indirect evidence that platelets may be important in this process.[2] More direct evidence of increased platelet deposition on prosthetic grafts compared with normal vascular endothelium is derived from imaging techniques using indium-111–labeled platelets.[3,4] In animal studies platelet deposition can be quantitated by removing the graft and measuring its radioactivity in a gamma counter.[5] Currently, however, only a qualitative assessment of platelet deposition on arterial grafts in human subjects can be made from gamma camera images.

For evaluation of the thrombogenicity of prosthetic biomaterials and the effect of antithrombotic therapy in human subjects, methods of quantitation are necessary. We report herein a quantitative, noninvasive method of measuring platelet deposition in man and the effect of platelet inhibitor therapy on platelet deposition on both Dacron aortofemoral and polytetrafluoroethylene femoropopliteal grafts in patients in the days immediately after operation.

## Methods

**Patients studied:** Twenty-six patients (19 men and 7 women) with a mean age of 62 years (range 44 to 79) were studied after informed consent had been obtained. Their characteristics are listed in Table I.

Sixteen patients underwent aortobifemoral operation with insertion of a 12 mm (n = 2), 14 mm (n = 11), or 16 mm (n = 3) preclotted Dacron double-velour (Microvel®) bifurcation graft. The diameter of the limbs of the graft was half that of the proximal anastomosis—that is, 6, 7, or 8 mm. The grafts extended from the bifurcation of the aorta to the common femoral artery on each side.

Ten additional patients underwent unilateral femoropopliteal artery operation in which an expanded polytetrafluoroethylene Gore-Tex® (W. L. Gore and Associates) graft of 6 mm diameter was anastomosed proximally to the common femoral artery and distally to the popliteal artery.

**Platelet labeling and imaging procedures:** Forty-eight hours postoperatively 43 ml of blood was collected in 7 ml of acid citrate dextrose (ACD) anticoagulant (Squibb). The platelets were separated and labeled with indium-111 oxine according to the method of Heaton et al.[6] Platelet-aggregation function is preserved by this method[7] as we have also observed in previous unpublished studies. After resuspension in 6 ml of plasma, the platelets were reinfused into the patient. The mean labeling efficiency was 68.5% (range 25 to 80) and the mean injected dose of radiolabel was 426 μCi (range 305 to 500).

On the fourth, fifth, and sixth days postoperatively, that is, 48, 72, and 96 hours after platelet labeling, scintigrams of the operated region were obtained with a gamma camera interfaced with a Medical Data Systems computer. The imaging period was exactly 5 minutes. A medium-energy parallel hole collimator was used and the gamma ray spectrometer was adjusted to include the 174 and 247 keV peaks of indium-111 radionuclide. The camera was placed as close to the skin as possible without actual contact, and the whole graft was included in the image.

**Qualitative analysis:** Two observers viewed all graft images blinded as to whether they were from treated or control patients. Visually enhanced radioactivity was recorded for a proximal or distal anastomosis if both observers agreed that the anastomosis had more radioactivity than the visually estimated average radioactivity of the remainder of the graft on at least 2 of the 3 days of imaging.

**Method of quantitation:** Platelet deposition on the graft was measured by outlining the image of the whole graft with a light pen. Anastomoses taken from a 2 mm segment at each end of the graft image were outlined separately. The computer-generated images were then used to quantitate counts per 100 pixels in the 3 regions of interest: proximal anastomosis, graft, and distal anastomosis. The differences in dose of radioactivity between patients were then normalized by dividing the activity by the injected activity corrected for decay. Hence, results are expressed as counts per 100 pixels per microcurie injected. Background radioactivity was estimated in patients with femoropopliteal artery operation by measuring the radioactivity from an area of thigh image 3 mm by 10 mm located 2 mm lateral to the graft. No background activity was measured on patients with aortofemoral artery grafts.

**Treatment groups:** *Treated patients:* Eight patients undergoing Dacron aortobifemoral (12 mm, n = 1; 14 mm, n = 5; 16 mm, n = 2) and 5 patients undergoing polytetrafluoroethylene femoropopliteal artery grafting procedures received platelet-inhibitor therapy based on a dosage schedule that improves a shortened platelet survival[8–11] and reduces aortocoronary vein bypass graft occlusion[12]: dipyridamole 100 mg was given orally 4 times in the 24 hours before operation, orally at 6 A.M. on the day of operation, and down the nasogastric tube at 1 hour after operation; then aspirin, 325 mg, in combination with dipyridamole, 75 mg, was administered 3 times a day starting down the nasogastric tube 8 hours postoperatively and orally when able.

*Control patients:* Eight patients undergoing Dacron aortobifemoral (12 mm, n = 1; 14 mm, n = 6, 16 mm, n = 1) and 5 patients undergoing polytetrafluoroethylene femoropopliteal artery grafting procedures received no platelet inhibitor drugs and served as the controls.

**Statistical analysis:** A close correlation existed between the measured activity in the right and left limbs of the Dacron

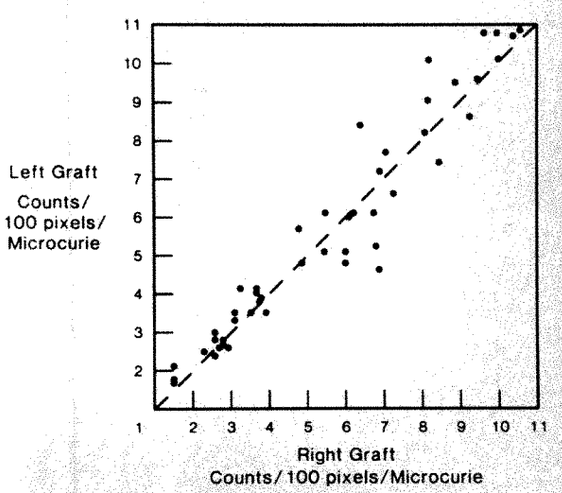

**FIGURE 1.** Correlation between radioactivity in right and left Dacron aortofemoral artery grafts on 3 consecutive days of imaging.

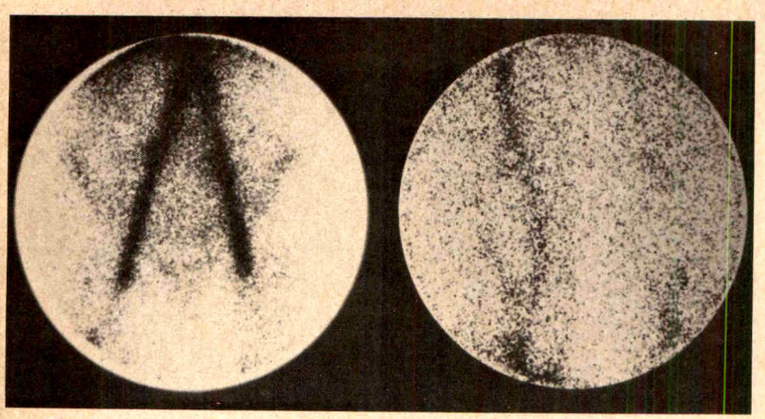

**FIGURE 2.** Examples of images obtained of aortofemoral artery Dacron bifurcation graft (**left panel**) and polytetrafluoroethylene femoropopliteal artery graft (left side of **right panel**) after injection of indium-111–labeled platelets.

aortofemoral artery grafts ($r = 0.96$, $n = 48$, $p < 0.001$) (Fig. 1). Therefore, in these patients the analysis was made on the mean value of the activities from the limbs of each graft. Results are expressed as median values, and the Mann-Whitney U test for comparison of independent samples was used for statistical analysis.

## Results

**Platelet deposition on Dacron and polytetrafluoroethylene grafts:** All grafts remained patent during the study, and they were all easily visualized as areas of increased radioactivity compared with the adjacent native artery (Fig. 2). Platelet activity was not uniform along the length of the graft. The Dacron aortofemoral artery grafts were more distinct against the background than were the polytetrafluoroethylene femoropopliteal artery grafts (Fig. 2); the less distinct polytetrafluoroethylene grafts had a median ratio of radioactivity of graft to adjacent thigh of 3.5 (range 2.9 to 6.0) to 1.

Platelet deposition in control patients was significantly greater on Dacron aortofemoral artery grafts than on polytetrafluoroethylene femoropopliteal artery grafts (see Fig. 3 for median values, range, and p values). Quantitative measurement of radioactivity of control grafts showed that only on the Dacron aortofemoral artery grafts was the radioactivity significantly increased at 96 hours compared with 48 hours for proximal anastomoses ($p < 0.01$) and for grafts ($p < 0.05$) (see Fig. 3, middle and upper panels, for values for Dacron).

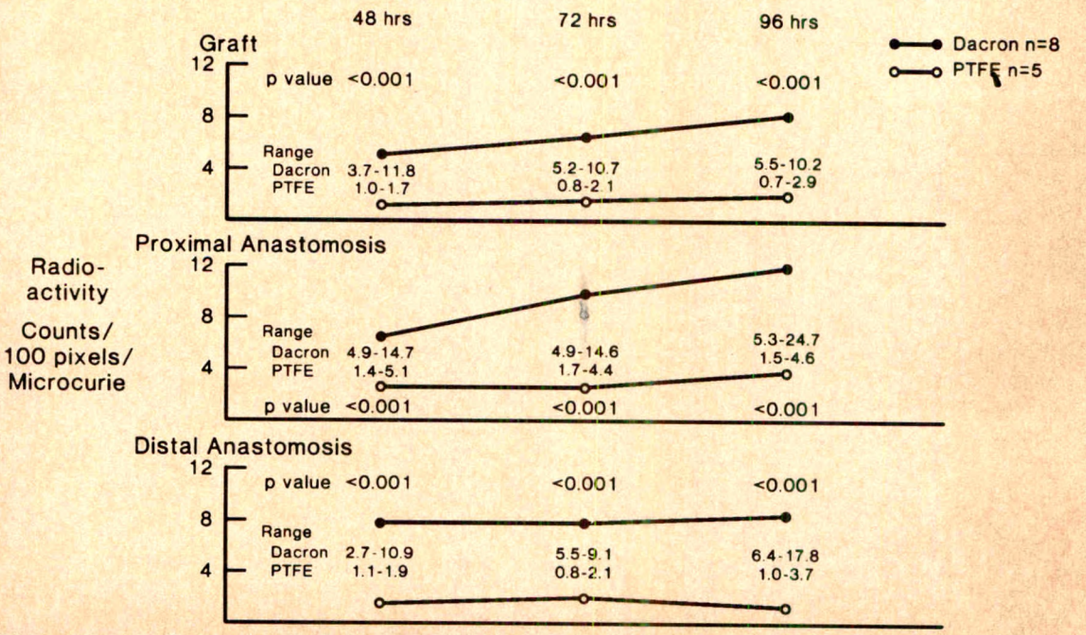

**FIGURE 3.** Graphs of median radioactivities of grafts (**upper panel**) and anastomoses (**middle and lower panels**) of Dacron aortofemoral artery prostheses compared with those of polytetrafluoroethylene (PTFE) femoropopliteal artery prostheses 48, 72, and 96 hours after injection of indium-111–labeled platelets in control patients. Ranges of radioactivity are listed in each panel for each of the 3 days.

As seen in Table II, visual estimation of enhanced radioactivity at the artery-graft anastomosis compared with the rest of the graft showed that approximately half of all anastomoses showed enhanced radioactivity.

**Effect of platelet inhibitor therapy:** *Dacron grafts:* Significantly fewer platelets were deposited on the aortofemoral artery grafts during each of the 3 days of imaging in treated patients (Fig. 4) compared with control patients. This effect was seen on the graft and on both proximal and distal anastomoses. There was no increase in radioactivity from 48 to 96 hours for proximal anastomoses or for grafts in the treated group.

*Polytetrafluoroethylene grafts:* No reduction in platelet deposition on the femoropopliteal grafts occurred in treated patients from the already low levels observed in control patients (Fig. 5).

## Discussion

**Quantitation of graft imaging:** In agreement with other investigators,[13,14] we found that both aortofemoral artery and femoropopliteal artery prosthetic grafts were readily visualized by the use of indium-111–labeled platelets. Platelet deposition along the graft was not uniform and especially tended to be enhanced at artery-graft anastomoses in both control and treated patients; this emphasizes the need to outline the whole graft, rather than just a section of it, and the need for quantifying platelet deposition.

The anastomoses might be expected to be regions of greater platelet accumulation compared with the rest of the graft. Both the presence of sutures and the differences in compliance between the native artery and the graft lead to turbulence which stimulates platelet adhesion. By injecting the platelets 48 hours after operation, postoperative bleeding does not contribute to any increase in extraluminal activity seen in these regions.

Any noninvasive method for measuring differences in radioactivity between patients encounters the problems of background blood pool activity and tissue attenuation. Our studies in dogs[5] demonstrated that as early as 3 hours after insertion the activity of a patent polytetrafluoroethylene graft can be up to 10 times that of the circulating blood. In addition, the half-life of indium-111 is short. By imaging 2 to 4 days after platelet

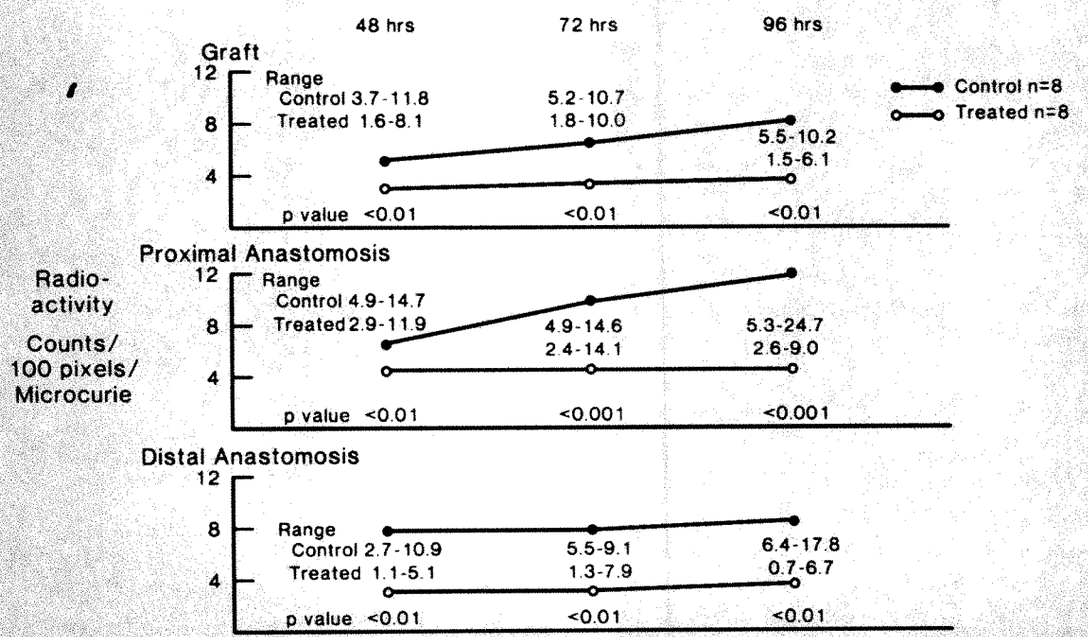

**FIGURE 4.** Graphs of median radioactivities of Dacron aortofemoral artery grafts (**upper panel**) and anastomoses (**middle and lower panels**) in control patients compared with those in patients treated with platelet inhibitors 48, 72, and 96 hours after injection of indium-111–labeled platelets. Ranges of radioactivity are listed in each panel for each of the 3 days.

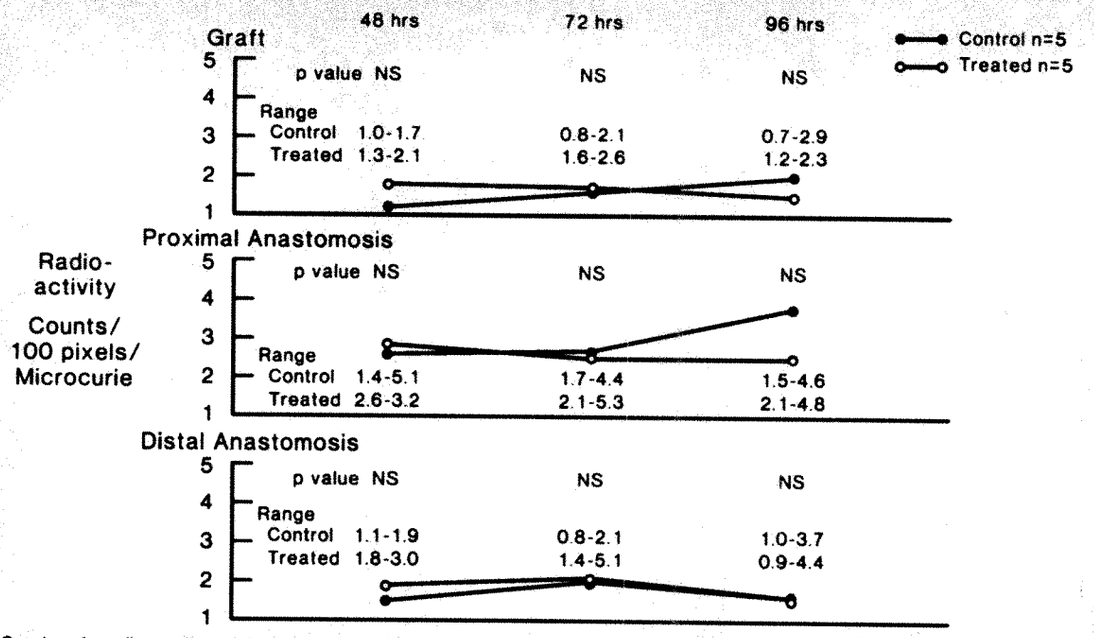

**FIGURE 5.** Graphs of median radioactivities of polytetrafluoroethylene femoropopliteal artery grafts (**upper panel**) and anastomoses (**middle and lower panels**) in control patients compared with those in patients treated with platelet inhibitors 48, 72, and 96 hours after injection of indium-111–labeled platelets. Ranges of radioactivity are listed in each panel for each of the 3 days.

labeling, the activity of the blood was at a minimum. Thus, the platelets deposited on the graft, rather than those circulating in the blood, contributed principally to the image of the graft.

Because the diameter of each femoropopliteal artery graft was the same and 7 of 8 of the aortofemoral artery grafts were also of equal diameter (the other differed by only 1 mm), the blood volumes per unit length of graft were similar in each group of patients. Furthermore, we standardized differences in blood pool activity between patients by incorporating the decay-corrected injected dose into the calculated figure.

The smaller diameter of the femoropopliteal artery grafts also results in less radioactivity per unit area of image, but this does not account for all of the difference in activity between the polytetrafluoroethylene and Dacron grafts. Platelets may be less adherent to polytetrafluoroethylene than to Dacron, as reported by others,[14] but this conclusion cannot be drawn from this study because the different graft materials were placed in different anatomic locations. Blood flow is greater in the aortofemoral position, so more platelets per unit of time come into contact with these grafts than with those in the femoropopliteal position.

Differences in tissue absorption of radioactivity may reduce the validity of comparisons between patients. The anatomic position of the aorta and the femoral artery remains relatively constant although the body habitus and amount of subcutaneous tissue may vary. The bifurcation of the aorta is anterior to the vertical column, and the graft passes anteriorly and inferiorly to just under the skin below the inguinal ligament. Because there was little difference in the body habitus between patients in the control and those in the treated groups (Table I), the variation in tissue attenuation was not large and would not be expected to account for the differences observed in the treated and control patients. By contrast, the anatomic position of the femoropopliteal artery grafts can vary, lying either subcutaneously or deep within the muscle layer. Furthermore, because the background tissue activity from the bone marrow may contribute to the measured activity of the graft, measurements of these grafts with low levels of platelet deposition may be subject to greater error.

To avoid these problems, some investigators[14] use activity ratios, comparing the grafts with the contralateral artery; such a comparison presupposes that in the contralateral artery the platelet endothelial interaction is normal, the luminal diameter is almost the same as that of the graft, and the blood flow is almost the same as that in the grafts, all of which assumptions are unlikely in a disease so diffuse as atherosclerosis.

**Platelet inhibitor therapy:** Dipyridamole and aspirin therapy has been shown to reduce platelet deposition and thrombosis in vein grafts both in dogs[15–17] and in patients.[12] In this study a similar drug regimen to that which showed a beneficial effect on the early occlusion rate of aortocoronary saphenous vein bypass grafts[12] in patients was associated with less deposition along the aortofemoral grafts, including the anastomoses, compared with the control grafts. However, the amount of platelet deposition on polytetrafluoroethylene femoropopliteal artery grafts was small, even in the control patients, and may have been below the level at which an effect of platelet inhibitor drugs could be observed.

Dipyridamole and its combination with aspirin takes advantage of the potentiation of the 2 drugs[9,10,18] with

interference of platelet metabolism at different levels,[9] allowing smaller dipyridamole doses with less expense and better tolerance, and enhanced dipyridamole absorption.[19] The maximal inhibition of platelet deposition in flowing blood in rabbits was obtained by using intermediate doses of dipyridamole (3 mg/kg) and aspirin (10 mg/kg).[18] The accumulation of salicylate may protect vascular prostacyclin from inhibition by aspirin.[20] Likewise, intermediate doses of dipyridamole (225 mg/day) and aspirin (1 g/day)[8,9,11] or larger doses of dipyridamole alone (400 mg/day)[10] prolong a shortened platelet survival in patients toward normal and appear to show in vivo suppression of platelet-arterial wall or platelet-prosthetic material interaction.[5,8–12,15] In our view suppression of this in vivo interaction in patients and animals is a good approach for choosing drugs and drug doses that may be of clinical antithrombotic benefit and value in a clinical trial.[12,21]

The clinical importance of this study is uncertain, although it suggests that this method may be an important way of screening for effective platelet inhibitor drugs in man. We have demonstrated that the percentage of injected dose per unit area, computed from the graft image, is a normalized variable that can be used to compare differences in platelet deposition. Longitudinal studies are necessary to establish whether late occlusion correlates with the level of platelet deposition observed in the early postoperative period.

# Cardiovascular Effects of a Newly Synthesized Cardiotonic Agent (TA-064) on Normal and Diseased Hearts

MASAYA KINO, MD, YUZO HIROTA, MD, SHOJI YAMAMOTO, MD, KENICHI SAWADA, MD, MASATOMO MORIGUCHI, MD, MASAHIRO KOTAKA, MD, SHINICHIRO KUBO, MD, and KEISHIRO KAWAMURA, MD

**A new inotropic agent, TA-064, (−)-α-(3,4-dimethoxyphenethylaminomethyl)-4-hydroxybenzylalcohol, was shown to have strong effects in experimental animals. Its effectiveness and associated adverse effects were tested in humans invasively (n = 6) and noninvasively (n = 17). Increasing doses of intravenous infusion (1, 2, and 4 μg/kg/min) increased plasma levels to 15, 35, and 82 ng/ml, respectively, resulting in marked increases in the peak rate of left ventricular pressure rise (dP/dt) (1,450 ± 63 to 3,042 ± 349 mm Hg/s) (mean ± standard error of the mean [SEM], p <0.01) and the ratio of dP/dt to left ventricular pressure at a developed pressure of 40 mm Hg (25 ± 3 to 39 ± 2 $s^{-1}$) (p <0.01), with a reduction in left ventricular end-diastolic pressure (12 ± 2 to 4 ± 1 mm Hg) (p <0.01). Minimal or no changes were seen in heart rate and left ventricular systolic pressure. After a single oral dose (10 mg), the plasma level reached its peak at 90 minutes (16 ± 9 ng/ml, n = 17). A positive inotropic effect was confirmed echocardiographically in both healthy volunteers (n = 8) and patients with congestive heart failure (CHF) (n = 9) who were maximally treated with conventional regimens: increase in mean velocity of circumferential fiber shortening (healthy volunteers: 1.29 ± 0.05 to 1.60 ± 0.11 circ/s [p <0.05]; patients with CHF: 0.69 ± 0.08 to 0.93 ± 0.09 circ/s [p <0.01]), ejection fraction (healthy volunteers: 68 ± 2 to 75 ± 2% [p <0.05], patients with CHF: 37 ± 4 to 45 ± 5% [p <0.01]) without change in heart rate. The cardiac index was increased only in the CHF group (2.71 ± 0.22 to 3.21 ± 0.24 liters/min/$m^2$) (p <0.05). No significant untoward effects were observed. Thus TA-064 is a potent inotropic agent and can be used either parenterally or orally. Salutary effects can be expected in patients with congestive heart failure who are treated with digitalis and diuretic agents.**

The goal of medical management of the patient with severe heart failure refractory to the conventional regimen of digitalis and diuretic agents is to improve the quality of life and prolong it. Intensive efforts have been directed toward development of efficacious and safe drugs for ambulatory use to minimize disabling symptoms of dyspnea and fatigue. To attain this goal, various combination therapies of digitalis and afterload or preload-reducing agents have been used to increase cardiac pump function with some success.[1–5] However, the clinical use of digitalis is limited because of its narrow therapeutic range and serious arrhythmogenic effects in patients with severe heart failure; only a limited number of inotropic agents are available for ambulatory therapy.[6–10] The catecholamines dopamine and dobutamine, which have a strong positive inotropic effect, cannot be used because of their lack of oral effectiveness. Thus, an orally effective new class of inotropic agent is necessary. To this end, various inotropic agents have been developed and are currently under investigation.[6–14]

TA-064 was synthesized recently at Tanabe Seiyaku, Osaka, Japan (Fig. 1). It has been shown to have a strong

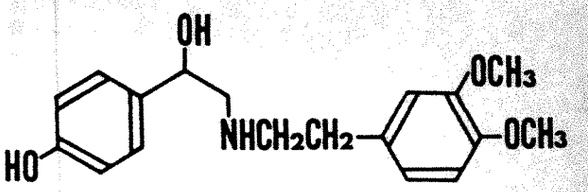
positive inotropic effect. In the experimental animal, when given orally, TA-064 is quickly absorbed from the gastrointestinal tract and its inotropic effect lasts for 7 hours.[15-17] Its oral effectiveness and lack of significant toxicity in the experimental animal makes it potentially important for clinical use as a cardiotonic agent in the therapy of human heart failure.

In this report we describe the acute cardiovascular effects of the new cardiotonic agent TA-064 on normal and diseased human hearts.



## Methods

This study comprises 3 parts: (1) the dose response effects of intravenous TA-064 on hemodynamic variables (n = 6), and (2) the echocardiographic effects of TA-064 given orally to healthy volunteers (n = 8), and (3) to patients with congestive heart failure (CHF) (n = 9).

### Dose Response of Intravenous TA-064

The purpose of this part of the study is to examine the hemodynamic effects of intravenous TA-064 precisely and the dose response of positive inotropic and chronotropic effects, if any. Six patients were selected and agreed to participate in this study on the basis of mild valvular disease or a normal heart confirmed by routine diagnostic cardiac catheterization; 1 had mitral regurgitation, 1 had mitral and aortic regurgitation, and 4 other patients had undergone routine diagnostic catheterization for angina pectoris and were proven to have normal coronaries. All patients were placed in class I to II, according to the New York Heart Association functional classification scheme. The ages of the patients ranged from 32 to 65 years, with a mean of 47.3. The catheterization was performed using the brachial approach with the patient in the fasting state after oral premedication with 5 mg of diazepam; all medications except digitalis were withheld for 10 to 16 hours before the procedure. Left ventricular pressure was recorded in each patient with a high-fidelity micromanometer-tipped angiocatheter (Mikrotip, model PC-471 or 481, Millar Instruments) at high and low gains; left ventricular dP/dt (mm Hg/s) was recorded simultaneously. Zero level was calibrated electronically by a transducer control unit (model TCB-100, Millar Instruments) before the insertion of the catheter, and the zero shift was adjusted to the level of mid-chest position by way of the water-filled system using a Statham P23Db pressure transducer. Right ventricular, pulmonary arterial, and pulmonary capillary wedge pressure were recorded with use of a water-filled system (Swan-Ganz thermodilution catheter, Edwards Laboratories). Cardiac output was measured by the thermodilution technique (model 9510-A, Cardiac Output Computer, Edwards Laboratories). Photographic recordings were obtained at paper speed of 25, 50, and 100 mm/s in each patient, using an 8-channel optical recording system (model 4588D, Hewlett-Packard). Five consecutive complexes in cases of normal sinus rhythm and 10 consecutive complexes in patients with atrial fibrillation were averaged for determination of the pressure, peak rate of left ventricular pressure increase (dP/dt), and the ratio of left ventricular dP/dt at a developed pressure of 40 mm Hg (dP/dt/DP40) ($s^{-1}$).[18] Premature complexes and immediate postpremature complexes were discarded.

Upon completion of baseline measurements, TA-064 was administered intravenously, starting at 1 μg/kg/min with graded increments to 2 and 4 μg/kg/min for a 10-minute infusion period, respectively. At each period, hemodynamic measurements were repeated. Electrocardiogram and the patients' clinical condition were monitored continuously throughout this study.

**FIGURE 1.** Chemical structure and name of TA-064.

### Effects of Oral TA-064: Echocardiographic Study

**Effects on the normal heart:** After informed consent was obtained, 8 healthy male medical students participated in this study (age range from 18 to 28 years, mean 23.3). After 30 minutes of bed rest, an echocardiographic study was performed in the standard method with the patient in the supine position, with a 78° phased electronic sector scanner with 32 elements (Toshiba SSH-11A), using a 2.4 MHz transducer placed in the third or fourth intercostal space. While cardiac motion was observed in 2-dimensional long- and short-axis images, the M-mode echocardiogram was displayed on a fiberoptic recorder (Honeywell model 1218A) at a paper speed of 100 mm/s with simultaneous electrocardiographic, carotid pulse, and phonocardiographic recordings. Echocardiographic measurements were made according to the recommendation by the committee on M-mode standardization of the American Society of Echocardiography.[19] Left ventricular ejection time was obtained from the carotid pulse tracing. After the baseline echocardiogram was obtained, 1 single dose (10 mg) of TA-064 was given orally and echocardiographic study was repeated 30, 45, 60, 90, and 120 minutes after its administration. Blood pressure was automatically measured by cuff method (sphygmomanometer BP-203X, Nihon Kohrin, Tokyo) throughout this study. Fractional shortening (FS) was calculated as FS = (Dd − Ds)/Dd, where Dd = internal dimension of the left ventricle at end-diastole, and Ds = internal dimension of the left ventricle at end-systole. Left ventricular volume at end-diastole and end-systole was calculated according to the method of Teichholz et al[20] as V = (7.0/2.4 + D)($D^3$), where V = volume and D = the internal dimension of the left ventricle at end-diastole and end-systole. Ejection fraction, mean velocity of circumferential fiber shortening,[21] cardiac output, and systemic vascular resistance were also calculated by the standard formulas. Five consecutive beats in normal sinus rhythm were averaged for the echocardiographic measurements.

**Effects on diseased hearts with CHF:** This part of the study was conducted to determine whether positive inotropic effects demonstrated in normal hearts can be elicited in diseased hearts as well by a single oral dose (10 mg) of TA-064. It is not our intention to demonstrate the maximal effect of TA-064. Since we chose to use M-mode echocardiograms to assess left ventricular function, 9 patients with diseased hearts were selected on the basis of uniform hypocontraction of the left ventricle without any segmental dyskinetic area. All had CHF (New York Heart Association functional class II to IV) after full medical treatment with bed rest, low sodium diet, digitalis, diuretics, and other preload- and afterload-reducing agents. The causes of CHF were peripartum cardiomyopathy, terminal stage of syphilitic aortic regurgitation, and ischemic cardiomyopathy, 1 case each; the other 6 patients had con-

CI = cardiac index (liters/min/m$^2$); HR = heart rate (beats/min); LVED = left ventricular end-diastolic pressure (mm Hg); LVMWI = left ventricular minute work index (kg·m/min/m$^2$); LVS = left ventricular systolic pressure (mm Hg); PAM = mean pulmonary artery pressure (mm Hg); SI = stroke index (ml/m$^2$); SWI = stroke work index (g·m/min/m$^2$).

gestive cardiomyopathy. All cases except 1 with congestive cardiomyopathy (Patient 4, Table III) were studied by cardiac catheterization, including left ventriculography and coronary cineangiography. The diagnosis was based not only on the findings of cardiac catheterization but also on the typical clinical presentation and echocardiographic findings, according to the criteria of the National Study Group of Idiopathic Cardiomyopathies of Japan[22] after modification of the criteria of Goodwin and Oakley.[23] The method of this part of the study is almost identical to that described in the previous section on the normal heart. In summary, after informed consent was obtained, the patients were evaluated in the postabsorptive state, 3 to 5 hours after receiving their daily oral dose of digitalis, diuretics, or other conventional regimens. Bed rest of at least 30 minutes stabilized blood pressure and heart rate. After baseline echocardiographic measurements were obtained, the patient was given 1 single dose (10 mg) of TA-064 orally. Echocardiographic examination was repeated 30, 45, 60, 90, 120, and 180 minutes later. Five consecutive beats in cases of normal sinus rhythm and 7 consecutive beats in cases of atrial fibrillation were averaged for the determination of echocardiographic variables. Premature and postpremature beats were discarded.

In each study period, peripheral venous blood samples were obtained for the determination of plasma catecholamine levels and TA-064 concentrations. Plasma catecholamine levels were measured fluorimetrically by high performance liquid chromatography using the trihydroxyindole (THI) method.[24] TA-064 was measured using selected ion monitoring technique by gas chromatography mass spectrometry. We used Student's

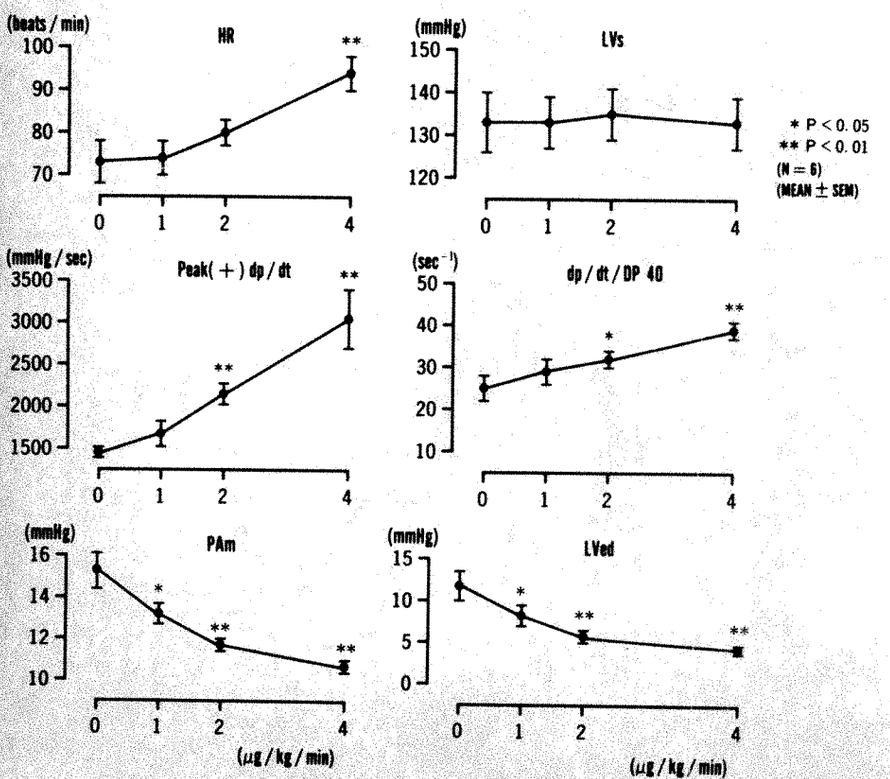

**FIGURE 2.** Dose response effects of intravenous TA-064 upon hemodynamic variables. Peak (+) dP/dt and dP/dt/DP40 were significantly increased even at the dose of 2 μg/kg/min, where the heart rate (HR) and left ventricular systolic pressure (LVs) remained unchanged, and continued to increase at higher doses of TA-064. Mean pulmonary arterial (PAm) and left ventricular end-diastolic pressure (LVed) decreased. Only at a high dose of TA-064 (4 μg/kg/min) did the heart rate increase significantly.

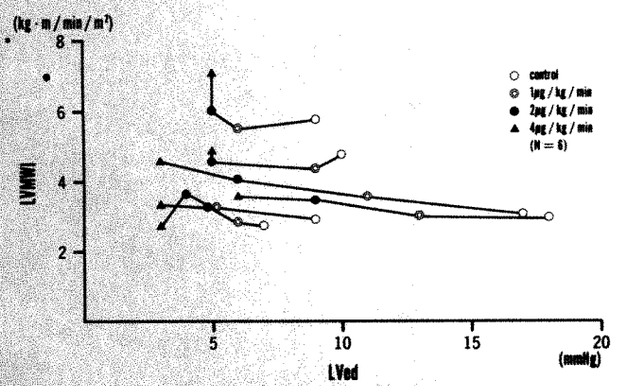
$t$ test for paired data for the comparison of measurements before and after TA-064 administration. All group data in this report are presented as mean ± SEM.

## Results

**Dose response effects of intravenous TA-064 on hemodynamic variables (Table I):** Intravenous infusion of TA-064 with increments to 1, 2, and 4 μg/kg/min increased the mean plasma concentration of TA-064 to 14.7, 34.9, and 81.7 ng/ml, respectively. Left ventricular systolic pressure was not altered. Only with a high dose of TA-064 (4 μg/kg/min) was the heart rate increased significantly. Peak (+) dP/dt and dP/dt/DP40 were significantly increased even at the dose of 2 μg/kg/min, at which heart rate and left ventricular systolic pressure remained unchanged, and continued to increase at higher doses of TA-064 (Table I, Fig. 2). Mean pulmonary and left ventricular end-diastolic pressures were decreased significantly, depending on the dose of TA-064. The cardiac index was not increased. Total pulmonary vascular resistance was significantly reduced. The positive inotropic effect of TA-064 becomes more apparent when the left ventricular end-diastolic pressure-left ventricular work index relation is studied (Fig. 3). In all patients the pressure-work relation was shifted upward toward the left, suggesting an increased inotropic effect of TA-064.

**Effects of oral TA-064 on the normal heart:** After oral administration, TA-064 appeared in the blood at 30 minutes, reached its peak (12.6 ± 2.2 ng/ml) at 90 minutes, and remained in the plasma over 120 minutes. Baseline echocardiographic data and their response to oral TA-064 are presented in Table II. With oral TA-064, the heart rate was increased slightly (11%, 61.1 ± 1.9 to 67.7 ± 2.5 beats/min, $p < 0.01$). Systolic blood pressure increased (14%, 118 ± 4 to 135 ± 4 mm Hg, $p < 0.01$) and diastolic pressure showed a trend toward a decrease, resulting in unchanged mean blood pressure. Left ventricular end-diastolic volume remained unaltered, whereas left ventricular end-systolic volume was significantly reduced (23%, 31 ± 3 to 24 ± 2 ml, $p < 0.05$).



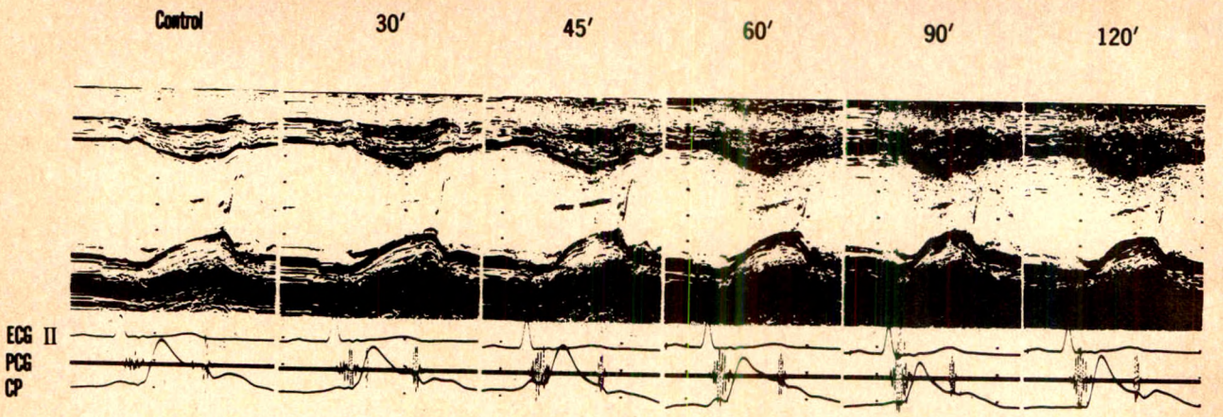


**FIGURE 3.** Dose response effects of intravenous TA-064 and the left ventricular end-diastolic pressure (LVed) left ventricular minute work index (LVMWI) relation. With increasing doses of intravenous TA-064, the pressure-work relation was shifted upward toward the left, suggesting an increased inotropic effect of TA-064.

**FIGURE 4.** Echocardiographic response of oral TA-064 in normal volunteers. A representative case is shown. TA-064 appeared in the plasma 30 minutes after oral administration and reached its peak at 90 minutes. With increasing plasma concentration of TA-064, augmented left ventricular contraction is evident in the echocardiographic tracing. CP = carotid pulse tracing; Dd = end-diastolic diameter; Ds = end-systolic diameter; ECG = electrocardiogram; EF = ejection fraction; HR = heart rate; PCG = phonocardiogram; Vcf = velocity of circumferential fiber shortening.

Cardiac index showed a trend toward an increase, and total systemic vascular resistance a trend toward a decrease. The ejection fraction was significantly increased (10%, 67.7 ± 1.8 to 74.6 ± 2.2%, $p < 0.05$) and mean velocity of circumferential fiber shortening was significantly increased 30 minutes after oral administration of TA-064 and continued to increase (24%, 1.29 ± 0.05 to 1.60 ± 0.11 circ/s, $p < 0.05$). These inotropic effects continued over 120 minutes. A representative case is shown in Figure 4. With increasing plasma concentration of TA-064, augmented left ventricular contraction is evident in the echocardiographic tracings.

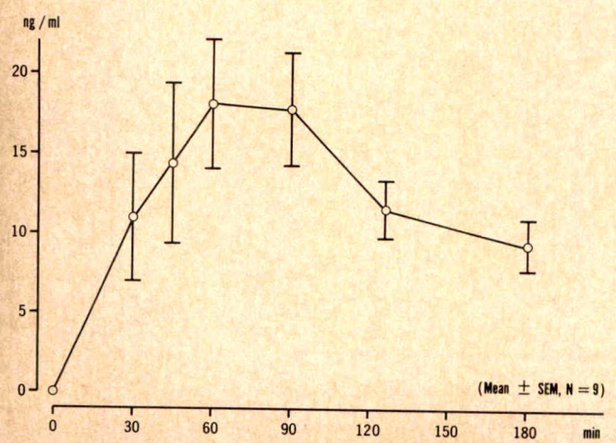

**FIGURE 5.** Plasma concentration of TA-064 in patients with CHF after oral administration of TA-064. TA-064 appeared in the plasma at 30 minutes and reached its peak at 60 to 90 minutes.

**Effects of oral TA-064 on diseased hearts with CHF:** Clinical characteristics and echocardiographic responses are presented in Table III. The plasma concentration of TA-064 is shown in Figure 5. After a single oral dose, plasma TA-064 appeared at 30 minutes and reached its peak at 60 as well as 90 minutes (17.7 ± 3.8 ng/ml); it remained until 180 minutes. In patients with CHF, heart rate and mean blood pressure were not changed, while systolic blood pressure increased only at 180 minutes (107 ± 9 to 117 ± 10 mm Hg, $p < 0.05$) with 10 mg of oral TA-064. Left ventricular end-systolic volume was significantly reduced while left ventricular end-diastolic volume was unchanged, resulting in increased stroke volume (21%, 57 ± 6 to 69 ± 7 ml, $p < 0.01$). The cardiac index increased significantly (18%, 2.71 ± 0.22 to 3.21 ± 0.24 liters/min/$m^2$, $p < 0.05$). Total systemic vascular resistance showed a trend toward a decrease. Ejection fraction increased significantly (21%, 37.1 ± 4.3 to 45.0 ± 4.6%, $p < 0.01$). Mean velocity of circumferential fiber shortening also increased significantly (35%, 0.69 ± 0.08 to 0.93 ± 0.09 circ/s, $p < 0.01$) (Fig. 6).

Findings from individual case examinations indicated the plasma level of TA-064 at 90 minutes did not reach

* 90 minutes after oral TA-064.

AR = aortic regurgitation; CCM = congestive cardiomyopathy; CI = cardiac index (liters/min/$m^2$); DBP = diastolic blood pressure (mm Hg); Dd = internal dimension of the left ventricle at end-diastole (cm); Ds = internal dimension of the left ventricle at end-systole (cm); Dx = diagnosis; EF = ejection fraction (%); FS = fractional shortening; HR = heart rate (beats/min); ICM = ischemic cardiomyopathy; LVEDV = left ventricular end-diastolic volume (ml); LVESV = left ventricular end-systolic volume (ml); mean Vcf = (circ/s); PPCM = peripartum cardiomyopathy; SBP = systolic blood pressure (mm Hg); SV = stroke volume (ml); TSR = total systemic vascular resistance (dynes s $cm^{-5}$).

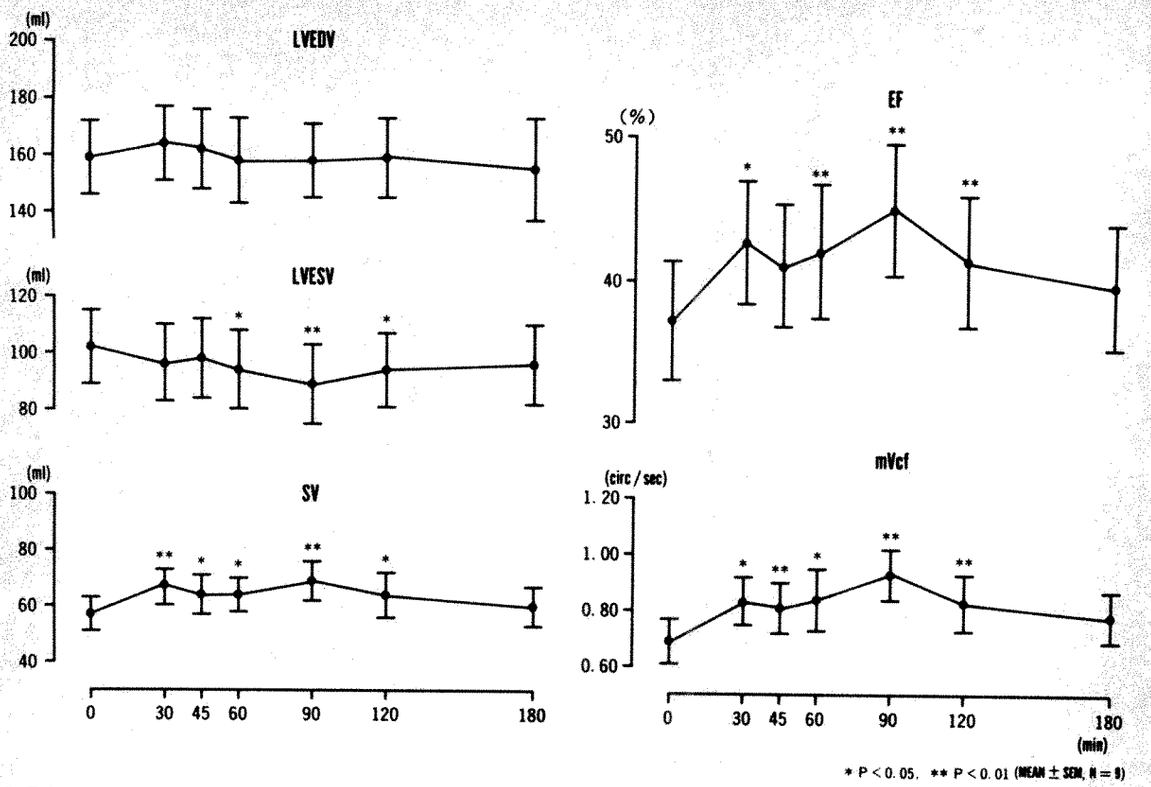

**FIGURE 6.** Echocardiographic response after oral TA-064 in patients with CHF. Left ventricular end-systolic volume (LVESV) was significantly reduced while left ventricular end-diastolic volume (LVEDV) was unchanged, resulting in increased stroke volume (SV). Ejection fraction (EF) and mean velocity of circumferential fiber shortening (mVcf) increased significantly with oral TA-064.

sufficient concentration in 4 patients (Patients 2, 3, 7, and 8, Table III) (<10 ng/ml). However, in these 4 patients the peak plasma level of TA-064 reached was 30 (Patient 2), 60 (Patient 3), 180 (Patient 7), and 120 (Patient 8) minutes, respectively. Moreover, the dose response of TA-064 is evident. The plasma level of TA-064 correlated well with the degree of improvement of mean velocity of circumferential fiber shortening ($r = 0.746$, $p < 0.05$) and ejection fraction ($r = 0.657$, $0.05 < p < 0.1$).

In 2 of 9 patients, 200 to 300 ml of diuresis was obtained 120 to 180 minutes after TA-064 administration. None had noticeable adverse effects. In 1 patient (Patient 7, in Table III), frequent premature ventricular contractions observed at control period were completely abolished during TA-064 administration.

The control value of plasma norepinephrine concentration was increased in 2 patients, both of whom were in New York Heart Association functional class IV (Patient 6, 0.49 ng/ml; Patient 9, 0.80 ng/ml) before study. At 180 minutes after oral administration of TA-064, the plasma concentration of epinephrine was lowered ($0.06 \pm 0.02$ to $0.04 \pm 0.01$ ng/ml, $p < 0.05$), while that of norepinephrine remained unaltered ($0.33 \pm 0.07$ to $0.32 \pm 0.09$ ng/ml).

## Discussion

Although it is well-known that both isovolumic and ejection phase indexes employed in this study are influenced by preload, afterload, and heart rate,[18,25–28] the increase in heart rate and systolic blood pressure were minimal and left ventricular end-diastolic pressure was reduced with TA-064 administration. Therefore, it can be concluded that the marked increase in both isovolumic and ejection phase indexes of contractility seen here were solely due to the inotropic effect of this drug. The inotropic effect of TA-064 is also evident from the cardiac function curve; the left ventricle performs the same or more work at a reduced filling pressure (Fig. 3).

The peak plasma concentration of TA-064 after a single oral administration (normal 12.6 ng/ml; CHF 17.7 ng/ml) corresponds with that of 1 μg/kg/min during intravenous infusion (14.7 ng/ml). Even with this small dose, TA-064 was shown to have a strong positive inotropic effect in patients already on a maximal medical regimen with digitalis and a diuretic agent, resulting in an increased cardiac index.

TA-064 increased contractile function at a dose that did not affect heart rate and blood pressure. Moreover, this inotropic effect of TA-064 is dose-dependent. Thus, a stronger cardiotonic effect can be expected at a higher oral dose of TA-064.

During intravenous infusion study, all 6 patients had a significant reduction in left ventricular filling pressure. Although these reductions could be mediated by improvement in contractility with enhanced systolic emptying of the left ventricle, the marked decrease in left ventricular filling pressure may limit the ability of the drug to further increase cardiac output. This fact

may explain the lack of significant increase in cardiac index in healthy subjects.

TA-064 did not alter plasma norepinephrine concentration. Only the plasma epinephrine level was reduced significantly with TA-064, although this is considered biologically insignificant. We can comment on this only by stating that TA-064 may influence adrenal metabolism directly and its inotropic effect is not mediated by the release of intrinsic catecholamines.

Although the exact mechanism remains to be determined, TA-064 is thought to act on the beta-1 adrenergic receptor. In the experimental animal, increased left ventricular contractile force was inhibited by practolol.[15,17] However, TA-064 was found to have unique but important cardiovascular effects.

The direct effect of TA-064 on cardiac muscle was investigated using isolated guinea pig papillary muscle and right atrium preparation. The effect of TA-064 appeared more rapidly than that of ouabain without inducing any arrhythmia, as usually observed with the latter. Moreover, TA-064 augmented the increase in contractile force induced by ouabain, and vice versa.[17]

Thus, the potentially synergistic effect of TA-064 is to be expected when it is used with digitalis.

In conscious instrumented dogs, after oral administration TA-064 is quickly absorbed from the gastrointestinal tract, metabolized mainly in the liver, and excreted in the urine as glucuronide form. After a single oral dose, TA-064 remained in the plasma >7 hours,[15,17] which is suitable for 3 to 4 times daily administration in ambulatory patients.

While the protocol of this study was not designed to compare the effectiveness of TA-064 with other new classes of inotropic agents, particular comment on amrinone should be made. Amrinone, recently discovered by the investigators at the Sterling-Winthrop Laboratories, was also found to have potent positive inotropic effects on diseased as well as normal hearts. Its effects are not inhibited by beta blockade or in the heart where catecholamine stores are depleted. $Na^+$-$K^+$ adenosine triphosphatase activity is not inhibited as it is by digitalis.[10–14,29] Using various experimental models, positive isotropic and chronotropic effects of TA-064 were compared with those of isoproterenol and amrinone. The positive inotropic effect of TA-064 was 1/50th to 1/100th that of isoproterenol and 100 to 1,500 times stronger than that of amrinone. The positive chronotropic effect of TA-064 was 1/200th to 1/300th that of isoproterenol and 100 to 1,000 times stronger than that of amrinone.[17] The separation of positive inotropic and chronotropic effects was almost identical to that of amrinone.[15,17] These observations showed that TA-064 is a potent inotropic agent, comparable to amrinone.

Since TA-064 exerts its inotropic action by way of beta 1-adrenergic receptor, this drug should be used with great caution in patients with a normal heart size, especially in those with ischemic heart disease. Any inotropic agent such as this one would be expected to increase myocardial oxygen consumption of the nonfailing heart. However, in the failing heart with dilated left ventricular cavity, the overall effect on the cardiac metabolism depends on the interplay of several factors. The increase in myocardial oxygen consumption induced by any inotropic agent may be offset somewhat by the reduction in left ventricular chamber size and therefore systolic-wall tension (the law of LaPlace). Since wall tension during systole and the duration of systole are major determinants of myocardial oxygen consumption,[30] any reduction in these values lessens the effect of augmented myocardial contractility on myocardial oxygen consumption. A potent inotropic agent is thus said to reduce myocardial oxygen consumption in patients with heart failure.[14] The present study does not answer whether this fact may also play a part in the action of TA-064. TA-064, however, was well tolerated and was without noteworthy adverse effects in this study. Indeed, no subject had chest pain or palpitations without development of any change in the electrocardiogram or dysrhythmia. Frequent premature ventricular contractions were completely abolished during this study in 1 patient, and significant diuresis was obtained in 2 of 9 patients. Thus, it may be stated that TA-064 can be safely administered and a potentially beneficial effect can be expected in patients with CHF. However, our study population was small and administration of the drug was short-term; these observations must therefore be considered preliminary. Documentation of a lack of chronic toxicity in human subjects will be necessary before the drug can be considered for long-term administration.

**Acknowledgment:** We thank Tadasu Takatsu, MD, Professor of Medicine Emeritus, Osaka Medical College, for providing the opportunity to perform this study.

Because of a printing error, 2 table headings were transposed in the article by Hirota et al (Hypertrophic Nonobstructive Cardiomyopathy: A Precise Assessment of Hemodynamic Characteristics and Clinical Implications) in our November 1982 issue. The error appears in Table IV, on page 994. The correct placement of the 2 headings is as follows:

| $(dP/dt)/DP_{40}$ ($s_{-1}$) | Peak (−)dP/dt (−mm Hg/s) |
|---|---|
| 32.9 ±7.0 | 1,079* ±329 |
| 31.4 ±5.3 | 1,923 ±440 |

**One of as many as 60* blood pressure readings taken throughout the day by an ambulatory patient.**

# Remler Ambulatory Blood Pressure Recorder...

## Light, compact one-piece unit weighs only 25 ounces

The Remler patented Ambulatory Blood Pressure Recorder has been in use for more than ten years by leading physicians and research institutions throughout the world. It is a proven, easy-to-use system and the only available blood pressure device that completely prints out calibrated blood pressure measurements showing all Korotkoff sounds.

This Model M-2000 records blood pressures during the wearer's working or leisure day. Wearing this unobtrusive, light-weight device on a belt, your patient can easily record blood pressure data onto the micro-cassette as many as sixty times daily. This method *totally eliminates bias,* and the pressor effect of an observer's presence.

A further advantage of the Remler system is the substantial savings in cost over manual methods for obtaining a multiple series of blood pressure measurements.

*Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...*

# THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

**Libi Sherf, MD, FACC** Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

**Henry N. Neufeld, M.D., FACC,** Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon—indeed, *every physician*—should have a good basic knowledge of the Pre-excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

*"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."*
*Thomas N. James, MD*
*The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals.*

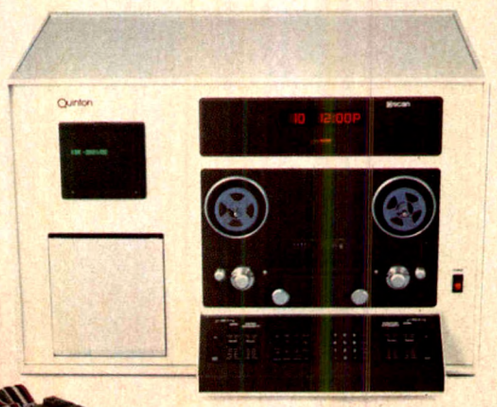
# Q-SCAN TELLS ALL.

Now you can look at every single heartbeat of your patient's day—without wading through complicated charts or relying on mechanical analysis. Because now there's Q-Scan, a new full-disclosure Holter monitoring system from Quinton.

### The information you need in a simple-to-read format.

Q-Scan was designed to make the best use of both your time and expertise. It doesn't make value judgments. Instead it gives you *all* the information you need to make your diagnostic decisions.

In just six minutes, it accurately reproduces every heartbeat from a 24-hour period in a simple-to-read report. You can print the entire 24 hours. Or just those segments that interest you.



Q-Scan gives you a choice of paper, too. A high-speed ultraviolet printer is standard, with a hard copy printer available as an option. An innovation in Holter monitoring, the hard copy printer gives you permanent black and white copies on inexpensive paper.

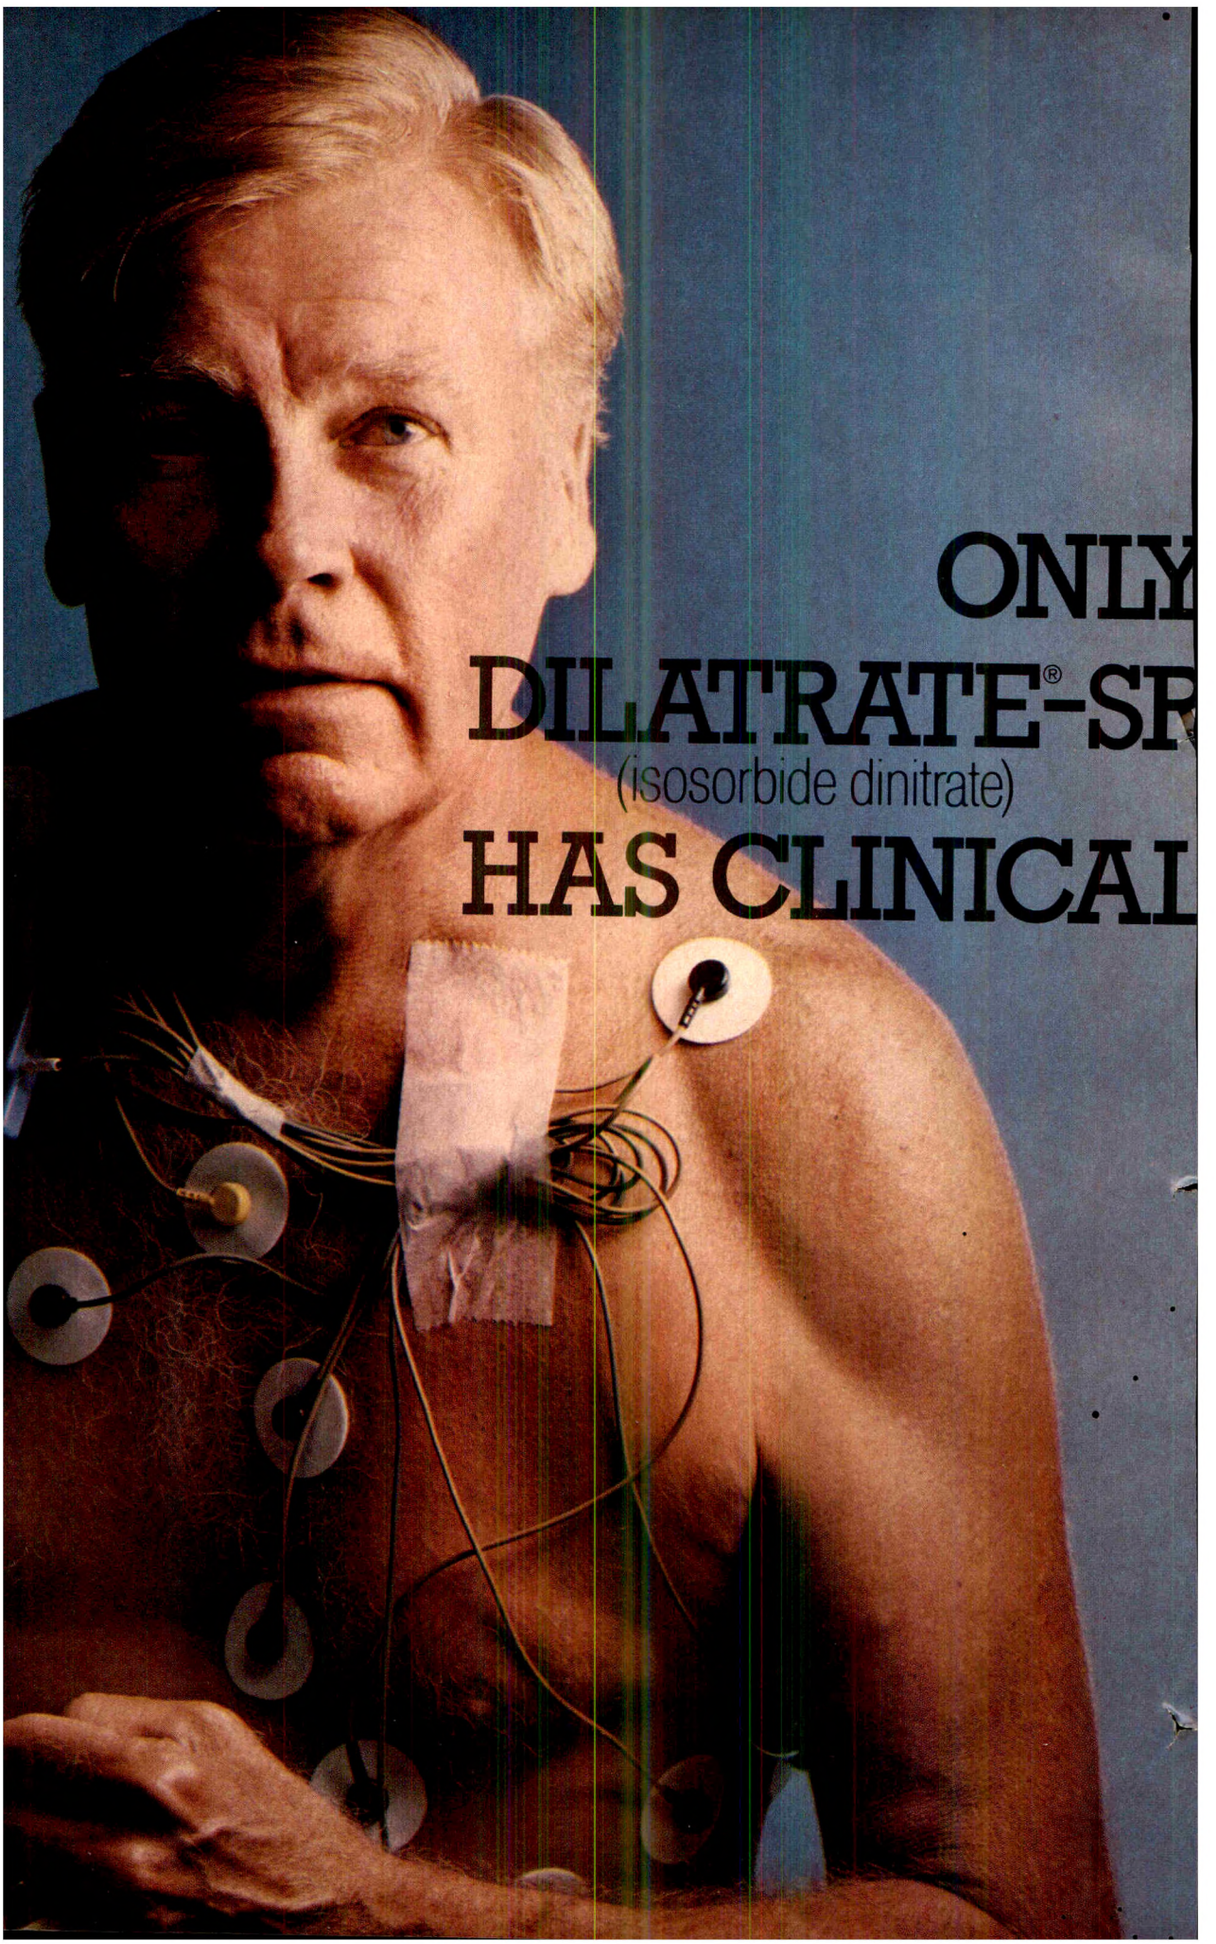
### Magnification of key data segments.

With Q-Scan, you have the option of taking a closer look at critical time periods. Simply choose the time you'd like to examine. Q-Scan will automatically expand and print those segments. Or, you can evaluate the trace full-size on standard ECG paper, using the optional chart recorder.

For your convenience, Q-Scan also has an optional Arrythmia Detection Program. It gives you an hour by hour summary of abnormal beats and average heart-rate in a simple-to-read report. Abnormal beats are counted and classified in premature and wide, premature and narrow, and couplet, run and non-classified categories.

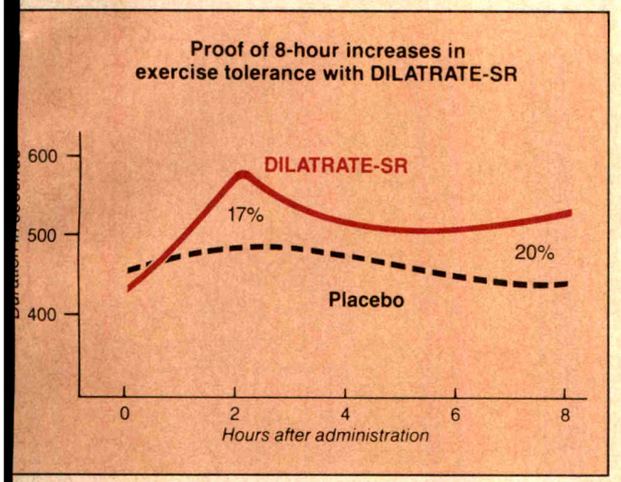
## INTRODUCING THE HOLTER SYSTEM THAT NEVER MISSES A BEAT.

### Hospital proficiency. Office economy.



With Q-Scan, you can generate top quality diagnostic information right in your office—without special staffing or training. Q-Scan is simple to use. And priced to be affordable for almost any practice. With a lower cost per test than outside services.

Most important, Q-Scan is manufactured with the same quality and dependability that's made Quinton the leader in cardiac electronics.



***For information on Q-Scan or Quinton's Q family of products, call or write Quinton Instrument Company, Cardio Fitness Division, 2121 Terry Avenue, Seattle, Washington, 98121, 1-800-426-0347, Telex 328840. Distributed worldwide.***

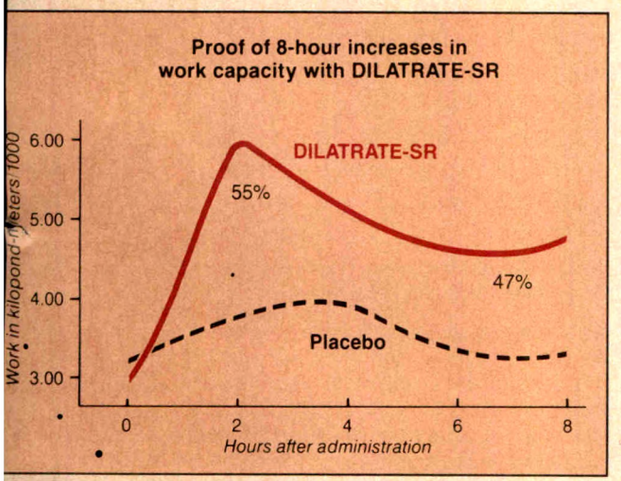
ONLY
DILATRATE®-SR
(isosorbide dinitrate)
HAS CLINICAL

eadmill tests, DILATRATE-SR produced a 17% ease in mean total exercise duration within 2 hours; 8 hours the increase was 20%.

### *Exercise duration and work capacity increased for a full 8 hours in angina patients**

In a double-blind, placebo-controlled study involving patients with chronic stable angina, significant improvement in exercise capacity was sustained for eight hours following administration of one 40 mg DILATRATE-SR capsule.[1]

This is the first study to demonstrate that a sustained-release nitrate formula can provide clinical effectiveness for a full eight hours. And, the advantage over placebo did not appear to be decreasing at the end of eight hours.



### *Increases in exercise tolerance translate into true patient benefits*

Exercise tolerance tests provide objective measurements of improvement in work capacity that can be correlated with the anginal patient's daily activities. These results demonstrate that DILATRATE-SR can provide a positive impact on your patient's lifestyle.

### *Clinical support of plasma level studies*

This clinical study supports previous blood assays which demonstrated that DILATRATE-SR provides significant plasma levels of ISDN for up to 12 hours.[2]

# PROOF: 8-hour antianginal activity*

20% increase in duration of treadmill exercise means other minute or two at higher speed on a steeper line. When mean work performance was calculated, LATRATE-SR provided a 47% increase at 8 hours.

### *A unique method of delivering isosorbide dinitrate*

DILATRATE-SR employs a unique delivery system — an advanced microdialyzing membrane that releases ISDN at a steady rate independent of gastric pH and enzymes. The water-activated membrane continually adjusts permeability to maintain constant nitrate release.

### *DILATRATE-SR simplifies antianginal therapy*

The proven sustained activity of DILATRATE-SR offers anginal patients convenient b.i.d. dosage and can reduce the need for sublingual nitroglycerin.

*Please see brief summary of full prescribing information on following page. For full prescribing information, consult package insert.

2. Dinsdale J, Allen J: Data on file, Medical Department, Reed & Carnrick.

# Dilatrate®-SR
## (isosorbide dinitrate) 40 mg

Reed & Carnrick / Piscataway, New Jersey 08854

# Dilatrate®-SR
## (isosorbide dinitrate) 40 mg

**BRIEF SUMMARY**

Indications: Based on a review of this drug by the National Academy of Sciences – National Research Council and/or other information, FDA has classified the indications as follows:

"Possibly" effective: When taken by the oral route, is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indication requires further investigation.

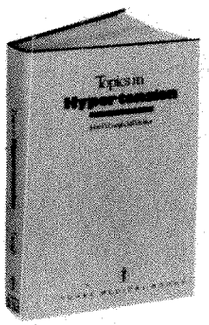
**CONTRAINDICATION:** Idiosyncrasy to this drug.

**WARNINGS:** Data supporting the use of nitrates and nitrites during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

**PRECAUTIONS:** Tolerance to this drug, and cross-tolerance to other nitrates or nitrites may occur.

In patients with functional or organic gastrointestinal hypermotility or malabsorption syndrome it is suggested that either the 5 mg. or 10 mg. oral tablets or 2.5 mg. or 5 mg. sublingual tablets be the preferred therapy.

**ADVERSE REACTIONS:** Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents.



An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

For full prescribing information, consult package insert.

Reed & Carnrick / Piscataway, New Jersey 08854

*Laragh's eagerly awaited new book on the silent killer*

# TOPICS IN HYPERTENSION

Edited by

**John H. Laragh, MD**

*Master Professor of Medicine*
*Director, The Cardiovascular Center Chief, Cardiology Division The New York Hospital-Cornell Medical Center*

**644 pages. 36 chapters by 85 internationally known specialists. Illustrated. Comprehensively indexed. $49.00. Available on 30-day approval.**

High blood pressure is no longer only a problem of worldwide interest and relevance. It is now one in which the knowledge base has exploded to the point where the informed physician can do more and more about it in his daily practice...and can apply, to an ever-increasing extent, more sophisticated and individually tailored therapies.

Laragh's TOPICS IN HYPERTENSION places this kind of vital knowledge within instant reach of the physician. It presents a carefully selected array of discussions. It deals in depth with recent breakthroughs in understanding, diagnosing, and treating this problem.

This book is conveniently organized for effective consultation and reading:

- **Section 1** considers recently maturing biochemical and pathophysiologic aspects of the problem.
- **Section 2** deals with new physiologic approaches to diagnosis.
- **Section 3** discusses new perceptions of the clinical and prognostic aspects of hypertension.
- **Section 4** considers in detail the more recently introduced modes of therapy. These new agents presage the beginning of a new era of more selective and specific therapy for increasing numbers of patients.

**YORKE MEDICAL BOOKS** AJC©3

Box C-757, Brooklyn, New York 11205

Send me, on approval, _____ copies of Laragh's TOPICS IN HYPERTENSION at $49.00. I will consult and read this new manual for 30 days, then remit only if I consider it a necessary addition to my library. Otherwise I will return it without further obligation.

# In Holter studies, one system gives you the data you're used to getting

## ...in your hands...in your office ...in minutes. Without a specially trained operator.

THE LOGICAL ALTERNATIVE

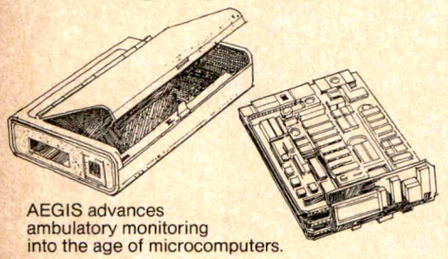
AEGIS™

*Ambulatory Monitoring System*

A123

**Minutes after your Holter patient returns,**

# AEGIS™ gives you the same clinical information as a scanning service...

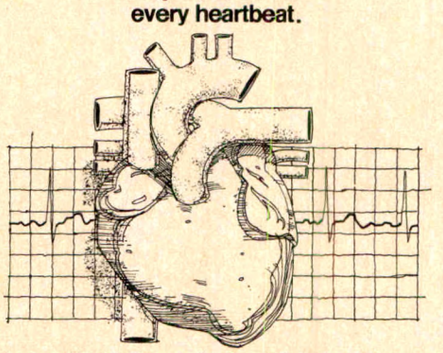


# ...with none of the drawbacks.

Although scanning services are well established, they do have their drawbacks. The first is turnaround time. It's not unusual for two, three or even four days to pass before you receive a report on your Holter patient. Then you'll pay a hefty charge for this time consuming service.

What's even more critical, some physicians question the consistency of the reports they receive from scanning services... with good reason. The high speed at which scanners operate has made it difficult to incorporate sensitive enough computer recognition criteria at an affordable cost.

Compounding the problem is technician fatigue. Since a technician normally scans a number of Holter tapes at one sitting, significant data may be missed. And since technician capabilities vary from person to person, the doctor receiving a report has no way of knowing just how reliable the report is or is not.



### Now the new technology of microcomputers does the work of the technician and scanner right in your office.

AEGIS advances ambulatory monitoring into the age of microcomputers.

After more than six years of development and rigorous clinical evaluation, AEGIS advances ambulatory monitoring and reporting into the age of microcircuity and sophisticated computers. Now both the recording and analyzing activities are combined into one compact unit that analyzes, counts and categorizes arrhythmias as they occur. Because analysis occurs in real time, the inefficient high-speed scanner and the fatigue-prone technician can now be replaced by a real time analyzer and an automatic, consistently reliable playback unit that prints out rhythm strips as well as summation and categorization reports...in your office...within minutes after your Holter patient returns. AEGIS does all this without a specially trained operator.

### Analyzes each and every heartbeat.

Real time analysis of each heartbeat.

Unlike traditional Holter monitoring equipment, AEGIS *does not analyze a recording* of your patient's heartbeat, nor does it rely upon visual identification of condensed rhythm strips. Rather, AEGIS analyzes each heartbeat as it occurs. No scanning service or human eye can practically match AEGIS in consistency and speed.

Here's how it works. AEGIS automatically establishes a "normal" reference for each patient, then compares each heartbeat to the normal pattern, looks for deviations in rate, rhythm and morphology, distinguishes each arrhythmia, and performs highly refined classification decisions. All of this data, analyzed in real time, is stored on an integral digital tape.

Because the microcomputer works in real time, it is able to apply many more computer cycles in its decision making than those computers used with high-speed Holter scanners.

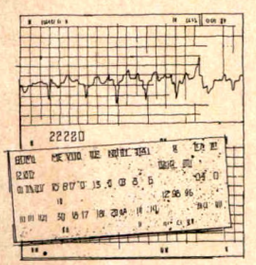
### Compares against what's abnormal for each individual patient...not against some "universal norm."

AEGIS recognizes that no two patients are exactly alike. In order to analyze deviations more accurately, the AEGIS microprocessor automatically establishes the "normal" reference for each patient. The sophisticated computer program used for this function can find and reference a patient's "normal" beat in less than two minutes. Furthermore, it has been proven that AEGIS can establish a "normal" reference under a variety of difficult conditions such as chronic bigeminy, atrial fibrillation and bundle branch block.

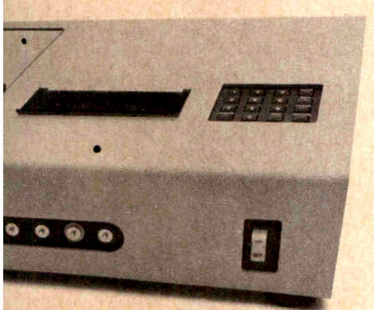
In addition, the "normal" reference is continually updated throughout the analysis period to account for changes in the position of the heart due to body movement and changes in the patient's position.

### Puts the control of evaluating Holter studies directly into your hands.

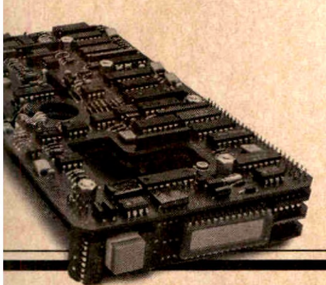
AEGIS gives you *both* a rhythm strip along with a summary report for your confirmation. The rhythm strip is a two-channel electrocardiogram with the time and classification of the recording and the specific lead processed printed right



on the rhythm strip for easy reference.



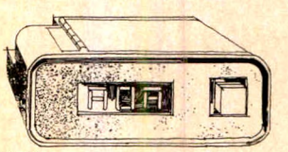
The printed report summarizes the frequency and classification of arrhythmias, as well as heart rate information for each one hour or quarter hour increment of the 24-hour monitoring period. It also calls out specific morphologies that require your review.



Since rhythm strip and summary report are both time-stamped, it's easy for you to compare both documents and verify the data. Together, the strip chart and summary report provide you with all the visual and quantitative data you need to make an in-depth diagnosis.

In addition, the rhythm strip record and summary report can be used as a basis for comparison with follow-up rhythm strips and reports in order to determine patient progress and to evaluate methods of treatment.

Rhythm strip and summary report for your confirmation. Highlights morphologies requiring your review.



**Review results at your convenience or begin treatment immediately when it's called for.**

No need to wait days for Holter results.

The AEGIS System gives you all the data you need to make a sound diagnosis right in your office. Instead of waiting a day or more for results, you get them when you need them—a most important plus when dealing with patients for whom further diagnostic testing is suspected or must be scheduled. In short, you fit the AEGIS System to your schedule.

**The system validates itself—no need for repeat studies due to "lost" data or faulty equipment.**

LED display alerts you to system or procedure problems.

AEGIS overcomes the problems of interference or artifacts overcoming accurate analysis. AEGIS automatically senses when artifacts are overwhelming the usefulness of information, and switches to the other lead signal for processing. Thus, there's no need for retakes due to artifacts.

In addition, self-diagnostic checks are built into the Real Time Analyzer and the Report Generator so you can verify all system operations from patient hook-up to report generation. No more invalid studies due to malfunctioning recorders, weak batteries or over-used tapes. AEGIS is the only completely self-validating system.

**No need to hire specially trained operators.**

The AEGIS System is totally self-contained and so easy to use, it requires no dependence on specially trained personnel in or out of your office.

Patient hook-up to the Real Time Analyzer is identical to that of traditional Holter ECG monitoring systems. And the Report Generator is so automatic that once the cassette tape is inserted and the printout process is started, it requires no operator attendance.

**Takes up no more space than a desk-top copier.**

The AEGIS System fits easily into any office practice. The Real Time Analyzer is approximately the same size as other ambulatory monitoring units and the compact Report Generator requires only about four square feet of counter space.

AEGIS is protected against obsolescence, too. As new software developments and technological advances are made, the AEGIS System can be inexpensively updated.

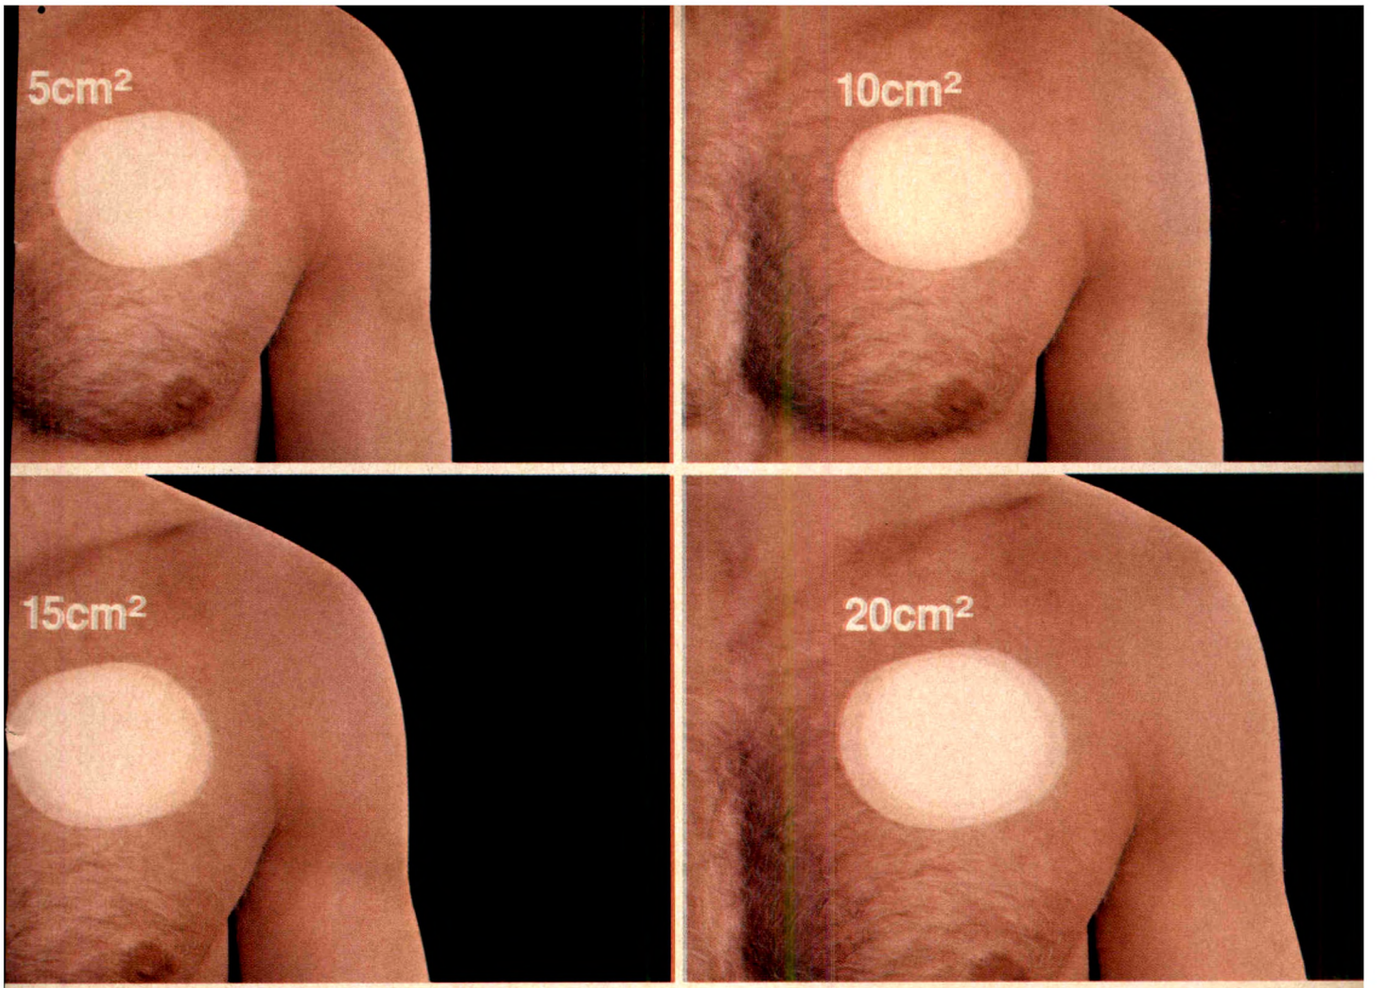
Fits compactly into any office.

# In Holter studies, one system gives you the data you're used to getting

## ...in your hands...in your office ...in minutes. Without a specially trained operator.

- Provides the same clinical information as a scanning service—with none of the drawbacks.
- Replaces the high-speed scanner and technician—brings those activities into your office. More convenient. More efficient.
- Analyzes each heartbeat as it occurs; counts and categorizes arrhythmias in real time.

- Puts the control of evaluating Holter studies directly into your hands. Provides time-stamped rhythm strip and summary report for your confirmation.
- System validates itself—no need for repeat studies due to "lost" data or faulty equipment.
- Fits easily into any office.



**For a 15-minute, no obligation demonstration of AEGIS in your office, call toll-free: 800-257-5750**

AEGIS™

*Ambulatory Monitoring System*

**MEDICAL CONCEPTS, Inc.**
137 Gaither Drive
Mt. Laurel, New Jersey 08054

# Two added strengths for ease of titration.

## The new 5 cm² size.

Nitro-Dur™ (nitroglycerin) is the only transdermal nitroglycerin with four dosage strengths—5, 10, 15 and 20 cm² (approximately 2.5 mg, 5 mg, 7.5 mg and 10 mg released in 24 hours), permitting titration in increments of 5 cm². This gives Nitro-Dur greater dosage flexibility than any other form of transdermal nitroglycerin.

Nitro-Dur also has a sophisticated product design which includes a wide, microporous adhesive strip. The strip insures firm matrix-to-skin contact and helps keep the system sealed and in place.

Greater dosage flexibility and better adhesion. Two reasons why Nitro-Dur is the most widely prescribed transdermal nitroglycerin system.

# Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

## The most widely prescribed transdermal nitroglycerin system.

Please see next page for a summary of prescribing information.

# Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

## The most widely prescribed transdermal nitroglycerin system.

**DESCRIPTION:** The Nitro-Dur Transdermal Infusion System contains nitroglycerin in a gel-like matrix composed of glycerin, water (purified), lactose, polyvinyl alcohol, povidone and sodium citrate to provide a continuous source of the active ingredient. Nitro-Dur is available in dosage sizes 5cm², 10cm², 15cm² and 20cm², containing 26 mg, 51 mg, 77 mg and 104 mg of nitroglycerin, respectively, thereby providing precise dosing levels of nitroglycerin. Nitro-Dur has a rated release *in vivo* of approximately 0.5mg/cm²/24 hours. Each unit is sealed in a polyester-foil-polyethylene laminate. The bandage portion consists of a medical grade non-woven, heat sealable, microporous tape.

**CLINICAL PHARMACOLOGY:** When the Nitro-Dur system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In bioavailability studies,[1] transdermal absorption of nitroglycerin from the gel-like matrix achieved steady state venous plasma levels comparable to that of sublingual nitroglycerin and maintained these levels for 24 hours. Therapeutic effect is achieved within 30 minutes after application of the unit, and persists about 30 minutes after removal of the unit.

**INDICATIONS AND USAGE:** Prevention and treatment of angina pectoris due to coronary artery disease.

**CONTRAINDICATIONS:** Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

**WARNINGS:** The Nitro-Dur system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of angina patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

**PRECAUTIONS:** Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced.

Nitro-Dur is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

**ADVERSE REACTIONS:** Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing Nitro-Dur therapy. If headache persists, the Nitro-Dur dosage should be reduced.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the Nitro-Dur dosage should be reduced or use of the product discontinued.

**HOW SUPPLIED:** Nitro-Dur Transdermal Infusion System, 5cm², 10cm², 15cm² and 20cm², is available in unit dose packages of 28.

**CAUTION:** Federal law prohibits dispensing without a prescription.

**PATIENT INSTRUCTIONS FOR APPLICATION:** Patient instructions are furnished with each unit dose package.

*For complete prescribing information, please see package insert.*

# Cardiac Bioprostheses

**Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982**

**edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD**
**ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00**

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

## Who are the editors?

**Lawrence H. Cohn, MD,** is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982*.

**Vincenzo Gallucci, MD,** is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

# Vulnerability of Patients With Obstructive Hypertrophic Cardiomyopathy to Ventricular Arrhythmia Induction In the Operating Room

## Analysis of 17 Patients

KELLEY P. ANDERSON, MD, EDWARD B. STINSON, MD, GERALDINE C. DERBY, RN, PHILIP E. OYER, MD, and JAY W. MASON, MD

**To evaluate vulnerability to ventricular arrhythmia induction, programmed electrical stimulation was performed in the operating room in 17 consecutive patients undergoing myotomy-myectomy for obstructive hypertrophic cardiomyopathy (HC). A control group of 5 patients undergoing coronary artery bypass grafting with normal left ventricular function and no previous myocardial infarction also was tested. Of the 17 patients with HC, 14 had inducible sustained ventricular tachycardia (VT) or ventricular fibrillation (VF), 1 had inducible unsustained VT and the remaining 2 had <6 ventricular beats. In contrast, none of the 5 control patients had an inducible sustained ventricular arrhythmia, 1 had inducible unsustained VT, and the remaining 4 had <3 ventricular beats. The difference between the 2 groups with respect to induction of a sustained ventricular arrhythmia, unsustained VT or <6 ventricular beats was significant ($p < 0.001$). It is concluded that patients with severe obstructive HC are unusually vulnerable to ventricular arrhythmia induction. This suggests that spontaneous ventricular tachyarrhythmias may be an important cause of sudden death in patients with HC.**

Death in patients with hypertrophic cardiomyopathy (HC) is usually sudden,[1,2] but the mechanism is uncertain in most cases. Ventricular tachyarrhythmias are a prominent etiologic possibility; unsustained ventricular tachycardia (VT) detected on ambulatory electrocardiography has been associated with subsequent sudden death or cardiac arrest.[3–6] Programmed electrical stimulation of the heart has been used to diagnose and treat arrhythmias in patients with syncope or cardiac arrest of unknown cause.[7–9] No systematic study of arrhythmia induction in patients with HC has been reported. We performed programmed electrical stimulation in the operating room in patients undergoing myotomy-myectomy for obstructive HC in order to safely evaluate their vulnerability to ventricular arrhythmia induction. We compared findings in these patients with those in a control group without HC.

From the Cardiac Arrhythmia Study Unit and the Department of Cardiovascular Surgery, Stanford University School of Medicine, Stanford, California. Dr. Anderson is Research Fellow of the American Heart Association, California Affiliate, Burlingame, California. Dr. Mason is an Established Investigator of American Heart Association, Dallas, Texas. Manuscript received September 23, 1982; revised manuscript received and accepted November 12, 1982.

### Methods

The study group consisted of 17 consecutive patients who underwent myotomy-myectomy for obstructive HC at Stanford University Hospital between January 1, 1981 and June 1, 1982. The diagnosis was based on typical clinical characteristics[10] and on at least 2 of the following echocardiographic and hemodynamic features: a ventricular septal to left ventricular posterior free wall thickness ratio ≥1.3, systolic anterior motion of the anterior leaflet of the mitral valve, a pressure gradient at rest across the left ventricular outflow tract ≥30 mm Hg, and a provocable left ventricular outflow tract gradient ≥60 mm Hg. The diagnosis was supported at the time of operation by the presence of a hypertrophic septal ridge and a septal endocardial plaque in all patients. The presence or absence of myocardial fiber disarray was noted during pathologic examination of the resected septal tissue. Other causes of myocardial hyertrophy and left ventricular outflow obstruction were excluded by preoperative evaluation and intraoperative inspection.

The control group consisted of 5 patients who underwent coronary artery bypass grafting during the same time period. Those patients fulfilled the following criteria: normal elec-

trocardiogram at rest, normal left ventricular angiogram, no history of myocardial infarction or ventricular arrhythmias, no family history of sudden death or hypertrophic cardiomyopathy, and no evidence of valvular disease. The protocol was approved by the Standard University Medical Committee for Human Subjects in Research and informed written consent was obtained.

The patients were maintained on their chronically prescribed medications until operation. The patients were premedicated with scopolamine and diazepam or morphine sulfate, or all 3. Pancuronium bromide was the muscle relaxant used in all cases. Fentanyl or hydromorphone hydrochloride was used for general anesthesia. When necessary, a volatile agent (enflurane, halothane, or isoflurane) was added. The heart was exposed using a midline sternotomy and the formation of a pericardial cradle. After systemic heparinization the superior and inferior venae cavae were cannulated through the lateral right atrium. The distal ascending aorta was cannulated and appropriate connections to the pump oxygenator were made. A quadripolar electrode plaque was sutured to the anterior right ventricular epicardium. An Electronics for Medicine VR16 and an Ampex PR2200 were used for continuous display and recording of the epicardial electrograms and 6 surface electrocardiograms. A WPI programable stimulator was used to deliver rectangular pulses with a duration of 2 ms and current 2 to 4 times diastolic threshold. Stimulation was performed before the initiation of cardiopulmonary bypass.

An identical stimulation protocol was used for all patients. The steps described were followed until a tachyarrhythmia was induced. A single ventricular extrastimulus ($V_2$) was placed in late diastole after every eighth spontaneous beat and brought closer by 20 ms decrements until the refractory period of the spontaneous beat was reached. With $V_2$ just outside the refractory period of the spontaneous beat, a second ventricular extrastimulus ($V_3$) was applied 360 ms after $V_2$ and brought progressively closer until the refractory period of $V_2$ was reached. Ventricular pacing was then begun at 100 beats/min and a ventricular extrastimulus ($V_2$) placed 360 ms after every eighth ventricular paced beat ($V_1$). The $V_1$-$V_2$ interval was progressively reduced by 20 ms until the $V_2$ stimulus no longer captured the ventricles. The $V_1$-$V_2$ interval was then increased by 10 ms intervals until ventricular capture was obtained to define the right ventricular refractory period during ventricular pacing. The pacing rate was increased to 120, 140, and 150 beats/min. At each rate the $V_1$-$V_2$ interval was decreased until ventricular capture no longer occurred. The pacing rate was then decreased to 100 beats/min, $V_2$ placed just outside the refractory period of $V_1$, and $V_3$ added at about 360 ms after and brought progressively closer to $V_2$. The pacing rate was again increased to 120, 140, and 150 beats/min, and at each rate $V_1$-$V_2$-$V_3$ stimulation was carried out to the minimal obtainable $V_1$-$V_2$ and $V_2$-$V_3$ intervals. The same process was performed with a third ventricular extrastimulus ($V_4$) so that $V_1$-$V_2$-$V_3$-$V_4$ stimulation was carried out at the minimal intervals at each pacing rate. Interstimulus intervals <200 ms were not used. If a ventricular arrhythmia lasting at least 5 seconds was not induced with the foregoing measures, 10 to 20 beat bursts of rapid ventricular pacing were performed beginning at a rate of 200 beats/min, which was progressively increased until 1 to 1 capture of the ventricles was no longer obtained. If a ventricular tachyarrhythmia was not induced the experiment was terminated. In the first 6 study patients the stimulation protocol differed slightly in that a third extrastimulus was applied during the patient's spontaneous rhythm.

When a ventricular arrhythmia lasting at least 5 seconds was induced, normothermic cardiopulmonary bypass was immediately instituted. If the arrhythmia terminated spontaneously during this period (5 patients), reinduction was attempted during circulatory support using the same stimulation program. In 4 additional cases the arrhythmia was terminated by a single countershock and reinduction attempted using the same stimulation program during bypass.

VT was defined as ≥6 consecutive ventricular beats. VT was unsustained if it terminated spontaneously in <15 seconds. Sustained VT lasted >15 seconds. Pleomorphic VT was de-

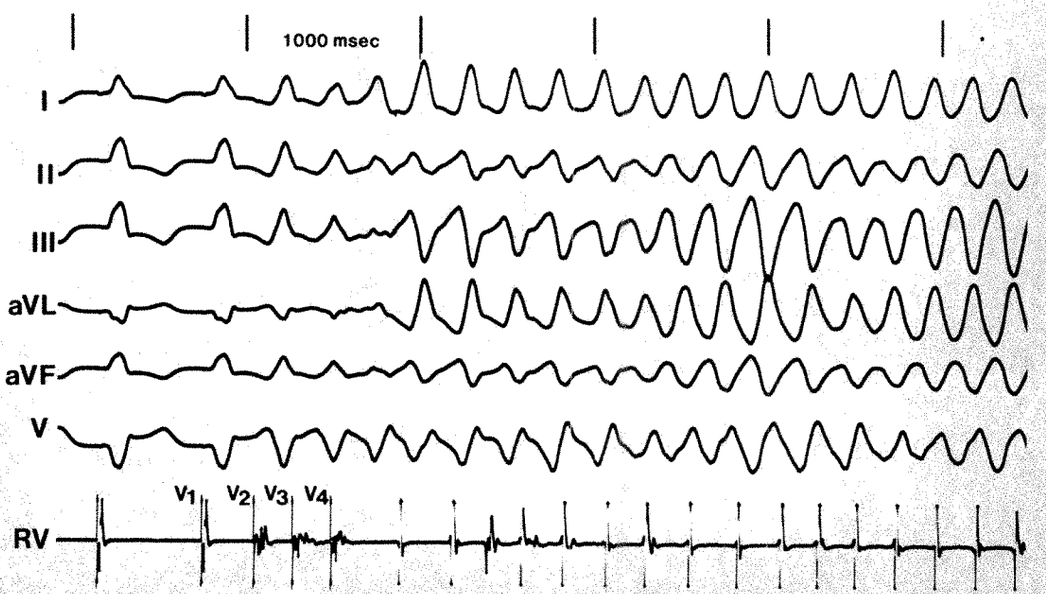

**FIGURE 1.** Pleomorphic ventricular tachycardia. A right ventricular epicardial electrogram (RV) is recorded with 6 surface electrocardiograms, leads I, II, III, aVL, and aVF, and a posterior chest lead (V). Three ventricular extrastimuli ($V_2$, $V_3$, and $V_4$) applied during ventricular pacing ($V_1$) induce ventricular tachycardia with a changing QRS morphology and discrete right ventricular electrograms. The rate averages 250 beats/min.

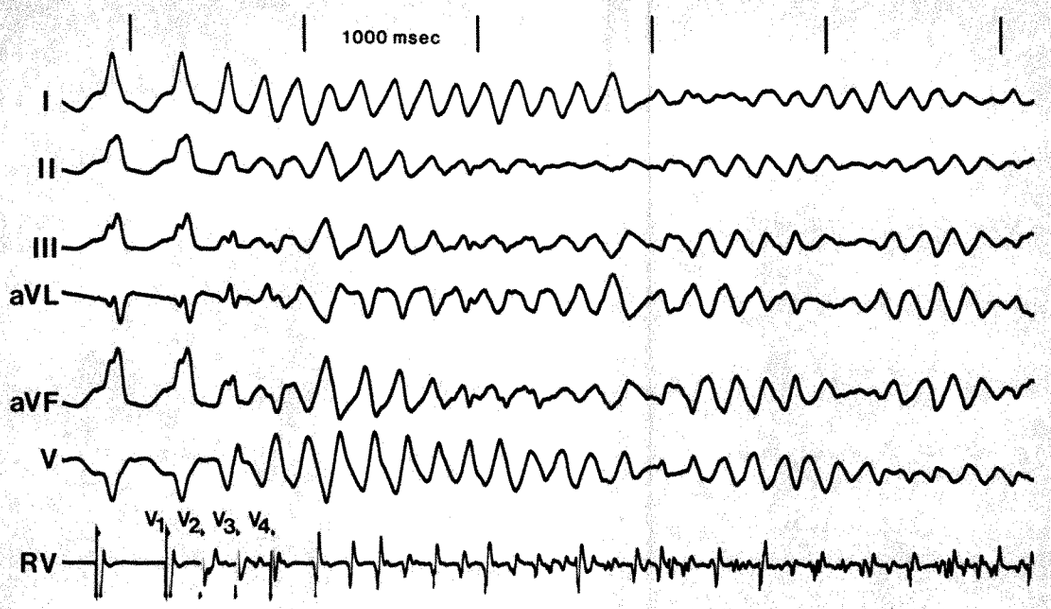

**FIGURE 2.** Ventricular fibrillation. Same leads as in Figure 1. Three ventricular extrastimuli ($V_2$, $V_3$, and $V_4$) applied during ventricular pacing ($V_1$) induced ventricular fibrillation with continuously changing QRS morphology and fragmentation of the right ventricular electrograms. The rate is >300 beats/min. Abbreviations as in Figure 1.

fined as VT with continuously changing QRS morphology, a rate less than 300 beats/min, and discrete right ventricular electrograms (Fig. 1). Ventricular fibrillation (VF) was defined as a ventricular rhythm with continuously changing QRS morphology, a rate ≥300 beats/min, and fragmentation of the right ventricular electrograms (Fig. 2).

Statistical analysis was performed by Mann-Whitney U test and unpaired *t* test.

## Results

Several clinical, echocardiographic, hemodynamic, and pathologic characteristics of the patients with HC are listed in Table I. The group consisted of 6 men and 11 women with a mean age of 46 years. Dyspnea was the most common presenting complaint, followed by chest pain. One patient had suffered a cardiac arrest and 5 others had a history of syncope. All but 2 patients demonstrated systolic anterior motion of the anterior leaflet of the mitral valve. Five of 6 patients who had septal to posterior left ventricular free wall thickness ratios <1.3, had diastolic ventricular septal wall thicknesses >20 mm. A hypertrophic ridge with endocardial fibrosis was noted at operation in all patients. Myocyte

LVOT = left ventricular outflow tract; ND = not done or not measurable; SAM = systolic anterior motion of the anterior mitral valve leaflet. + = present; − = absent.

**TABLE II Ventricular Arrhythmia Induction**

| Induced Ventricular Arrhythmia | Patients (n) With Hypertrophic Cardiomyopathy | Patients (n) With Coronary Disease |
|---|---|---|
| Sustained VT or VF | 14 | 0 |
| Unsustained VT | 2 | 1 |
| Less than 6 VB | 1 | 4 |

VB = ventricular beats; VF = ventricular fibrillation; VT = ventricular tachycardia.

disarray was noted in the resected tissue of 10 of 14 patients. Histologic examination was not performed in 3 patients.

The 5 control patients consisted of 4 men and 1 woman with a mean age of 56 years. The chief complaint was chest pain in all. All had >70% stenoses of the left anterior descending and right coronary arteries, and all but 1 had >70% stenosis of the left circumflex artery or 1 of its major branches.

In 14 of the 17 patients with hypertrophic cardiomyopathy sustained, rapid, pleomorphic VT (9 patients) or VF (5 patients) was induced (Table II). In 3 of these 14 patients a sustained ventricular arrhythmia was induced with 2 ventricular extrastimuli during ventricular pacing. In the remaining 11 patients VT or VF was induced with 3 ventricular extrastimuli during sinus rhythm or ventricular pacing. VF never terminated spontaneously. The rates of pleomorphic VT varied between 210 and 300 beats/min and there was often beat-to-beat cycle length variation. Pleomorphic VT degenerated into VF within 2 to 15 seconds in 5 patients. It lasted 6 to 14 seconds in the other 4 patients but terminated during the initiation of cardiopulmonary bypass. In each case the same stimulation program reapplied during circulatory support produced pleomorphic VT which degenerated into VF.

A sustained ventricular arrhythmia could not be induced in 3 of 17 patients with HC. In 1 of these patients VT lasting 4 seconds was induced. In the other 2 patients <5 consecutive ventricular beats were induced. These 2 patients (Cases 6 and 17, Table I) did not have any clinical, electrocardiographic, echocardiographic, or hemodynamic characteristics that distinguished them from the other patients with HC.

The stimulation protocol failed to induce a sustained ventricular arrhythmia in all of the control patients. A 15 beat run of unsustained VT was induced in 1 patient with a burst of rapid ventricular pacing at a rate of 250 beats/min. No more than 2 ventricular beats were induced in the remaining 4 control patients. The difference in inducibility between the study and control groups was analyzed with respect to the arrhythmia categories as shown in Table II: sustained ventricular tachyarrhythmia, unsustained VT, and <6 ventricular beats. The difference was highly significant ($p < 0.001$) using the Mann-Whitney U test. If the 6 patients with a history of syncope or cardiac arrest are excluded from the study group, the difference is still significant ($p < 0.005$). If the 4 study patients in whom VT terminated during the initiation of bypass are included in the group with unsustained VT the difference is still significant ($p < 0.005$).

There was no significant difference between the right ventricular refractory periods obtained during ventricular pacing at 100 beats/min in 14 patients with HC (mean ± standard deviation 284 ± 25) and the 5 control patients (274 ± 15 ms). There was no significant difference between the refractory periods of 13 patients (12 study and 1 control) with inducible sustained or unsustained VT or VF (280 ± 23 ms) and 6 patients (2 study and 4 control) without inducible VT or VF (283 ± 25 ms). The mean minimal $V_2$-$V_3$ interval obtained in the control patients with no inducible arrhythmia (207 ± 4 ms) was lower than that obtained in the patients with HC who had inducible sustained VT or VF (224 ± 29 ms), but the difference was not significant. The minimal $V_3$-$V_4$ intervals obtained in the control patients (202 ± 4 ms) were significantly lower than those obtained in the study group (218 ± 18 ms, $p < 0.025$) because arrhythmia induction occurred before refractoriness in the study group.

Medications taken within 24 hours before operation in the patients with HC included beta-adrenergic blocking agents in 12, calcium antagonists in 2, a beta-adrenergic blocking agent plus a calcium antagonist in 1, and no medications in 2. One of the patients with coronary artery disease was receiving a calcium antagonist plus a beta-adrenergic blocking agent, and the other 4 were receiving beta-adrenergic blocking agents. There was no association between arrhythmia induction and preoperative medications. Fentanyl was the primary anesthetic agent in 12 patients with HC and 3 patients with coronary artery disease. Hydromorphone hydrochloride was the primary agent in 5 study patients and 2 control patients. Nine patients with HC received supplemental anesthesia with enflurane and 5 with halothane, and 3 received no additional agents. Three of the patients with coronary artery disease received enflurane, 1 received halothane, and 1 received isoflurane. There was no association between anesthetic agents and arrhythmia inducibility.

To evaluate the effect of left ventricular outflow obstruction on arrhythmia inducibility, defibrillation was accomplished in 4 study patients in whom a sustained arrhythmia had been induced and the stimulation program was reapplied during cardiopulmonary bypass, which obviates the hemodynamic effects of obstruction. The arrhythmia was reinduced in each case.

## Discussion

The incidence of sudden death is high in patients with HC, roughly 2%/year.[1,2] It appears to be even higher in younger patients.[1] Sudden death may be the first manifestation of HC in some patients.[11] The mechanism of sudden death is unknown in most cases. Several investigators have suggested that ventricular tachyarrhythmias are the primary cause of sudden death,[1,3] although other potential mechanisms include acutely exacerbated outflow obstruction, reflex vasodilation,[12] acute myocardial infarction,[13] bradyarrhythmias,[14] heart block,[15,16] and supraventricular arrhythmias.[17,18]

VF has been documented in several patients at the time of attempted resuscitation,[2,3,11,19,20] but it has rarely been possible to determine whether VF was the initial event or a terminal phenomenon. In 2 patients with HC and accessory pathways VT, which rapidly degenerated into VF, was the cause of death.[17,21] Longitudinal studies of patients with HC have demonstrated an association between VT (≥3 consecutive ventricular beats) detected on ambulatory monitoring and subsequent sudden death or cardiac arrest.[3,6] The significance of this relation is tempered by the large number of patients with complex ventricular arrhythmias who did not have a catastrophic event. Maron et al[3] and McKenna and Goodwin[22] suggest that VT detected during monitoring may only be a marker of severe disease and that other coexisting variables may be necessary for a short run of consecutive ventricular beats to evolve into a terminal arrhythmia.

The purpose of this investigation was to determine the vulnerability of patients with HC to ventricular arrhythmia induction. The methods were similar to those routinely employed in the management of recurrent VT in our hospital.[23] The study group consisted of patients referred for surgical management of obstructive HC, and all patients were included whether or not previous arrhythmias were suspected. In selecting the control group an effort was made to reduce the potential for inducible arrhythmias by selecting patients with no evidence of myocardial damage.

A ventricular tachyarrhythmia was induced in 88% of the patients with HC and was sustained in all but 1 patient. In 4 study patients the induced arrhythmia terminated within 15 seconds during the initiation of cardiopulmonary bypass. The sudden change in milieu that occurs when the pump prime perfuses the heart and left ventricular afterload and coronary perfusion pressure decrease may have been responsible for the termination of these arrhythmias. Nevertheless, in each case a sustained tachyarrhythmia was induced with the same stimulation program during bypass. None of the control patients had a sustained arrhythmia despite vigorous stimulation. The difference in tachyarrhythmia inducibility between the study and control patients was highly significant despite the small number of control patients. The difference in vulnerability could not be explained on the basis of preoperative medications, which may still have been present in physiologically active concentrations in some patients, or on the basis of differences in anesthetic agents used in the 2 groups.

Several possible explanations for the different responses in the 2 groups exist. It is possible that the patients with HC had myocardial ischemia as a result of ventricular pacing. However, the control patients had critical lesions of at least 2 coronary vessels and could also be expected to have myocardial ischemia. Eight of 9 patients with HC had a sustained arrhythmia induced when the effects of left ventricular outflow obstruction were circumvented by cardiopulmonary bypass. This suggests that the vulnerability to arrhythmia induction is not due to ischemia or an acute effect of outflow obstruction.

A myocardial electrophysiologic abnormality in the patients with HC seems the most likely explanation for their vulnerability to ventricular tachyarrhythmia induction. Other investigators have demonstrated abnormal myocardial electrophysiologic properties in patients with HC.[24,25] Koyanagi et al[26] recently showed an increased incidence of sudden cardiac death in dogs with left ventricular hypertrophy subjected to coronary artery occlusion. Aronson[27] demonstrated triggered automaticity in rat hypertrophic tissue.

The unusual susceptibility to malignant ventricular tachyarrhythmia induction we observed suggests that electrophysiologic testing in some patients with HC may be hazardous. Reports of VF resulting in death during the electrophysiologic evaluation of accessory pathways in 2 patients with HC support this contention.[17,21]

Our patients with HC had symptoms and obstruction severe enough to warrant surgery. Therefore our results may not be applicable to patients with less severe symptoms.

The extension of findings obtained in the operating room to the "normal" awake state requires caution. Also, the significance of inducible ventricular tachyarrhythmias in subjects without previous spontaneous tachyarrhythmias is not fully known. However, tachyarrhythmia inducibility and noninducibility in anesthetized patients has correlated well with previous and subsequent spontaneous ventricular tachyarrhythmias.[28] Furthermore, the inducibility of ventricular tachyarrhythmias has been found to predict future sudden death in patients after infarction without previous tachyarrhythmias.[29,30] Thus, our findings suggest that patients with severe, symptomatic obstructive HC may be unusually vulnerable to spontaneous ventricular tachyarrhythmias.

# Myocardial Texture Characterization by Two-Dimensional Echocardiography

ANIL K. BHANDARI, MD and NAVIN C. NANDA, MD

**Twenty-four normal subjects and 181 patients with various cardiac disorders (36 autopsies) were studied by 2-dimensional echocardiography. In vitro echocardiographic studies were performed on 26 of 36 autopsied hearts utilizing an ultrasonically visible metallic probe to correlate myocardial echo patterns with histopathologic features. All normal subjects and the majority of patients with ventricular hypertrophy due to valvular or hypertensive lesions showed a uniformly speckled or an echolucent appearance of the myocardium (type I texture). No autopsied heart with this texture had gross fibrosis (visible to the naked eye) or infiltrative disease. All patients with infiltrative disorders (amyloidosis, 7 of 7; Pompe's disease, 4 of 4) had multiple, discrete, and small (3 to 5 mm) highly refractile echoes (HREs) in the myocardium involving the ventricle or ventricles completely (type IIA texture) or partly (type IIB texture). However, this finding was nonspecific and was observed in many other conditions such as left heart hypoplastic syndrome (10 of 10), hypertrophic cardiomyopathy (19 of 26), and chronic renal failure (4 of 9). In the noninfiltrative group, HREs in the autopsied cases were shown to result from gross fibrosis or endocardiofibroelastosis utilizing in vitro echocardiographic studies and metallic probe-guided biopsies, while HREs in the autopsied cases with cardiac amyloidosis could be correlated only with amyloid deposits since fibrosis was absent. Larger HREs (>5 mm) presenting as broad patches or long linear echoes in the myocardium (type IIC texture) was seen in old myocardial infarctions (9 of 21) and congestive cardiomyopathy (4 of 26) and were correlated with large areas of myocardial fibrosis. Two-dimensional echocardiographic studies of myocardial texture help identify various infiltrative and degenerative processes in the heart.**

Real-time 2-dimensional echocardiography has assumed an important role in the identification and evaluation of patients with various cardiac disorders.[1,2] Its clinical value has depended to a large extent on changes in the cardiac chamber size, wall thickness, cardiac contractility, and structural alterations in the cardiac valves. Little emphasis has been placed on the echocardiographic evaluation of myocardial texture until recently, when attention was drawn to altered myocardial echo patterns in cardiac amyloidosis[3,4] and idiopathic hypertrophic subaortic stenosis.[5] However, a detailed and systematic 2-dimensional echocardiographic analysis of alterations in the myocardial texture in various myocardial disorders has not been reported so far.

With the use of 2-dimensional echocardiography, we report our findings on the echocardiographic analysis of myocardial texture in 24 normal subjects and 181 patients (36 autopsies) with various cardiac disorders.[6] In addition, in vitro 2-dimensional echocardiographic studies were performed on 26 of 36 autopsied hearts in an attempt to precisely correlate echo patterns with local histopathologic changes.[7]

## Methods

The study population was comprised of 205 randomly selected patients (41 children, 164 adults), all of whom were seen at Strong Memorial Hospital from 1980 to 1982. The clinical and diagnostic profiles of these patients are summarized in Table I. Twenty-four normal subjects had no known disease and had normal findings on physical examination, electrocardiography, and echocardiography. One hundred eighty-one patients had various cardiac disorders which met standard diagnostic criteria. Based on echocardiographic criteria reported previously,[8,9] 55 patients had single or biventricular

**TABLE I Clinical Profile of 205 Patients**

| Disease Category: Patients (n) | Mean Age (yr) | Comments | Autopsy |
|---|---|---|---|
| 1. Normal 24 (19A, 5P) | 28 | No known disease | 2 |
| 2. UVH 55 (40A, 15P) | 43 | 5 BVH (moderate) 44 LVH, 5 RVH (mild 20, moderate 11, severe 18) | 12 |
| 3. CRF 9 (8A, 1P) | 50 | 9 LVH (3 moderate, 6 severe) all on maintenance dialysis | 3 |
| 4. CCM 26 (24A, 2P) | 52 | No valvular or coronary disease | 3 |
| 5. HCM 26 (23A, 3P) | 52 | Resting SAMs and ASH in all | 2 |
| 6. AMI 14 (14A) | 58 | History, cardiac enzymes and electrocardiographic changes in all | ... |
| 7. CMI 21 (20A, 1P) | 60 | | 2 |
| 8. Amyloidosis 7 (7A) | 63 | CHF in all, 5 had systemic biopsy positive for amyloid | 2 |
| 9. Pompe's disease 4 (4P) | 0.5 | CHF and skeletal muscle biopsy in all | ... |
| 10. Hemochromatosis 9 (9A) | 55 | CHF in 1, liver biopsy in all | ... |
| 11. LHH 10 (10P) | Newborn | Systemic hypoperfusion in all | 10 |

A = adult; AMI = acute myocardial infarction; BVH = biventricular hypertrophy; CCM = congestive cardiomyopathy; CHF = congestive heart failure; CMI = chronic myocardial infarction; CRF = chronic renal failure; HCM = hypertrophic cardiomyopathy; LHH = left heart hypoplastic syndrome; P = pediatric; SAM = systolic anterior motion; UVH = uncomplicated single/biventricular hypertrophy.

hypertrophy due to rheumatic heart disease (14 patients), bicuspid or degenerative aortic stenosis (17 patients), hypertensive heart disease (7 patients), and congenital heart disease (17 patients) (uncomplicated ventricular hypertrophy group).

Two-dimensional echocardiography was performed using a commercially available real-time wide angle (90°) mechanical sector scanner and a 3.0 or 5.0 mHz transducer (Advanced Technology Laboratories). Images were recorded on videotapes (Sanyo or Panasonic half-inch tapes) for later analysis in real time or slow motion. Polaroid photographs were made of stop action frame images for illustrations.

Standard echocardiographic examinations were performed with the patient in the supine and/or left lateral decubitus positions.[1,10] The instrumental gain settings were adjusted to obtain optimal images of the myocardial and valvular structures. All patient examinations were done using a 45 dB logarithmic gray scale curve (GSC) which is recommended by the manufacturer for routine echocardiographic studies. This GSC assigns most of the available 8 gray shades to the low

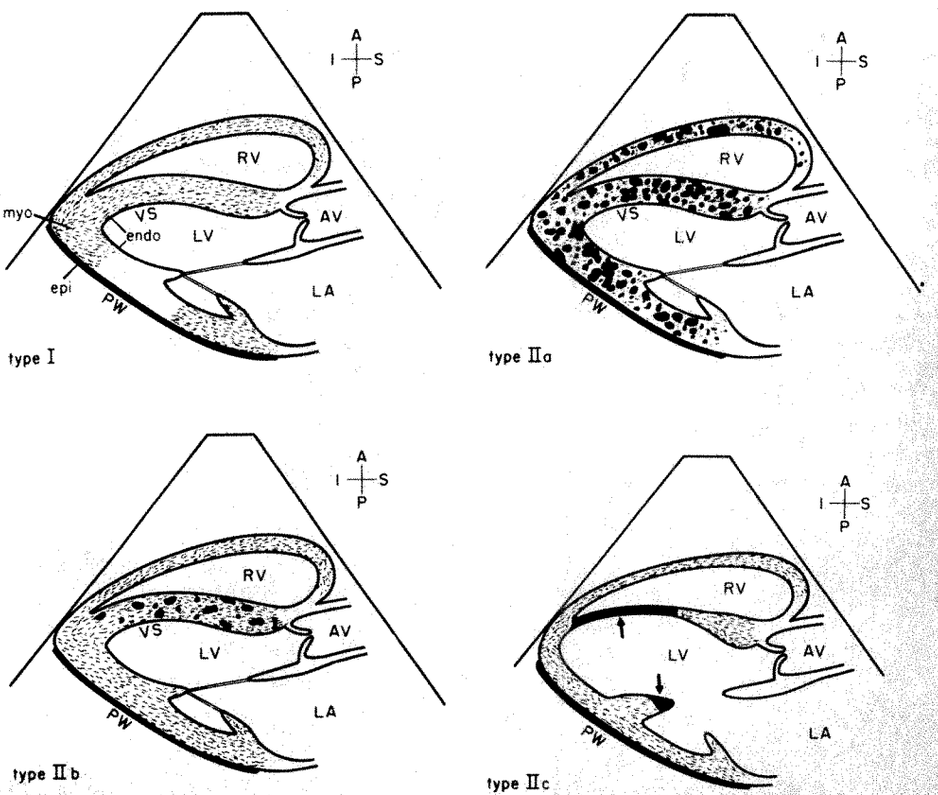

**FIGURE 1.** Schematic representation of the types of myocardial texture. Type I texture is characterized by a fine, speckled, and homogeneous or an echolucent appearance of the myocardium. In both types IIA and IIB texture, multiple, small, and discrete HREs shown as dark areas are seen in the myocardium and are separated from one another by lower-amplitude fine speckled echoes. In type IIA, HREs involve all walls of 1 or both ventricles while only some but not all walls are involved in type IIB texture. Larger HREs presenting as long linear or broad patches (**dark areas**) in the myocardium characterize type IIC texture.

amplitude echosignals for their better differentiation. Additionally, echocardiographic images were also studied using a linear GSC (available in ATL model 850A), which assigns gray shades in a uniform manner regardless of range of echo signal amplitudes. An attempt was made to visualize all walls of both ventricles in each patient by obtaining parasternal long- and short-axis views, apical 4-chamber and 2-chamber views, and subcostal views.

Thirty-six hearts available for postmortem studies were examined in a standard manner. Histopathologic studies were performed on multiple sections obtained routinely from both the ventricular septal and left ventricular posterior walls at the level of the papillary muscles and just below the mitral anulus and on those taken from the areas of discernible disease. Special stains were employed whenever endofibroelastosis and infiltration with amyloid, mucopolysaccharide, or iron were suspected. The cut surfaces of the ventricles were closely inspected for areas of gross fibrosis (visible to the naked eye); these were subsequently confirmed by histologic study. Additionally, histologic sections from multiple sites were carefully examined for the presence of interstitial or perivascular fibrosis.

In vitro 2-dimensional echocardiography was performed by suspending the heart specimens or isolated slices of the ventricular walls to a depth of 4 to 5 cm in a water bath at 22°C.[7] Keeping the transducer at the water surface, multiple echocardiographic views of the suspended hearts—some simulating in vivo long- and short-axis views of the left ventricle, were obtained using 45 dB logarithmic and linear GSCs. A long thin metallic probe which could be ultrasonically imaged was advanced under echo control to identify and penetrate areas of the myocardium giving rise to different echo patterns; biopsies were taken along the probe to precisely correlate echo patterns with histopathology. The contact between the tip of the metallic probe and the myocardium was echocardiographically recognized by "dimpling" and motion of myocardial surface as the probe touched it.

For the purposes of our study, left ventricular hypertrophy was graded based on diastolic left ventricular posterior wall thickness as mild (12 to 15 mm), moderate (16 to 18 mm), or severe (>18 mm). Right ventricular hypertrophy was graded based on diastolic right ventricular diaphragmatic wall thickness as mild (6 to 8 mm), moderate (9 to 10 mm), or severe (>10 mm). Myocardial texture was evaluated in a qualitative fashion by analyzing visual appearances of the amplitude and spatial distribution of echo signals reflected by the myocardium. Particular attention was paid to areas of very bright or highly refractile echoes in the myocardium. Highly refractile echoes were defined as echoes which persisted at gain settings low enough to completely eliminate the adjacent left ventricular/right ventricular endo- or myocardial echoes. Their size, shape, and distribution in the myocardium were studied in multiple echocardiographic planes obtained by different transducer positions and angulations. All echocardiograms were independently reviewed by 2 observers for the presence or absence of HREs and their size and spatial distribution in the myocardium. All histopathologic sections were reviewed by 2 members of the pathology department.

## Results

There was no disagreement in the interpretation of myocardial echo patterns of all patients as studied by 2 independent observers; echo patterns could be classified in 2 broad categories (Fig. 1).

**Type I myocardial texture** was characterized by a fine, speckled, and uniform appearance of the myocardium bordered by a thin linear echo from the endocardium and a bright thick echo from the epicardial-lung interface. The echo signals reflected from the myocardium were of low amplitude and the myocardium often appeared echolucent, especially at low gain settings or when linear GSC was used.

Type I myocardial texture was observed in 133 patients (as shown in Fig. 2) and included all normal subjects, all patients with acute myocardial infarctions, the majority of patients with uncomplicated ventricular hypertrophy (Fig. 3) as well as congestive cardiomyopathy, and some patients with chronic renal failure, systemic hemochromatosis, chronic myocardial infarction, and hypertrophic cardiomyopathy. Postmortem studies available in 15 patients with this texture (2 normal, 9 uncomplicated ventricular hypertrophy, 2 chronic renal failure, 2 congestive cardiomyopathy) demonstrated no gross fibrosis, endocardiofibroelastosis, calcification, or infiltrative pathology involving the ventricular myocardium (Fig. 4). Some patients, however, had microscopic fibrosis in the myocardium.

**Type II myocardial texture** was characterized by the presence of very bright or highly refractile echoes in the myocardium. The visual differences between HREs and the surrounding low amplitude echoes became more prominent when linear rather than 45 dB logarithmic GSC was utilized. Based upon the size, shape, and distribution of HREs in the myocardium, 3 subtypes were recognized as follows (Fig. 1): *Type IIA:* All walls of 1 or both ventricles were involved with multiple, small (3 to 5 mm), and discrete HREs. The

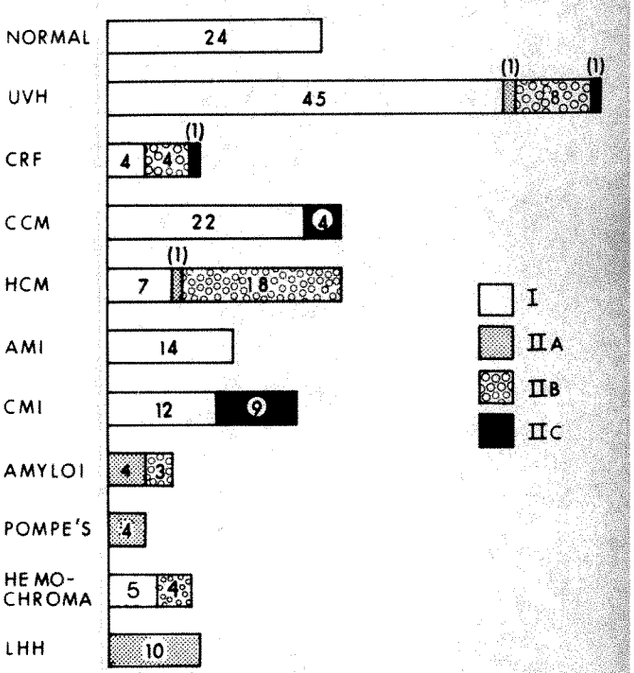

**FIGURE 2.** Types of myocardial texture observed in various disease categories. AMI = acute myocardial infarction; AMYLOI = amyloidosis; CCM = congestive cardiomyopathy; CMI = chronic myocardial infarction; CRF = chronic renal failure; HCM = hypertrophic cardiomyopathy; Hemochroma = hemachromatosis; LHH = left heart hypoplastic syndrome; UVH = uncomplicated ventricular hypertrophy.

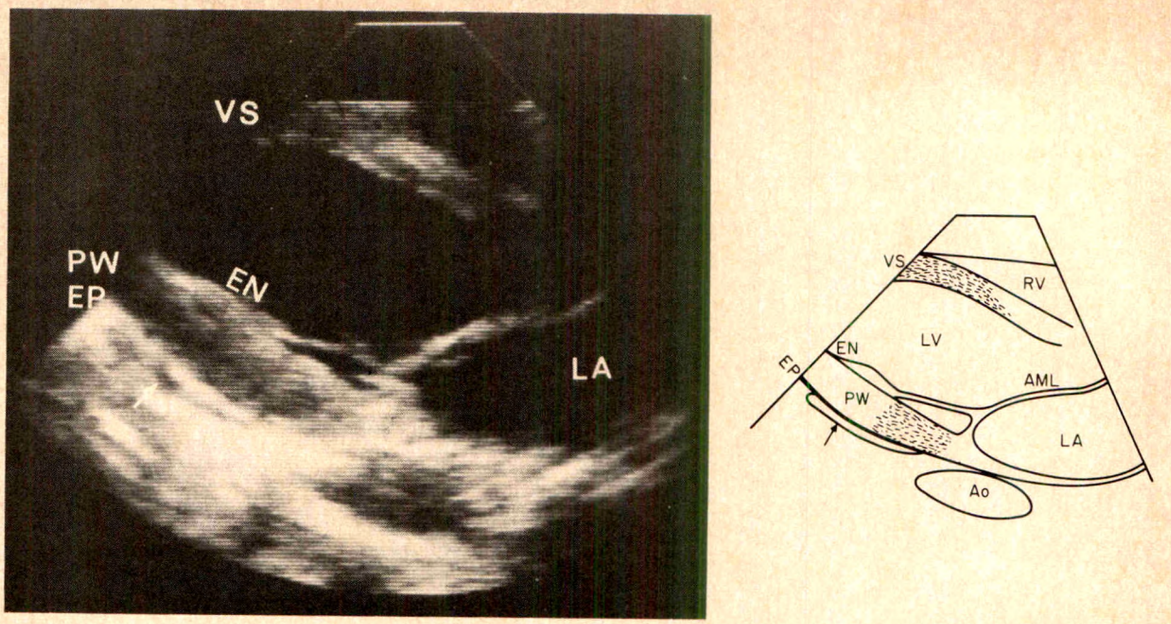

**FIGURE 3.** Type I myocardial texture. Long-axis view of the left ventricle (LV) in a patient with left ventricular hypertrophy demonstrates a fine, speckled, and homogeneous appearance of the septal and posterior wall (PW) myocardium. Bright echoes are absent in the myocardium. The left ventricular posterior wall epicardium (EP) appears thicker and brighter than the endocardium (EN). The **arrow** represents a small posterior pericardial effusion space. AML = anterior mitral leaflet; AO = aorta; LA = left atrium; RV = right ventricle; VS = ventricular septum.

latter were round or irregular in shape and were separated from one another by low amplitude echoes. *Type IIB:* One or more but not all walls of a ventricle or ventricles were involved with multiple HREs of characteristics similar to those in type IIA. *Type IIC:* The whole ventricular wall or a large localized segment (>5 mm) of a ventricular wall presented a very bright or highly refractile appearance. Small and discrete HREs seen in types IIA and IIB were absent.

**Type IIA texture** was observed in 20 patients as shown in Figure 2 and included all patients with

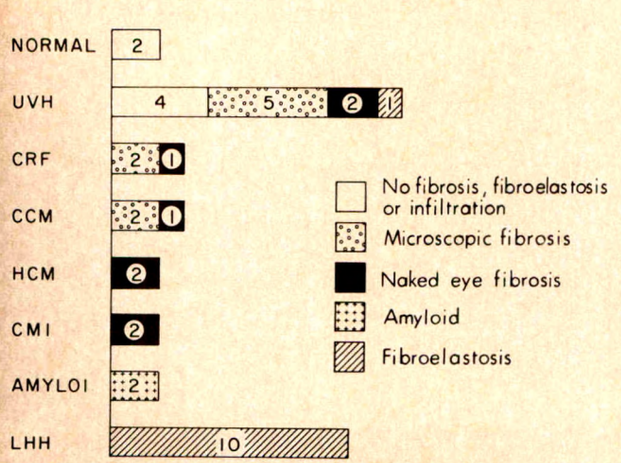

**FIGURE 4.** Histopathologic findings in 36 autopsied patients. AMYLOI = amyloidosis; CCM = congestive cardiomyopathy; CMI = chronic myocardial infarction; CRF = chronic renal failure; HCM = hypertrophic cardiomyopathy; LHH = left heart hypoplastic syndrome; UVH = uncomplicated ventricular hypertrophy.

Pompe's disease, all with left heart hypoplastic syndrome, the majority of patients with cardiac amyloidosis, 1 adult with hypertrophic cardiomyopathy, and an infant with left ventricular hypertrophy secondary to aortic stenosis. In patients with cardiac amyloidosis and Pompe's disease, HREs diffusely involved all walls of both ventricles which were markedly thickened (Fig. 5); all of them had severe congestive heart failure. In other patients with this type of texture, HREs selectively involved left ventricular walls only. Postmortem studies demonstrated severe endofibroelastosis in the left ventricle of all 10 newborns with left heart hypoplastic syndrome and in the infant with left ventricular hypertrophy. Both autopsied patients with amyloidosis had extensive myocardial deposits of amyloid in both ventricles with no associated fibrosis or calcification (Fig. 4.)

**Type IIB texture** was seen in 37 patients as shown in Figure 2 and included the majority of patients with hypertrophic cardiomyopathy and some patients with cardiac amyloidosis, chronic renal failure, systemic hemochromatosis, and uncomplicated ventricular hypertrophy. In patients with hypertrophic cardiomyopathy, HREs were seen in the ventricular septum alone in 15 (Fig. 6) and both ventricular septal and left ventricular posterior walls in 3. In patients with amyloidosis and type IIB texture, HREs were predominantly seen in the ventricular septum or posterior wall, or both, and all of them had moderate ventricular "hypertrophy" and well-compensated congestive heart failure. Postmortem studies available in 3 patients with this texture (2 hypertrophic cardiomyopathy and 1 uncomplicated ventricular hypertrophy) demonstrated discrete areas of gross fibrosis without calcification in the left ven-

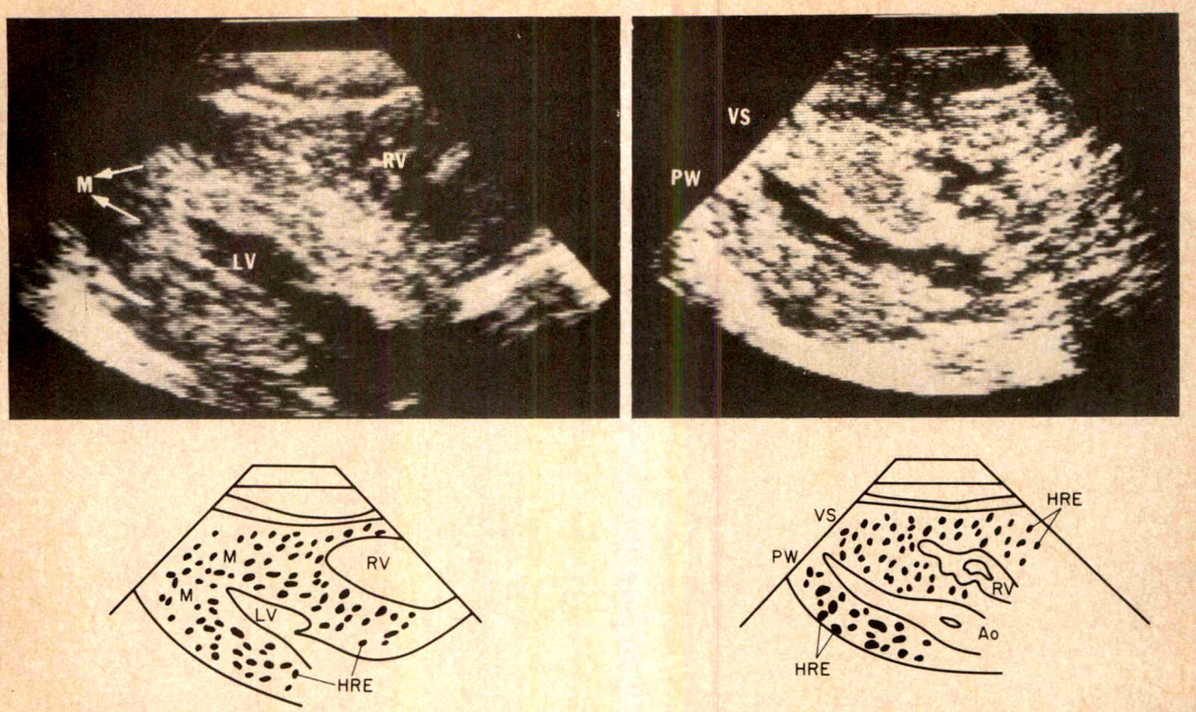

**FIGURE 5.** Type IIA myocardial texture. Subcostal views. Multiple, discrete, and small HREs involve all walls of both ventricles in a patient with cardiac amyloidosis (**left**) and in another patient with Pompe's disease (**right**). The ventricular walls are markedly thickened in both. Ao = aorta; LV = left ventricle; M = myocardium; PW = posterior wall; RV = right ventricle; VS = ventricular septum.

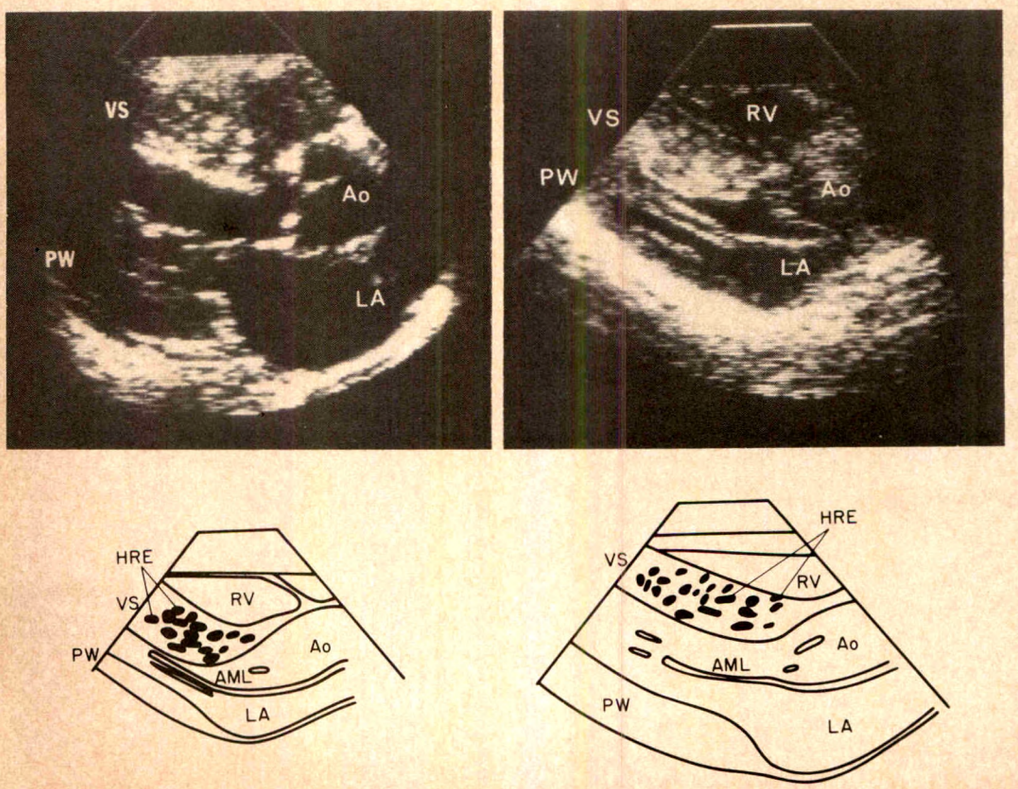

**FIGURE 6.** Type IIB myocardial texture. Long-axis view. Multiple, discrete, and small HREs are seen in the ventricular septum (VS) of a patient with chronic renal failure and concentric left ventricular hypertrophy (**left**) and in another patient with hypertrophic cardiomyopathy and asymmetrical septal hypertrophy (**right**). The left ventricular posterior wall (PW) is uninvolved in both and presents an echolucent (**left**) and fine speckled appearance (**right**). AML = anterior mitral leaflet; Ao = aorta; LA = = left atrium, RV = right ventricle.

tricular myocardium, corresponding in location to those of HREs seen in in vivo echocardiographic studies (Fig. 4).

**Type IIC texture** was observed in 15 patients as shown in Figure 2 and included about half of the patients with chronic myocardial infarction, some patients with congestive cardiomyopathy, an adult patient with chronic-renal failure and an infant with uncomplicated ventricular hypertrophy. Bright long linear echoes (25 to 42 mm long, 4 to 8 mm broad) were visualized in the mid and distal ventricular septum virtually replacing the normal myocardium in 4 of 7 patients with anteroseptal infarcts (Fig. 7). Similar echoes were also noted in the posterior wall in 2 of 6 patients with posteroinferior infarcts and in the anterior wall of 1 of 8 patients with anterolateral infarcts. In 1 patient with congestive cardiomyopathy, bright long linear echoes were seen involving the ventricular septum (44 mm × 5 mm) as well as the left ventricular posterior wall (33 mm × 6 mm) (Fig. 7). The inner third of the papillary muscles as visualized in the left ventricular long-axis view presented a uniformly bright or hyperrefractile appearance in 2 patients with prior myocardial infarction and 3 patients with congestive cardiomyopathy. All of them had systolic mitral regurgitant murmurs suggestive of papillary muscle dysfunction. Another infant with biventricular hypertrophy secondary to double-outlet right ventricle also demonstrated a similar appearance of the papillary muscle. In 1 patient with chronic renal failure, the whole ventricular septum presented a uniformly hyperrefractile appearance which persisted in all echocardiographic views. Postmortem studies available in 5 cases with this type of texture demonstrated areas of large macroscopic fibrosis without calcification involving the myocardium (1 congestive cardiomyopathy, 1 chronic renal failure) or papillary muscles (2 chronic myocardial infarction, 1 double-outlet right ventricle) (Fig. 4).

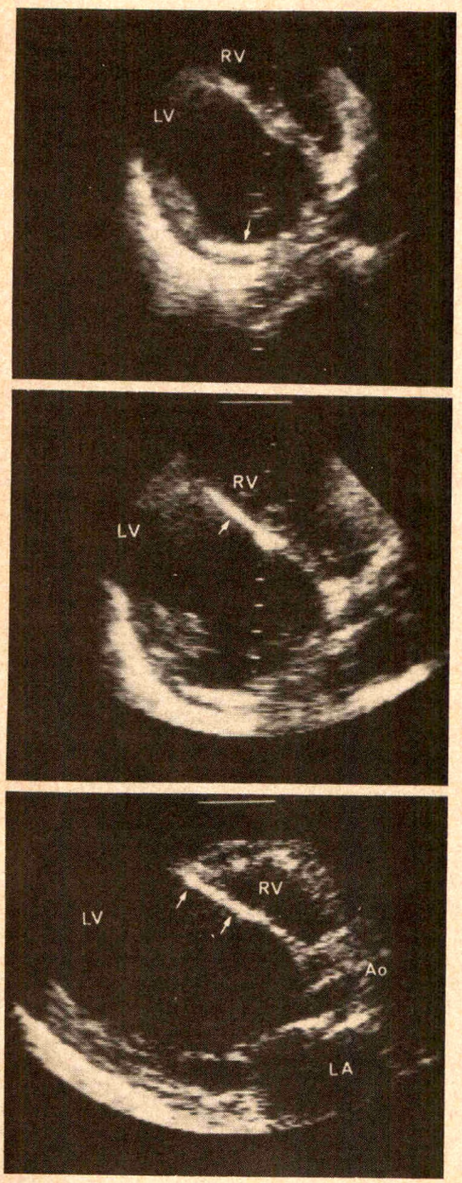

**FIGURE 7.** Type IIC myocardial texture. **Top and middle,** the oblique short-axis views of the left ventricle (LV) in a patient with congestive cardiomyopathy demonstrate very bright, long, linear thick echoes **(single arrows)** in the posterior wall (PW) myocardium and in the ventricular septum (VS), which were shown to be due to gross fibrosis without any calcification at subsequent autopsy. **Bottom,** the distal ventricular septum seen in long-axis view in this patient with old anteroseptal myocardial infarct is virtually replaced by a bright long linear thick echo **(double arrows)** consistent with scar tissue. Other abbreviations as before.

Myocardial echo patterns obtained from in vitro echocardiographic studies performed on 26 hearts were found similar in appearance to in vivo echo patterns in all cases. In vitro 2-dimensional echocardiographic studies were used to correlate areas of ultrasonic hyperreflectivity in the myocardium with histopathologic features by means of metallic probe-guided tissue biopsies. Areas of hyperreflectivity were shown to correlate with amyloid deposits (2 hearts with amyloidosis), endofibroelastosis (2 hearts with left heart hypoplastic syndrome, 1 with aortic stenosis), and naked eye fibrosis (2 hypertrophic cardiomyopathy, 1 chronic renal failure, 1 congestive cardiomyopathy, 1 double-outlet right ventricle, 2 chronic myocardial infarction) (Fig. 8). The remaining 14 hearts (2 normal, 9 uncomplicated ventricular hypertrophy, 2 chronic renal failure, 1 congestive cardiomyopathy) demonstrated a fine, speckled, and uniform appearance with no HREs; none had macroscopic fibrosis, calcification, endofibroelastosis, or infiltrative pathology.

## Discussion

Previous 2-dimensional echocardiographic studies have demonstrated altered myocardial echo patterns in patients with idiopathic hypertrophic subaortic stenosis,[5] cardiac amyloidosis,[3,4] and coronary artery disease.[11,12] Martin et al[5] reported a "ground glass texture" of the proximal ventricular septum in patients with idiopathic hypertrophic subaortic stenosis,[5] but the specificity or etiology of this finding was not determined. Chiaramida et al[4] found "bright patchy echoes" in the myocardium of a patient with cardiac

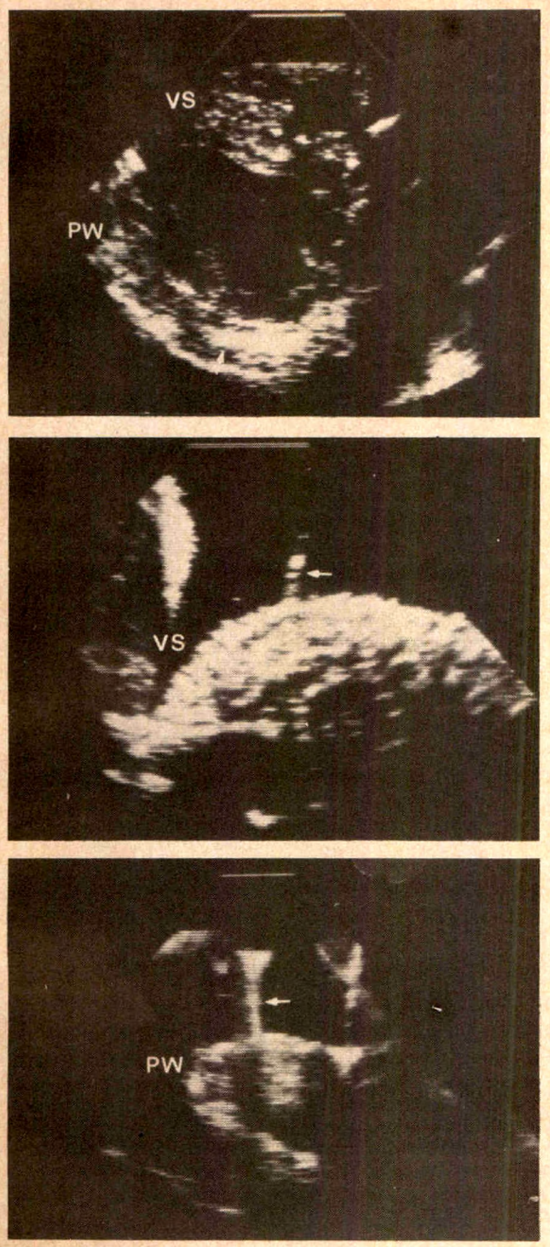

**FIGURE 8.** In vitro echocardiographic studies obtained by immersing parts of or whole heart specimens in a waterbath. **Top,** oblique short-axis examination of a heart specimen from an autopsied patient with congestive cardiomyopathy. The bright, long, linear thick echo (**arrow**) seen in the posterior wall (PW) myocardium (type IIC texture) was shown by a metallic probe-guided biopsy to be due to gross fibrosis. Note the similarities in shape and location of this finding to in vivo studies in this patient (Figure 7, top). **Middle,** in vitro echocardiographic examination of the ventricular septum (VS) obtained from an autopsied patient with cardiac amyloidosis. Note the presence of multiple, small, and discrete HREs within the ventricular septum. The **arrow** demonstrates the ultrasonically visible-probe in contact with the ventricular septal surface. Biopsy samples taken along the probe revealed extensive amyloid deposits without fibrosis or calcification. **Bottom,** In vitro echocardiographic study of the hypertrophied left ventricular posterior wall obtained from an autopsied patient with chronic renal failure. An ultrasonically visible metallic probe (which was advanced under echomonitoring) is seen (**arrow**) at the junction between the relatively bright and the echolucent myocardial areas. Subsequent biopsies showed normal myocardium in the echolucent portion and extensive fibrosis in the bright area.

amyloidosis and considered this finding to be specific for this entity since such a pattern had not been detected by them previously in any other cardiac disorder. Siqueira-Filho et al[3] also described a similar echo pattern in 12 of 13 patients with cardiac amyloidosis. Other workers have described increased echogenicity of the myocardium associated with chronic myocardial infarction[11] and discrete echolucent zones in patients with acute myocardial infarction.[12] Although these preliminary findings are encouraging, their diagnostic significance and clinical applicability remain to be studied.

Our results demonstrate that myocardial texture characterization by 2-dimensional echocardiography is useful in the evaluation of various myocardial disorders. The fine, speckled, and homogeneous, or echolucent appearance of the myocardium without HREs (type I texture) characterizes normal myocardium. Simple hypertrophy of the myocardium does not result in any visually recognizable alteration in the myocardial texture unless there is a severe degree of coexistent fibrosis, endofibroelastosis, or infiltration with amyloid or glycogen. Highly refractile echoes in the myocardium (type II texture) may be observed in a wide variety of myocardial disorders (Fig. 2) and are, therefore, not specific for a single cardiac disease process. However, diffuse and extensive involvement of all walls of 1 or both ventricles with HREs (type IIA texture) was noted in a relatively small number of pediatric and adult conditions, namely left heart hypoplastic syndrome, Pompe's disease, endofibroelastosis associated with left-sided cardiac anomalies, cardiac amyloidosis, and, rarely, hypertrophic cardiomyopathy. The first 3 disorders generally manifest in the newborn or first few years of life and can be distinguished from one another by clinical and other echocardiographic features.[13–15] Patients with hypertrophic cardiomyopathy rarely present with type IIA texture and HREs characteristically involve the left ventricle only. Therefore, the presence of type IIA texture with involvement of both ventricles by HREs in an adult patient would be highly suggestive of cardiac amyloidosis. This finding enabled us to prospectively diagnose cardiac amyloidosis in 2 patients with subsequent confirmation of the diagnosis at autopsy. However, some patients with cardiac amyloidosis, especially those with mild to moderate biventricular hypertrophy and compensated congestive heart failure, demonstrated less generalized involvement of the myocardium with HREs (type IIB texture). The latter texture does not aid in the diagnosis of cardiac amyloidosis since it was observed in many other cardiac disorders such as hypertrophic cardiomyopathy, chronic renal failure, systemic hemochromatosis, and uncomplicated ventricular hypertrophy. (Fig. 2) Bright long linear or broad patch-like echoes (type IIC texture) observed in the myocardium of patients with chronic myocardial infarction and congestive cardiomyopathy represented large areas of gross fibrosis on anatomical correlation. However, all areas of gross fibrosis may not always be identified echocardiographically. Unlike in the ventricular septum and posterior wall, many infarct scars in the anterior and inferior walls of the left ventricle were not identified, probably due to the inability

of echocardiographic tomographic planes to pass through these walls. It would be even more unlikely for standard echocardiographic planes to traverse very small areas of myocardial fibrosis, and this may explain our inability to echocardiographically detect microscopic fibrosis in any patient in this series. Myocardial calcification, though not found in any of our autopsied patients, would also be expected to produce HREs.

Myocardial texture depends on spatial distribution and amplitude of the echo signals reflected from its biologic interfaces.[16-21] Fine, speckled, and homogeneous appearance of the normal myocardium can be explained on the basis of low amplitude echo reflections from various myocardial components such as muscle fibers, capillaries, and collagen strands which present only small differences in acoustic impedances. Also, being irregular in shape and smaller in size than the wave lengths of the ultrasonic beam, they act as diffuse scatterers so that only a small percentage of the incident acoustic energy is returned to the transducer, producing low-amplitude echo signals.[16,19] The markedly bright image from the epicardium-lung interface can be attributed to the enormous acoustic impedance mismatch between heart muscle (1.65 to $1.74 \cdot 10^6$ kg $m^{-2}s^{-1}$)[22] and lung (0.26 to $0.46 \cdot 10^6$ kg $m^{-2}s^{-1}$)[22] and to the specular echo reflections from the relatively large and smooth epicardial surface. The proportional increase in the size of myocardial fibers and the capillary network in simple ventricular hypertrophy[23] would not be expected to significantly alter its acoustic impedance characteristics, and hence hypertrophied myocardium generally presents an echocardiographic appearance similar to that of normal myocardium (Fig. 3).

Fibrosis is well known to give rise to high-amplitude echoes due to marked acoustic impedance mismatch with the adjoining soft tissue.[20,21] This has been shown to be due to the high collagen content of the fibrous tissue.[21] Scar tissue also tends to act as a specular reflector of ultrasound due to its relatively smooth surface and the horizontal orientation of the collagen bundles.[11] Based on pathologic and in vitro echocardiographic studies of autopsied patients in our series, HREs were shown to correlate with areas of naked eye fibrosis in patients with congestive cardiomyopathy, chronic myocardial infarction, chronic renal failure, hypertrophic cardiomyopathy, and uncomplicated ventricular hypertrophy.[24] It is possible that myocardial fiber disarray in hypertrophic cardiomyopathy may be another important contributing factor in the genesis of HREs although neither of our 2 autopsied hearts with this disorder demonstrated fiber disarray in the regions of HREs. Iron deposition in the myocardium of patients with systemic hemochromatosis has been shown to result in reactive or degenerative fibrosis[25] which may explain the occurrence of HREs in this disorder. Endofibroelastosis seen in left heart hypoplastic syndrome and glycogen deposition Pompe's disease[14,15] are associated with considerable increase in collagen and elastin content of the myocardium and may account for the presence of HREs in these disorders. In cardiac amyloidosis, HREs appear to be directly related to amyloid deposits in the myocardium since significant fibrosis or calcification is not associated.[26] HREs may be due to specular reflections from multiple abnormal tissue interfaces produced by large sheet-like deposits of amyloid in the myocardium.

Although ultrasonic properties of myocardial tissue measured in vitro may change depending on time after excision, temperature, and mode of preservatives,[19] we observed no significant differences between in vitro and in vivo myocardial echo patterns. Therefore, it was possible for us to utilize in vitro echocardiographic technique to obtain precise histopathologic correlation of specific myocardial echo patterns. This was achieved by directing a metallic probe under echo monitoring to area of interest and taking tissue biopsies along it. For example, fibrotic areas in the myocardium could be identified as the source of HREs in contrast to the surrounding normal myocardium which gave rise to low-amplitude echoes (Fig. 8).

Certain technical considerations and other limitations need to be emphasized for myocardial texture characterization by echocardiography. Because of the many variable factors, such as the thickness of the chest wall, the depth of cardiac structures from the transducer and their orientation in relation to the ultrasonic beam direction, instrument gain as well as the time gain compensation curve require individual adjustments for examination of any given myocardial wall segment; therefore, routine echocardiographic studies cannot be performed using any fixed gain settings. In our study, instrument gain settings were adjusted in each case so as to obtain an optimal visualization of the endocardium, myocardium, and epicardium. Increases in instrument gain did not result in any significant change in the size of HREs unless gain was so high as to flood the oscilloscope images with noise signals. Since HREs were defined by us as those which persisted at gain settings low enough to completely eliminate the adjacent left ventricular/right ventricular endocardial or myocardial echo signals, echoes which appeared bright only at very high gain settings were automatically excluded from our study. Although we have no experience with other types of commercial echocardiographic instruments which may use different echo signal processing modes, investigators have been able to identify HREs in the myocardium of patients with cardiac amyloidosis[3,4] and idiopathic hypertrophic subaortic stenosis[5] using echocardiographic instruments different from ours. Visual interpretation of myocardial texture is qualitative in nature, but no differences were found in the interpretations of 2 independent observers. Though myocardial tissue characterization has also been attempted by complex quantitative measurements of acoustic properties of the normal and abnormal myocardium,[16,18,27,28] their advantage over qualitative texture characterization has not been shown yet. Since no complex computerized measurements were made in this study, our results show that clinically useful information can be obtained by carefully studying the myocardial texture during routine echocardiographic examinations. The use of multiple GSCs in the characterization of myocardial texture has not been evaluated so far in clinical settings. Although a recent study

has demonstrated the feasibility of combining luminosity modulation and color coding as an alternative to gray scale display,[29] its utility in myocardial texture characterization has not been systematically assessed. Theoretically, the complex interaction of ultrasound with the semirandomly distributed back scatterers in the myocardium can result in the erroneous production of high- or low-amplitude echoes by mechanisms of constructive or destructive interference, respectively.[18] However, this does not introduce any significant errors in qualitative tissue characterization.

In conclusion, myocardial texture characterization by 2-dimensional echocardiography is useful in the evaluation of myocardial infiltrative and degenerative processes and in their differentiation from normal myocardium. Further prospective studies using large numbers of patients and sophisticated equipment with advanced computer techniques for signal processing may permit a more accurate appreciation of tissue-specific echocardiographic patterns.

**Acknowledgment:** We are most grateful to Ian Stuard, MD, Associate Professor Pathology, and David Hicks, fourth year medical student, for assistance with the histopathologic studies. We also appreciate the secretarial assistance of Laurie Leonardi and Jane Wetrich in preparing this manuscript.

# Sensitivity of Technetium-99m–Pyrophosphate Scintigraphy In Diagnosing Cardiac Amyloidosis

RODNEY H. FALK, MB, MRCP (UK), VICTOR W. LEE, MD, ALAN RUBINOW, MD, WILLIAM B. HOOD, Jr., MD, and ALAN S. COHEN, MD

**To determine the value of technetium-99m–pyrophosphate myocardial scintigraphy in the diagnosis of amyloid heart disease this procedure was prospectively performed in 20 consecutive patients with biopsy-proven primary amyloidosis. Eleven patients had echocardiographic abnormalities compatible with amyloid cardiomyopathy, 9 of whom had congestive heart failure. Diffuse myocardial pyrophosphate uptake was of equal or greater intensity than that of the ribs in 9 of the 11 patients with echocardiograms suggestive of amyloidosis, but in only 2 of the 9 with normal echocardiograms, despite abnormal electrocardiograms ($p < 0.01$). Increased wall thickness measured by M-mode echocardiography correlated with myocardial pyrophosphate uptake ($r = 0.68$, $p < 0.01$). None of 10 control patients with nonamyloid, nonischemic heart disease had a strongly positive myocardial pyrophosphate uptake.**

**Thus, myocardial technetium-99m–pyrophosphate scanning is a sensitive and specific test for the diagnosis of cardiac amyloidosis in patients with congestive heart failure of obscure origin. It does not appear to be of value for the early detection of cardiac involvement in patients with known primary amyloidosis without echocardiographic abnormalities.**

Generalized amyloidosis commonly involves the heart and may present as heart failure of obscure origin,[1] sometimes with features suggestive of hypertrophic cardiomyopathy or constrictive pericarditis. Several invasive and noninvasive methods have been described for the diagnosis of cardiac amyloidosis. These include cardiac catheterization,[2,3] M-mode and 2-dimensional echocardiography,[4,5] and combined electrocardiographic and echocardiographic criteria.[6] Although these studies aid in the diagnosis of amyloidosis, the number of patients studied is generally small, some studies were retrospective, and unequivocally diagnostic findings have not been documented. Recently there have been reports of strongly positive technetium pyrophosphate scans in patients with cardiac amyloidosis.[7–9] All of these subjects had advanced cardiac involvement demonstrated by abnormal systolic time intervals, echocardiographic variables, or ejection fraction. Since patients with early or subclinical cardiac involvement were not included, it is not known how early pyrophosphate scans become positive in the course of cardiac amyloidosis. We therefore prospectively evaluated the role of technetium pyrophosphate scintigraphy in patients with primary amyloidosis[10] and varying degrees of cardiac involvement, and were able to further delineate its value in the early diagnosis of myocardial amyloid infiltration.

## Methods

The study population consisted of 20 consecutive patients with amyloidosis (mean age 58.7 ± 8.8 years) admitted to the Thorndike Memorial Laboratory Clinical Research Center of the Boston City Hospital between July 1980 and March 1982 (Table I). All patients had amyloid associated with plasma-cell dyscrasia (AL-amyloid).[10] The diagnosis was confirmed by observing the characteristic green birefringence after Congo red staining of biopsy tissue.[11] The diagnosis of cardiac amyloidosis was made if patients had biopsy-proven amyloidosis in other tissues, cardiac symptoms, and echocardiographic and electrocardiographic features compatible with amyloidosis. These include low voltage on the electrocardiogram (QRS deflection ≤5 mm in any limb lead), cardiac wall thickening on echocardiography in the absence of hypertension, and a "granular sparkling" appearance on 2-

dimensional echocardiography.[4] In 4 patients, cardiac catheterization at the referring center had established the diagnosis of a restrictive cardiomyopathy.

All patients had a complete history and physical examination by a cardiologist (RHF), and a 12-lead electrocardiogram, chest x-ray, and M-mode echocardiogram. Eighteen patients also had a 2-dimensional echocardiogram. All patients underwent a technetium-99m–pyrophosphate whole body scan. M-mode echocardiography was performed with a commercially available instrument (Irex) and recorded with a multichannel strip chart recorder at a paper speed of 50 mm/s. Echocardiographic measurements were made in accordance with the standards of the American Society of Echocardiography.[12] Two-dimensional echocardiography was performed on a Diasonics instrument using standard echocardiographic views. Recordings were made on a Sony videotape recorder. A granular sparkling appearance of left ventricular walls[4] was only diagnosed if it could be seen on a cross-sectional view of the left ventricle at the level of the papillary muscles.

Technetium-99m–pyrophosphate scanning was performed as follows: Fifteen mCi of radiopharmaceutical agent was administered by injection into a peripheral vein. Three hours later examinations were performed using either the Ohio Nuclear Sigma 410 wide field view camera or Raytheon camera II. Images were obtained of the entire skeletal system, either with multiple static scans or by a "moving camera" whole body technique. Whole body scans were obtained after the acquisition of 500,000 counts centered over the anterior chest. Using this preset imaging time, the remainder of the examination was completed. High resolution collimation was used on all studies. Scans were examined by a trained nuclear radiologist (VWL) and cardiac uptake was graded as negative, diffusely positive, or locally positive using the following grading system[13]: 0 = negative scan; 1+ = equivocal uptake by the heart; 2+ = definite uptake, intensity less than ribs; 3+ = intensity equal to ribs but less than sternum; 4+ = intensity equal to or greater than the sternum. Assessment was also made of isotope uptake by other soft tissues which do not normally take up pyrophosphate (for example, liver and spleen). The physician reading the scans was aware of the diagnosis of amyloidosis but was unaware of the clinical status of the patient with respect to specific organ involvement.

On the basis of the history, clinical examination, electrocardiogram, and echocardiogram, patients were divided into the following groups (Table I): Group A—definite symptomatic cardiac involvement (symptoms referable to the heart, abnormal electrocardiogram and echocardiographic findings compatible with amyloidosis, absence of other cardiac disorder sufficient to explain symptoms); Group B—definite asymptomatic cardiac involvement (abnormal electrocardiogram, thickened ventricular walls on echocardiogram, with or without granular sparkling appearance on 2-dimensional echocardiography, with or without abnormal physical findings); Group C—possible asymptomatic cardiac involvement (low voltage electrocardiogram in the absence of echocardiographic abnormalities); and Group D—no cardiac involvement (asymptomatic with normal tests).

**Control subjects:** In order to determine the prevalence of positive pyrophosphate scans in patients with nonischemic heart disease, we reviewed the records of patients who underwent pyrophosphate scanning at the Boston City Hospital between January 1978 and December 1980. Criteria for in-

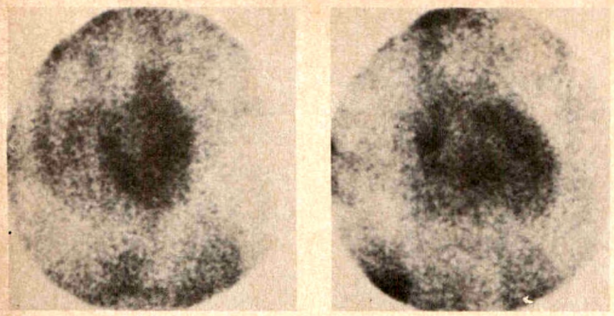

**FIGURE 1.** Technetium-99m pyrophosphate scintigram of Patient 5. Note the intense pyrophosphate uptake outlining the left ventricular cavity. **Left,** left anterior oblique 45° view. **Right,** anterior view.

clusion were absence of acute or prior myocardial infarction and a gated blood pool scan compatible with cardiomyopathy without regional wall motion abnormalities. Five such patients were identified, 4 with congestive cardiomyopathy and 1 with hypertrophic cardiomyopathy. In addition, 5 patients with nonischemic, nonamyloid heart disease prospectively underwent technetium pyrophosphate scanning. Two had congestive cardiomyopathy, 1 had noncalcific constrictive pericarditis, and 2 had hypertensive heart failure. The mean age of control subjects (56 ± 10 years) did not differ statistically from that of the amyloid patients.

All studies in control and amyloid patients were approved by the Human Studies Committee of the Boston City Hospital. Statistical analysis of data was performed using the Mann-Whitney U test for nonparametric data, Spearman's rank correlation coefficient, and Fisher's exact probability test.

## Results

Clinical data on the 20 patients are detailed in Table I. Nine of the 20 patients (Patients 1 to 9) were classified in Group A (definite, symptomatic involvement), 2 (Patients 10 and 11) in Group B, 4 in Group C (Patients 12 to 15), and 5 (Patients 16 to 20) in Group D.

Nine of the 11 patients with electrocardiographic and echocardiographic evidence of cardiac amyloidosis (Groups A and B) had strongly positive pyrophosphate scans (3+ or 4+) (Fig. 1). One patient (Case 9) had a negative pyrophosphate scan despite classical M-mode and 2-dimensional echocardiographic appearances of amyloidosis and recurrent episodes of congestive heart failure. One asymptomatic patient (Case 11) had classical echocardiographic features of amyloid and a 2+ pyrophosphate scan. Of the 9 patients in Groups C and D, only 2 (Cases 16 and 20) had positive pyrophosphate scans (3+). Neither of these patients had any other evidence of myocardial amyloid involvement. A comparison of Groups A and B with C and D revealed a significant relation between clinical and echocardiographic evidence of amyloid infiltration of the heart and a positive myocardial technetium pyrophosphate scan ($p < 0.05$ by Fisher's exact test). There was no correlation between the presence of low voltage alone and a positive scan. On the assumption that increased left ventricular wall thickness in these patients is related to amyloid infiltration, we analyzed the relation between echocardiographically measured wall thickness and scan positivity. Left ventricular posterior wall thickness was chosen as this was more accurately measured than septal thickness. No patient had asymmetric septal hypertrophy. There was a statistically significant relation between these 2 variables ($r = 0.68$, $p < 0.01$). This is illustrated graphically in Figure 2. There was also a significant relation between the presence of cardiac failure (Patients 1 to 9) and a left ventricular wall thickness >11 mm ($p < 0.02$).

**Isotope uptake in other organs:** Nine patients (Patients 4, 6, 7, 8, 10, 16, 18, 19, and 20) had isotope uptake in organs other than the heart. The liver was the most frequent site of uptake although uptake was occasionally seen in the spleen (Patients 7 and 18).

**Control subjects:** Technetium pyrophosphate scans had negative findings in 9 of the 10 control subjects with

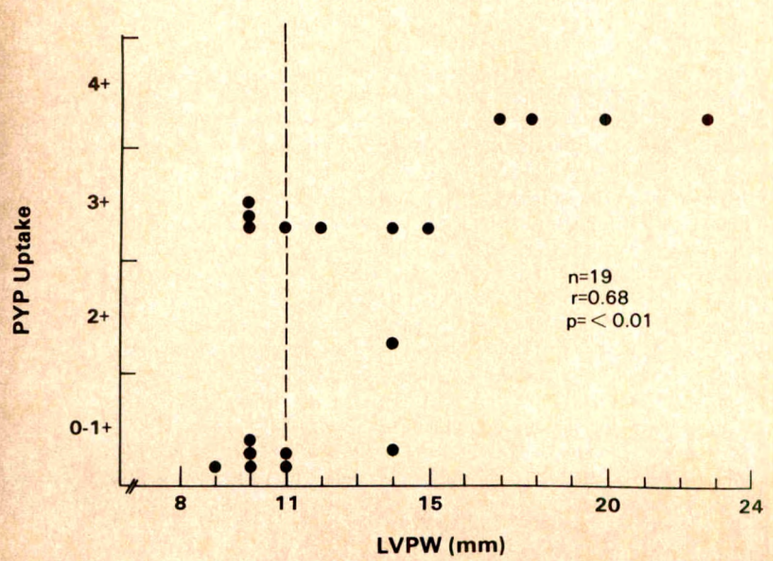

**FIGURE 2.** Pyrophosphate (PYP) uptake (0 to 4+) plotted against left ventricular posterior wall (LVPW) thickness. **Broken line** indicates upper limit of normal for LVPW thickness. For PYP grading, see text. Patient 14 (Table I) was excluded from analysis because of a history of poorly controlled hypertension. LVPW thickness was chosen because it was more accurately measured than septal thickness. No patient had asymmetric septal hypertrophy.

nonamyloid heart failure. One patient with severe congestive cardiomyopathy had a diffusely positive pyrophosphate scan of 2+ intensity. This was associated with positive linear isotope uptake in the femoral region, but no hepatic uptake. No control patient had 3+ or greater cardiac uptake compared with 8 of the 9 amyloid patients with heart failure ($p < 0.005$) and 11 of the total amyloid group ($p < 0.01$). Isotope uptake in the liver or spleen was not seen in the 6 control patients in whom scanning of these areas was performed.

In subjects with congestive heart failure, the sensitivity of a 3+ or 4+ isotope uptake for diagnosing amyloidosis was 89%, the specificity 100%, and the predictive accuracy 100%. The latter 2 figures should be interpreted with caution as they are based on a small control group.

**Follow-up:** During a mean follow-up period of 14 months there were 7 deaths. In Group A there was 1 sudden death (Patient 6) and 3 due to congestive heart failure (Patients 4, 7, and 8). The 3 remaining deaths were due to stroke (Patient 14), hepatic failure (Patient 15), and renal failure (Patient 18).

## Discussion

Since its introduction on 1974,[13] technetium pyrophosphate scanning has been shown to be a highly sensitive indicator of myocardial necrosis in acute myocardial infarction. Initial enthusiasm for this test as a specific diagnostic tool for acute infarction was tempered when other entities such as unstable angina,[14] left ventricular aneurysm,[15] acute pericarditis,[16] and myocarditis[17] were shown to produce positive scan results of either a diffuse or localized nature.

Recently, several reports have described avid myocardial pyrophosphate uptake in patients with advanced myocardial amyloidosis.[7-9] Wizenberg et al[7] described 10 patients with cardiac amyloidosis, 7 of whom had clinical evidence of congestive heart failure. Increased left ventricular wall thickness measured by echocardiography was present in all, and measurement of systolic time intervals suggested left ventricular systolic dysfunction. Technetium pyrophosphate scans were strongly positive in all 10 patients, but the investigators urged caution in the general application of pyrophosphate scanning for the diagnosis of cardiac amyloidosis until a greater number of patients representing a wider spectrum of the disease was examined.

We have deliberately limited our report to patients with primary (AL) amyloid, as this disease is associated with autopsy evidence of myocardial involvement in over 90% of cases.[1,18] Although the initial manifestations may involve 1 or more of several organ systems (such as liver, kidney, nervous system, heart), clinical cardiac involvement develops in the majority of cases and is responsible for death in approximately 50% of patients.[18] It is thus reasonable to assume that most patients will have some degree of myocardial amyloid infiltration at diagnosis, regardless of whether symptoms or signs of heart disease are present. Our results confirm the value of technetium pyrophosphate scanning in patients with congestive heart due to amyloidosis (90% sensitivity), but demonstrate that scans are rarely positive in patients presenting with amyloidosis in other organs in whom no echocardiographic abnormalities suggestive of myocardial infiltration can be demonstrated. Although 4 asymptomatic patients (Patients 12 to 15) demonstrated electrocardiographic abnormalities suggestive of myocardial amyloid involvement, pyrophosphate scans were negative in all, corresponding to their normal echocardiograms. That positive myocardial scans seem to depend in most cases on a critical mass of amyloid is demonstrated by the relation between scan positivity and left ventricular wall thickness (Fig. 1). Although occasionally asymptomatic patients with normal wall thickness may have positive pyrophosphate scans (Patients 16 and 20), most demonstrate no isotope uptake.

The exact mechanism of pyrophosphate uptake in amyloidosis remains unclear but is possibly related to increased calcium concentration in amyloid-infiltrated tissue, as studies of technetium pyrophosphate have demonstrated a strong relation between tissue uptake and calcium accumulation.[19] Amyloid fibrils in primary amyloidosis are composed of the N-terminal portion of kappa or lambda light chains (or the occasional whole light chain), and have a cross-beta tertiary structure as defined by x-ray diffraction studies, consisting of a high percentage of acidic amino acids.[20] Various serum proteins such as amyloid P-component and blood clotting factors bind to amyloid by a calcium-dependent mechanism. Yood et al[20] demonstrated an average calcium content in amyloid infiltrated livers 37 times greater than that of normal liver. Presumably, a similar high concentration of calcium is present in hearts heavily infiltrated with amyloid and is associated with the binding of pyrophosphate.

Eight patients in our series had pyrophosphate uptake by the liver. Four of these patients (Cases 4, 6, 7, and 8) had congestive heart failure and the remainder had no cardiac symptoms. Hepatic uptake of technetium isotopes is a rare finding, having been described in metastatic disease to the liver[21] and in isolated cases of amyloidosis.[20] Congestive heart failure per se does not cause hepatic pyrophosphate uptake and thus the finding of a positive hepatic and cardiac pyrophosphate scan in an individual with an obscure cardiomyopathy is suggestive of amyloidosis. However, the presence of cardiac uptake in the absence of hepatic uptake does not militate against amyloidosis as demonstrated by several patients (Cases 1, 2, 3, and 5) in whom uptake was localized to the heart.

Because of the small number of patients in our control group, the specificity of pyrophosphate scanning in the differential diagnosis of amyloid from other cardiomyopathies cannot be definitively estimated, but appears to be high. It is striking that none of the control patients had scans equal in intensity to bone. The single control patient with a 2+ positive scan also had linear femoral isotope uptake, which has been shown to correlate with falsely positive myocardial scans, probably due to persistent blood pool imaging.[22] Although few studies specifically document technetium pyrophos-

phate uptake in nonamyloid cardiomyopathy, it does appear that intense uptake is unusual. Duska et al[23] studied 5 adults with "nonobstructive" cardiomyopathy and found 2 with weakly positive scans and 1 with a 3+ diffuse scan. Scans were performed only 1 hour after injection of isotope, a period during which blood pool imaging may occur due to persistence of the isotope in the circulation.[22] It is also possible that the patient with a strongly positive scan may indeed have had cardiac amyloidosis, as no detailed clinical data are given. Berman et al[24] performed cardiac catheterization in 22 patients with chest pain, positive pyrophosphate scans and no evidence of acute myocardial infarction. Six were found to have cardiomyopathy (3 congestive and 3 nonobstructive hypertrophic). Pyrophosphate uptake was diffuse and of lesser intensity than bone in all. They suggest that the cause of this weakly positive scan in cardiomyopathy is due to persistent blood pool labelling, possibly related to the increased volume of blood in a dilated ventricular cavity. This clearly differs from amyloid cardiomyopathy, in which the intense uptake may sharply delineate the walls of the heart leaving a space in the center corresponding to the cavity (Fig. 1). Thus it appears that our finding of minimal or no pyrophosphate uptake in nonamyloid cardiomyopathy is consistent with most such cases reported in the literature.

There is a paucity of data concerning the prevalence of positive myocardial pyrophosphate scans in constrictive pericarditis—frequently clinically indistinguishable from amyloid cardiomyopathy. In the only study to examine this, 1 of 3 patients with constrictive pericarditis had a diffusely positive pyrophosphate scan of an intensity equal to that of the ribs.[16] This patient had pericardial calcification, whereas the 2 patients with negative scans had no calcification. Our single control patient with noncalcific constrictive pericarditis also had a negative pyrophosphate scan. Thus it appears that in differentiating amyloid cardiomyopathy from constrictive pericarditis, a positive technetium pyrophosphate scan would favor the former, providing no calcium is visible on x-ray examination.

*In summary*, our data indicate that avid myocardial pyrophosphate uptake is a sensitive indicator of cardiac amyloidosis. It is also highly specific, if only diffuse uptake equal to or greater than that of the ribs is considered positive. Although strongly positive scans have been described in patients with other disorders,[14–17] standard noninvasive tests can usually easily differentiate these disorders from amyloidosis. Since echocardiographic abnormalities in cardiac amyloidosis (for example, increased wall thickness) are seen in other diseases causing cardiac failure, the diagnosis may not be apparent from the echocardiogram alone. We thus believe that pyrophosphate scanning is a very useful complementary test to echocardiography. Technetium pyrophosphate myocardial scans are most valuable in the patient with congestive heart failure and suspected cardiac amyloidosis but may occasionally be positive in asymptomatic patients even when echocardiograms and electrocardiograms are normal. However, myocardial pyrophosphate scintigraphy does not appear to be a sensitive indicator of early myocardial involvement in the majority of asymptomatic patients with systemic amyloidosis. Such patients commonly have a negative scan despite an abnormal electrocardiographic finding and despite the fact that at autopsy almost all will have evidence of myocardial amyloid infiltration. It should be emphasized that these results apply only to patients with primary amyloidosis and should not be extrapolated to other forms of the disease (AA or familial amyloid polyneuropathy) as the different nature of amyloid protein in these disorders may differently affect pyrophosphate binding.[10]

# Survival in Men With Severe Chronic Left Ventricular Failure Due to Either Coronary Heart Disease or Idiopathic Dilated Cardiomyopathy

JOSEPH A. FRANCIOSA, MD, MARY WILEN, LPN, SUSAN ZIESCHE, RN, and JAY N. COHN, MD

**Congestive heart failure (CHF) is known to be highly fatal, but to better assess efficacy of therapeutic interventions a greater understanding of its course is required. Previous studies of survival are limited by heterogeneity of patient populations and diverse criteria for diagnosing CHF. We followed up 182 patients with chronic left ventricular failure who were symptomatic despite therapy. The length of the follow-up period averaged 12 ± 10 (mean ± standard deviation [SD]) months (range 1 to 41). The cause of CHF was coronary artery disease in 95 patients and idiopathic dilated cardiomyopathy in 87. A total of 88 deaths occurred, of which 40 (45%) were sudden; the incidence of sudden death was similar in patients with coronary artery disease and idiopathic dilated cardiomyopathy. The overall mortality rate was 34% at 1 year, 59% at 2 years, and 76% at 3 years. The mortality rate in patients with coronary artery disease was 46 and 69% at 1 and 2 years, compared with 23 and 48% at 1 and 2 years in those with idiopathic dilated cardiomyopathy ($p < 0.01$). Comparison of all survivors and nonsurvivors showed no difference in age or duration of symptoms at entry. Clinical class was significantly worse in nonsurvivors. Nonsurvivors had higher left ventricular filling pressure (29 ± 7 versus 24 ± 9 mm Hg) and systemic vascular resistance (25 ± 10 versus 21 ± 8 units) (both $p < 0.01$); they also had lower mean arterial pressure (87 ± 13 versus 94 ± 13 mm Hg), cardiac index (2.0 ± 0.7 versus 2.5 ± 0.8 liters/min/m$^2$), and stroke work (35 ± 19 versus 56 ± 33 g-m) than did the survivors (all $p < 0.001$). However, only left ventricular filling pressure was correlated with length of survival ($r = -0.31$, $p < 0.01$). Thus, 3-year mortality is very high in patients with severe chronic left ventricular failure. The prognosis is poorer in patients with CHF due to coronary artery disease and, as expected, in those with worse symptoms and hemodynamic abnormalities.**

Congestive heart failure is a highly fatal disorder with a 5-year survival rate below 50%, which is worse than that observed for cancer in general.[1] The efficacy of therapeutic interventions in heart failure is not easily established. Demonstration of improved resting hemodynamics and left ventricular function may not suffice for this purpose because such measurements do not reliably reflect functional capacity of patients.[2,3] However, demonstration of increased exercise tolerance in the laboratory may not necessarily be related to the symptomatic status or to the long-term prognosis of patients. Thus, reductions in morbidity and mortality remain the most acceptable proof of therapeutic efficacy.

To properly assess the results of clinical therapeutic trials in heart failure, a more thorough understanding of the course of this disorder is required. Several investigators have noted relations between clinical characteristics, hemodynamics, measures of cardiac function, and prognosis in patients with congestive heart failure (CHF).[4–10] However, epidemiologists have criticized many of these earlier reports because of their lack of uniformity in diagnostic criteria of CHF and in patient populations.[11]

We have recently been evaluating new treatments in patients with chronic left ventricular failure due to myocardial dysfunction. The present report describes

our experience during the long-term follow-up of these patients after a thorough clinical and hemodynamic evaluation. All patients had symptoms despite therapy and were referred to a cardiologist for further management. Thus, our study invovles a relatively homogeneous patient population in terms of the origin and severity of CHF, and they were evaluated, managed, and followed up uniformly by the same team of clinical investigators.

## Methods

The patient population consisted of men admitted to the Veterans Administration Hospital in Minneapolis, Minnesota between October 1, 1974 and January 31, 1979, and to the Veterans Administration Hospital in Philadelphia, Pennsylvania between October 1, 1979, and October 31, 1981. They were hospitalized or referred to the cardiology clinic because of decompensated chronic CHF. The cause of CHF was coronary artery disease or idiopathic dilated cardiomyopathy. Coronary artery disease was diagnosed by electrocardiographic and enzymatic documentation of previous myocardial infarction or by demonstration of significant obstructive coronary arterial disease by coronary angiography. Idiopathic dilated cardiomyopathy was diagnosed when no other cause of CHF was apparent.

An initial diagnosis of CHF required (1) a history of dyspnea or fatigue during exertion, and (2) one of the following physical signs: third heart sound, pulmonary congestion, jugular venous distention, or otherwise unexplained peripheral edema. The signs and symptoms of CHF must have been present for at least 3 months. Patients with the following were excluded: acute myocardial infarction within the previous 3 months, primary pulmonary disease, hypertrophic cardiomyopathy, primary valvular heart disease, exercise capacity limited by angina or symptoms other than dyspnea or fatigue, or any other associated disease that might limit long-term survival.

Patients satisfying the initial criteria underwent further evaluation. Symptomatic status was classified according to the criteria of the New York Heart Association. In addition, 1 of the following had to be present: (1) cardiothoracic ratio by chest X-ray of $\geq 55\%$; (2) left ventricular ejection fraction by radionuclide or contrast angiography $<46\%$; (3) left ventricular internal end-diastolic dimension by M-mode echocardiography $\geq 2.7$ cm/m$^2$; (4) left ventricular filling pressure $>15$ mm Hg; or (5) cardiac index $<2.5$ liters/min/m$^2$. Left ventricular filling pressure was obtained through right heart catheterization and taken as pulmonary arterial occluded or diastolic pressure. Cardiac output was measured by thermodilution, indicator dye dilution, or carbon dioxide rebreathing. We have previously validated the latter method in patients with CHF.[12] Blood pressure was measured by the standard cuff technique or from indwelling arterial cannula. Stroke volume, systemic vascular resistance, cardiac index, and stroke work were calculated from standard formulas.

On completion of evaluation, patients were followed up in the cardiology clinic where they were seen regularly by the same physician and nurses. No attempt was made to control therapy. However, all patients were taking at least digitalis or diuretics, or both, and many received vasodilators sometime during the follow-up period. The survival status of patients was determined from records of clinic visits or from telephone contact with the patient or his relatives. The cutoff date for determining survival status was February 28, 1979, for patients in Minneapolis and November 30, 1981, for patients in Philadelphia. All deaths that occurred were attributable to cardiovascular disease. Death was defined as sudden when it was unexpected at the time and was witnessed to occur within 24 hours of the onset of symptoms.

Probability of survival from the time of initial evaluation was analyzed by the life-table method, and survival curves were compared using the log-rank test.[13] Differences in characteristics between patient groups were compared by unpaired $t$ tests, and correlations between patient characteristics and length of survival were examined by regression analysis. A total of 194 patients was initially evaluated, and complete follow-up data were obtained in 182 patients (94%) who are the subject of this report.

## Results

Of the 182 patients with complete follow-up data, 95 had cardiomyopathy secondary to coronary artery disease and 87 had idiopathic dilated cardiomyopathy. The follow-up period averaged $12 \pm 10$ (SD) months (range 1 to 41). During this period a total of 88 deaths occurred, 58 in the coronary disease group and 30 in the idiopathic cardiomyopathy group ($p < 0.01$). Of the total number of deaths in the group with coronary artery disease, 25 (42%) were classified as sudden compared with 15 (50%) in the group with idiopathic dilated cardiomyopathy.

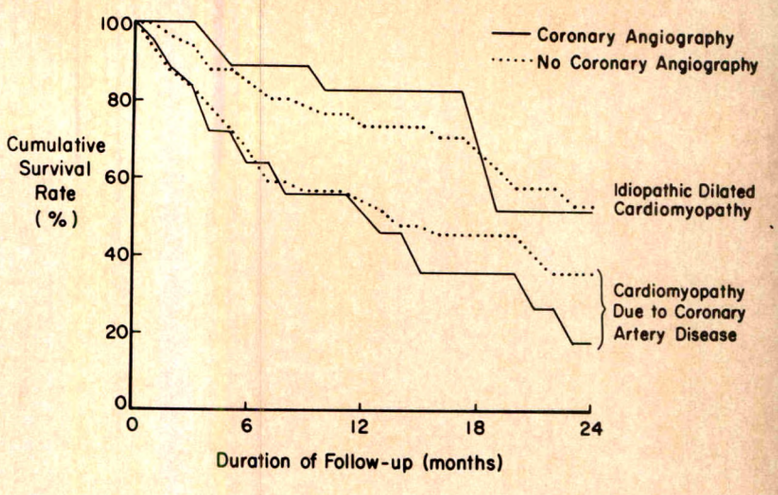

**FIGURE 2.** Survival curves in patients with severe chronic left ventricular failure due to cardiomyopathy with or without coronary angiography for diagnosis. The curves for coronary artery disease and idiopathic, dilated cardiomyopathy groups are significantly different ($p < 0.01$). Curves within diagnostic groups are not different.

The difference in incidence of sudden death was not statistically significant. Cumulative survival rates by the life-table method are shown in Figure 1. By 12 months 66% of all patients were still alive, and by 24 months only 41% were still alive. By 36 months 76% of patients had died. Survival rates for the etiologic groups were analyzed separately (Fig. 1). The survival curve of patients with idiopathic dilated cardiomyopathy indicated a 1-year survival rate of 77% compared with 54% for those with cardiomyopathy due to coronary artery disease. Differences between these groups were still present at 24 and 36 months, and the difference between the entire survival curves was statistically significant ($p < 0.01$). There were no significant differences in these 2 groups in baseline characteristics including age, duration or severity of symptoms, and hemodynamic variables.

Because only a minority of our patients (46 of 182 or 25%) underwent coronary angiography, their survival was compared with that of patients not subjected to coronary angiography within each etiologic group (Fig. 2). In the group with idiopathic dilated cardiomyopathy survival curves were not significantly different between patients with angiographically normal coronary arteries and those not subjected to coronary angiography, as their 2-year survival rates were 52 and 53%, respectively. Likewise, in the group with cardiomyopathy due to coronary artery disease, survival was not significantly different between patients with and those without angiographically proved coronary artery disease. The differing survival rates between etiologic groups were again apparent. Among the patients who underwent coronary angiography, mortality in the coronary disease group was 49% at 1 year and 82% at 2 years, compared with 17% at 1 year and 48% at 2 years in patients with idiopathic dilated cardiomyopathy ($p < 0.01$).

To further characterize differences between all survivors and nonsurvivors, symptomatic status and hemodynamic values at our initial evaluation were compared. No significant differences were noted between survivors and nonsurvivors in duration of symptoms or age at entry (Table I). However, nonsurvivors did have a significantly worse symptomatic status as judged by the criteria of the New York Heart Association. Except for heart rate, hemodynamic variables were significantly different between groups. Mean arterial blood pressure was lower in nonsurvivors, and left ventricular filling pressure and systemic vascular resistance were higher in this same group. Cardiac index, stroke volume, and stroke work were all significantly lower in nonsurvivors. Although hemodynamic variables overlapped considerably between survivors and nonsurvivors, life-table analysis also showed significantly different survival rates between hemodynamic subgroups. For this analysis the dividing point for each variable was arbitrarily taken as the point midway between the average value observed for survivors and the average value for nonsurvivors for any given variable. Figure 3 shows cumu-

**TABLE I Baseline Characteristics of Patients With Severe Chronic Left Ventricular Failure Due to Cardiomyopathy**

| | Nonsurvivors (n = 88) | Survivors (n = 94) | p |
|---|---|---|---|
| Age (yr) | 57 ± 10 | 56 ± 8 | NS |
| Duration of symptoms (mo) | 45 ± 43 | 39 ± 27 | NS |
| Clinical class (NYHA) | 3.3 ± 0.6 | 2.9 ± 0.6 | <0.001 |
| Heart rate (beats/min) | 87 ± 15 | 83 ± 16 | NS |
| Mean arterial pressure (mm Hg) | 87 ± 13 | 94 ± 13 | <0.001 |
| Left ventricular filling pressure (mm Hg) | 29 ± 7 | 24 ± 9 | <0.001 |
| Cardiac index (liters/min/m$^2$) | 2.0 ± 0.7 | 2.5 ± 0.8 | <0.001 |
| Stroke volume (ml/beat) | 45 ± 16 | 59 ± 5 | <0.001 |
| Systemic vascular resistance (units) | 25 ± 10 | 21 ± 8 | <0.01 |
| Stroke work (g-m) | 35 ± 19 | 56 ± 33 | <0.001 |

Values are listed as mean ± standard deviation.
NYHA = criteria of the New York Heart Association; NS = not significant.

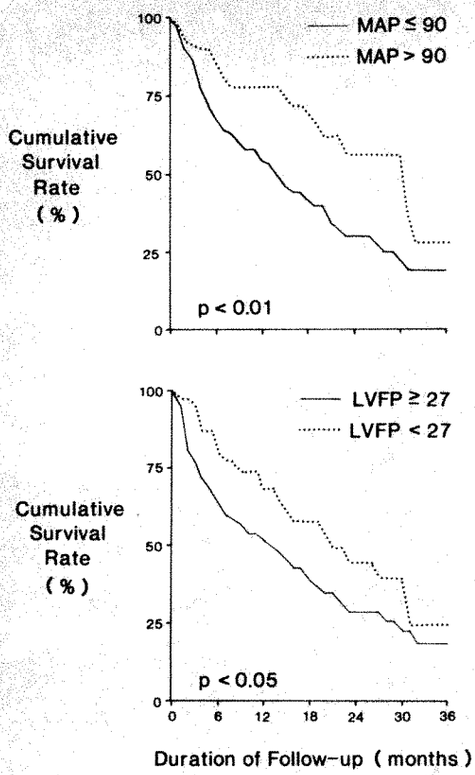

**FIGURE 3.** Survival curves in patients with severe chronic left ventricular failure due to cardiomyopathy according to blood pressure and left ventricular filling pressure at entry. LVFP = left ventricular filling pressure (mm Hg); MAP = mean arterial pressure (mm Hg).

lative survival curves according to baseline mean arterial blood pressure and baseline left ventricular filling pressure. Survival was significantly better in patients with a mean arterial pressure >90 mm Hg and with a left ventricular filling pressure <27 mm Hg. Only 52% of patients with a filling pressure of ≥27 mm Hg were alive after 1 year compared with 69% of those with lower filling pressure. Similarly, patients with a cardiac index ≥2.25 liters/min/m$^2$ had significantly better survival than did those with a lower cardiac index, with 14-month survival being exactly 1.5 times better (75 versus 50%) in those with a higher cardiac index (Fig. 4). As expected, calculated variables, which included measures of blood pressure, left ventricular filling pressure, and cardiac output, also revealed significantly different survival curves. Patients with systemic vascular resistance averaging <23 units had better survival than did those with higher systemic vascular resistance, and patients with stroke work averaging >45 g-m had better survival than did patients with lower stroke work (Fig. 5).

To determine if these same hemodynamic variables correlated with length of survival, linear regression analysis was carried out between baseline hemodynamics and time of survival until death in the nonsurviving patients. There were no significant correlations between any of the baseline hemodynamic characteristics and length of survival except for left ventricular filling pressure (Fig. 6). A slight but statistically significant inverse correlation was noted between left ventricular filling pressure and duration of survival.

## Discussion

The present results agree with those of previous reports of high fatality rates in patients with CHF. In the Framingham study 5-year survival from the time of initial diagnosis of CHF was <50%.[1] We observed higher mortality rates at 1 to 3 years, but we followed up patients from the time of appearance of refractory symptoms. A long preclinical latent period in patients with CHF has been noted.[4] The Framingham data for men from the time of the first episode of clinical CHF showed a survival rate of 79% at 1 year which is very similar to our observed 1 year survival rate of 66%. A major difference between the Framingham study and ours was the various causes of CHF included in that study which did not exclude valvular heart disease, angina pectoris, or cor pulmonale, as we did. Earlier studies of patients with cardiomyopathy tended to be retrospective reports that focused primarily on clinical features, although high total mortality was noted.[4,5,7] In a more recent report by Fuster et al[10] 104 patients with idiopathic dilated cardiomyopathy experienced a total mortality of 77% over 11 years, with two thirds of the deaths oc-

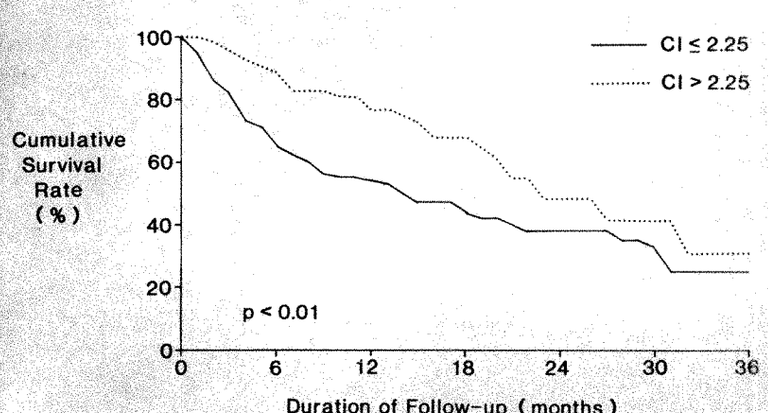

**FIGURE 4.** Survival curves in patients with severe chronic left ventricular failure due to cardiomyopathy according to cardiac index at entry. CI = cardiac index (liters/min/m$^2$).

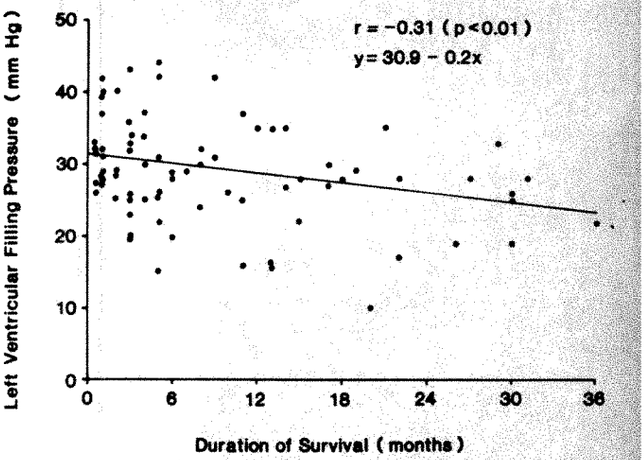

**FIGURE 6.** Relation between left ventricular filling pressure at entry and duration of survival in nonsurviving patients with severe chronic left ventricular failure due to cardiomyopathy.

curring during the first 2 years. Their survival rates of 70% at 1 year and 55% at 2 years are very similar to the 77 and 52% survival rates noted at 1 and 2 years, respectively, in our patients with idiopathic dilated cardiomyopathy. However, their study was retrospective and diagnosis of CHF was based on ventriculographic demonstration of left ventricular dysfunction. Our study differs from previous ones in that a large number of patients were followed prospectively. The study population was relatively homogeneous as all patients had chronic left ventricular failure due to cardiomyopathy and follow-up began at the time of refractory symptoms.

Our observation that survival was worse in patients with cardiomyopathy secondary to coronary artery disease has not been well appreciated. Among patients with ischemic heart disease, those with left ventricular dysfunction generally have a worse prognosis than do those without compromised ventricular function. However, most patients have clinically manifest myocardial ischemic episodes. In our series patients were limited by symptoms of CHF, and those with evidence of myocardial ischemic episodes were excluded. Yatteau et al[6] reported 50 to 69% 2-year survival in patients with ischemic cardiomyopathy which is better than the 31% survival we observed at 2 years.[6] However, although all our patients had moderately severe clinical CHF, <60% of their patients had symptomatic CHF. The worse prognosis in our patients should not be too surprising because cardiomyopathy from coronary artery disease tends to occur in patients with more severe multivessel coronary artery disease and multiple previous myocardial infarctions.[14] Clinical CHF probably represents the most extreme end of the spectrum in these patients with severe coronary artery disease.

Numerous earlier studies observed that prognosis in CHF is worse in patients with more abnormal hemodynamics.[4,6,8,10] Not surprisingly, therefore, we also observed higher mortality rates in patients with a higher left ventricular filling pressure or lower cardiac output, probably reflecting poorer left ventricular function in those patients. We also noted a worse prognosis in patients with higher systemic vascular resistance, which is consistent with a recent preliminary report that mortality is higher among patients with CHF who have high levels of circulating catecholamines.[15] Because of considerable overlap of hemodynamic values among survivors and nonsurvivors, these measurements are only of limited value in the prognosis of individual patients. The observed poor correlations between hemodynamics and duration of survival support this concept. Hemodynamic measurements are widely used to assess efficacy of therapeutic intervention, but recent demonstrations of the lack of correlation between such measurements and symptomatic status of patients with CHF have questioned the significance of such measurements.[2,3,16] The present findings that hemodynamic measurements do relate to prognosis even in patients with far advanced refractory CHF suggest that their use may still be of value because their modification might alter prognosis.

We have focused primarily on hemodynamics and prognosis because of the current popularity of hemodynamic measurements in diagnosing and managing patients with CHF. Previous studies related clinical and radiographic signs as well as left ventricular function with prognosis.[4–10] We have not emphasized these factors because our patients all had refractory symptoms of CHF at entry into the study and were required by protocol to have clinical and radiographic evidence of

CHF so that such measurements would be less likely to have significant discriminatory value. We did not quantitate left ventricular function by use of left ventricular ejection fraction because the noninvasive method required was generally unavailable in the centers involved when the study began. This measurement was obtained in a small number of patients entered later in the study and showed no significant differences between survivors and nonsurvivors, possibly because the period of risk might have been shorter in the patients who entered later.

Sudden death occurred in 22% of our patients and accounted for 45% of all deaths; the incidence was similar in idiopathic dilated cardiomyopathy and cardiomyopathy due to coronary artery disease. Others have noted the common occurrence of sudden death in patients with cardiomyopathy of either cause.[5,7,17] We did not attempt to characterize the type or frequency of arrhythmias in our patients, but others have observed that patients with CHF have a high incidence of ventricular arrhythmia, especially those who die suddenly.[8,18]

Interpretation of the present results must be qualified. Our patients entered at different points in their course. A long interval of relatively good prognosis probably exists between the initial cardiac insult and manifestations of clinical CHF. Long-standing preexisting radiographic or electrocardiographic abnormalities can be documented in a large percentage of patients who present with their first episode of clinical CHF.[4] Thus, it is difficult to ascertain the onset of CHF. Our approach was to follow up patients from the time of onset of symptoms that were refractory to treatment. Thus, our patients were far advanced in their course and are representative of patients likely to be referred to an internist or cardiologist. Another problem is that only a minority (25%) of our patients underwent left and right heart catheterization with coronary arteriography. Thus, the diagnosis, especially that of idiopathic, dilated cardiomyopathy, may not have been entirely accurate. The diagnosis of cardiomyopathy due to coronary artery disease was reasonably secure because a history of documented acute myocardial infarction or coronary arteriography was required. Some of our patients diagnosed as having idiopathic, dilated cardiomyopathy may indeed have had coronary heart disease. Finally, no attempt was made to control or account for the effects of treatment. Virtually all patients were receiving some form on therapy, and nearly all were taking at least digitalis and diuretics. The precise number taking vasodilators and the duration of such therapy are unknown. Because there is no strong evidence that any therapy affects long-term outcome in CHF, it is impossible to assess the role of treatment in affecting our results. The major advantages of our study are the relative homogeneity of the population studied, the prospective nature, and the relatively uniform management and follow-up provided by the same team of investigators.

BIOTRONIK

Pacers in a class of their own™

# Whichever way you look at it,

# it's the smallest

# BIOTRONIK

**Pacers in a class of their own™**

## On one hand even less pacemaker

- Smallest, thinnest pacemaker available (57 × 41 × 8.8 mm)
- Lightweight (only 37 g)
- Anatomically, optimized shape

## On the other hand an even larger scope of therapy

- Suitable for atrial or ventricular stimulation
- All clinically relevant parameters are programmable over a wide range
- A selection of high output voltages for the management of exit blocks
- Constant output voltage even during battery end-of-life; the output amplitude remains at the programmed value
- The entire pacemaker program can be interrogated and displayed in one complete block – not split into single parameters – by using the EPR 500 Programmer. A program printout is also supplied upon request.

BIOTRONIK pacemakers combined with the various BIOTRONIK active and passive fixation leads provide integrated pacing systems with the assurance of maximum reliability since all parts match one another and enable you to decide which system best suits the needs of each individual patient.

## A step ahead of long-acting oral nitrates

"Transdermal delivery of nitroglycerin...overcomes the inherent problems of the oral dosage forms regarding... bioavailability, convenience and compliance."*

**24-hour sustained therapeutic blood levels of nitroglycerin.**
In contrast, so-called long-acting oral nitrates must be given in repeated doses throughout the day.

**Eliminates the first-pass effect.**
Unlike oral nitrates, which are predominantly inactivated in the liver, transdermal nitroglycerin bypasses the liver and enters directly into systemic circulation.

**Only one simple application a day.**
Avoids the inconvenience of multiple dosages.

**Small, cosmetically acceptable and well tolerated.**
Will not leak or stain clothing. May even be worn while bathing or swimming. Few reports of skin irritation.

Note: Orthostatic hypotension may indicate nitroglycerin overdosage; reduce dosage if symptoms occur. Nitrates are contraindicated in patients with increased intraocular pressure. Withdrawal should be gradual if treatment is terminated. Do not apply to distal parts of the arms and legs.

# Transderm®-Nitro
(nitroglycerin)
**Transdermal Therapeutic System**

**DESCRIPTION**
Transderm-Nitro (nitroglycerin) transdermal therapeutic system is a flat unit designed to provide controlled release of nitroglycerin through a semi-permeable membrane continuously for 24 hours following application to intact skin. Nitroglycerin (glyceryl trinitrate) is a prompt-acting vasodilator for the relief and prevention of anginal attacks. Systems are rated to release *in vivo* 5 and 10 mg nitroglycerin over 24 hours and are in sizes of 10 and 20 $cm^2$ respectively.

One-fifth of the total nitroglycerin in the system is delivered transdermally to the patient over 24 hours; the remainder serves as the thermodynamic energy source to release the drug and remains in the system. The rated release of drug is dependent upon the area of the system; 0.5 mg nitroglycerin is delivered *in vivo* for every $cm^2$ of system size.

The Transderm-Nitro system comprises four layers as shown below. Proceeding from the visible surface towards the surface attached to the skin, these layers are: 1) a tan-colored backing layer (aluminized plastic) that is impermeable to nitroglycerin; 2) a drug reservoir containing nitroglycerin adsorbed on lactose, colloidal silicon dioxide, and silicone medical fluid; 3) an ethylene vinyl acetate copolymer membrane that is permeable to nitroglycerin; and 4) a layer of hypoallergenic silicone adhesive. Prior to use, a protective peel strip is removed from the adhesive surface.

Cross section of the system:

**ACTIONS**
When the Transderm-Nitro system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before being inactivated by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilatation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation and consequent reduced cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In clinical studies transdermal absorption of nitroglycerin from a nitroglycerin system occurred in a continuous and well-controlled manner, for a minimum of 24 hours. Therapeutic effect can be anticipated 30 minutes after application of the system and to be maintained for 30 minutes after its removal.

**INDICATIONS AND USAGE**
Transderm-Nitro system is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

**CONTRAINDICATIONS**
Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

**WARNINGS**
In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring.

In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

**PRECAUTIONS**
Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

**ADVERSE REACTIONS**
Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued.

**DOSAGE AND ADMINISTRATION**
Therapy should be initiated with application of one Transderm-Nitro 5 system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area. Transderm-Nitro system should not be applied to the distal parts of the extremities.

The usual dosage is one Transderm-Nitro 5 system every 24 hours. Some patients, however, may require the Transderm-Nitro 10 system. If a single Transderm-Nitro 5 system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 systems or one Transderm-Nitro 10 system. More systems may be added as indicated by continued careful monitoring of clinical response.

The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension especially during orthostasis indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.

Do not store above 86°F (30°C).

**PATIENT INSTRUCTIONS FOR APPLICATIONS**
A patient leaflet is supplied with the systems.

**HOW SUPPLIED**

| Transderm-Nitro System Rated Release *in vivo* | Total Nitroglycerin in System | System Size | Carton Size |
|---|---|---|---|

(temazepam)

## A more appropriate half-life

One 30-mg capsule, h.s.—*usual adult dosage.*
One 15-mg capsule, h.s.—*recommended initial dosage for elderly and/or debilitated patients.*

**INDICATIONS AND USAGE:** Restoril® (temazepam) is indicated for the relief of insomnia associated with complaints of difficulty in falling asleep, frequent nocturnal awakenings, and/or early morning awakenings. Since insomnia is often transient and intermittent, the prolonged administration of Restoril is generally not necessary or recommended. Restoril has been employed for sleep maintenance for up to 35 consecutive nights of drug administration in sleep laboratory studies.

The possibility that the insomnia may be related to a condition for which there is more specific treatment should be considered.

**CONTRAINDICATIONS:** Benzodiazepines may cause fetal damage when administered during pregnancy. An increased risk of congenital malformations associated with the use of diazepam and chlordiazepoxide during the first trimester of pregnancy has been suggested in several studies. Also, ingestion of therapeutic doses of benzodiazepine hypnotics during the last weeks of pregnancy has resulted in neonatal CNS depression. Restoril is contraindicated in pregnant women. Consider a possibility of pregnancy when instituting therapy or whether patient intends to become pregnant.

**WARNINGS:** Patients receiving Restoril (temazepam) should be cautioned about possible combined effects with alcohol and other CNS depressants.

**PRECAUTIONS:** In elderly and/or debilitated patients, it is recommended that initial dosage be limited to 15 mg. The usual precautions are indicated for severely depressed patients or those in whom there is any evidence of latent depression; it should be recognized that suicidal tendencies may be present and protective measures may be necessary.

If Restoril is to be combined with other drugs having known hypnotic properties or CNS-depressant effects, due consideration should be given to potential additive effects.

*Information for Patients:* Patients receiving Restoril should be cautioned about possible combined effects with alcohol and other CNS depressants. Patients should be cautioned not to operate machinery or drive a motor vehicle. They should be advised of the possibility of disturbed nocturnal sleep for the first or second night after discontinuing the drug.

*Laboratory Tests:* The usual precautions should be observed in patients with impaired renal or hepatic function. Abnormal liver function tests as well as blood dyscrasias have been reported with benzodiazepines.

*Pregnancy:* Pregnancy Category X. See Contraindications.

*Pediatric Use:* Safety and effectiveness in children below the age of 18 years have not been established.

**ADVERSE REACTIONS:** The most common adverse reactions were drowsiness, dizziness and lethargy. Other side effects include confusion, euphoria and relaxed feeling. Less commonly reported were weakness, anorexia and diarrhea. Rarely reported were tremor, ataxia, lack of concentration, loss of equilibrium, falling and palpitations. And rarely reported were hallucinations, horizontal nystagmus and paradoxical reactions, including excitement, stimulation and hyperactivity.

Restoril is a controlled substance in Schedule IV. Caution must be exercised in addiction-prone individuals or those who might increase dosage.

**DOSAGE AND ADMINISTRATION:** *Adults:* 30 mg usual dosage before retiring; 15 mg may suffice in some. *Elderly and/or debilitated:* 15 mg recommended initially until individual response is determined.

**SUPPLIED:** Restoril (temazepam) capsules—15 mg maroon and pink, imprinted "RESTORIL 15 mg"; 30 mg, maroon and blue, imprinted "RESTORIL 30 mg". Packages of 100, 500 and ControlPak® packages of 25 capsules (continuous reverse-numbered roll of sealed blisters). (RES-Z2 11/1/81)

# Evaluation of Left Ventricular Performance Using Digital Subtraction Angiography

MARVIN W. KRONENBERG, MD, RONALD R. PRICE, PhD, CLYDE W. SMITH, MD, ROSE MARIE ROBERTSON, MD, JAMES M. PERRY, MD, DAVID R. PICKENS, PhD, MICHAEL J. DOMANSKI, MD, C. LEON PARTAIN, PhD, MD, and GOTTLIEB C. FRIESINGER, MD

**Cardiac applications for digital subtraction angiography appear promising, but few correlative studies with contrast ventriculography have been done. Left ventricular volume, ejection fraction, and regional wall motion by digital subtraction angiography were evaluated after intravenous injection of 40 ml of iodinated contrast medium and after left venticular injection of 5 to 10 ml of contrast medium. A film-based system of the authors' own design was used. Results were compared with those after direct left ventricular injection of 40 ml of contrast medium.**

**The ventriculograms after intravenous injection were of diagnostic quality in 9 of 12 studies, and there were close correlations between intravenous and direct-injection studies for left ventricular ejection fraction ($r = 0.89$, $n = 9$, and $p = 0.001$) and for left ventricular volume ($r = 0.91$, $n = 18$, and $p < 0.001$). Regional wall motion scores showed close correspondence in 83% of sectors. After small-volume left ventricular injections, the ventricular image was enhanced considerably by digital subtraction. Correlations between small- and large-volume ventriculograms were close for left ventricular ejection fraction ($r = 0.91$, $n = 8$, and $p = 0.002$) and for left ventricular volume ($r = 0.96$, $n = 16$, and $p < 0.001$). There was close correspondence of wall motion scores in 87% of sectors.**

**Thus, digital subtraction angiography improves the visibility of the left ventricle after either intravenous or small-volume direct left ventricular injection. Digital images produce excellent estimates of left ventricular volume and should have considerable usefulness for the study of cardiac performance and anatomy.**

Digital subtraction angiography offers new prospects for evaluation of cardiovascular anatomy and physiology.[1-16] For cardiac applications, images of the thorax are stored in a computer digital matrix before and during passage of a contrast bolus dose through the central circulation. Subtraction of a control, unopacified (mask) image from a contrast-filled image is designed to produce images of contrast-filled structures without interference from soft tissue or bone. Initial reports have been encouraging; however, there is little quantitative, functional information concerning the heart. Thus, we undertook a study with 3 goals: (1) to compare intravenous digital subtraction angiographic images with those produced by conventional left ventricular injection; (2) to compare left ventricular volume and ejection fraction using intravenous angiography with the results of direct left ventricular injection; and (3) to examine the usefulness of digital subtraction angiography to enhance direct left ventriculography performed with small volumes of contrast medium.

Manuscript received February 22, 1982; revised manuscript received May 11, 1982, accepted May 13, 1982.

Address for reprints: Marvin W. Kronenberg, MD, Division of Cardiology, Vanderbilt University Medical Center, Nashville, Tennessee 37232.

## Methods

The subjects were stable adult patients who underwent cardiac catheterization for diagnostic purposes. All had coronary atherosclerosis. Informed consent was obtained on forms approved by the Vanderbilt Committee for the Protection of Human Subjects. Two protocols were employed.

**Protocol 1:** The results of intravenous and direct left ventriculography were compared in 12 subjects. Pigtail catheters were inserted in the femoral artery and vein using sterile technique, local anesthesia, and the Seldinger method. They were advanced to the abdominal aorta and the origin of the

inferior vena cava, respectively. The chest was marked with radiopaque markers, and cross-hair markers were placed on the image intensifier in most studies to aid image alignment.

Forty ml of a mixture of sodium and meglumine diatrizoate (Renografin®-76, E. R. Squibb and Son, Princeton, New Jersey) was injected into the inferior vena cava during held inspiration using a power injector at rates of either 12 or 15 ml/s. Thirty-five mm cineangiograms of the thorax in the 30° right anterior oblique projection were obtained before and during the passage of the contrast bolus through the central circulation. The film was exposed at either 30 or 60 frames/s with a 9 inch diameter field of view. The electrocardiographic R wave was denoted by a dot in the margin of the appropriate film frame.

The arterial pigtail catheter was advanced to the left ventricle without changing the patient position or the angle of the image intensifier, and 40 ml of contrast medium was injected during held inspiration with identical cineangiographic technique. A wire grid with 1 cm squares was filmed at the height of the heart to allow calculation of left ventricular volume.

Contrast-filled left ventricular end-diastolic and end-systolic frames were identified using R-wave markers and the points of greatest and least left ventricular chamber size. The end-diastolic mask (before contrast injection) was identified by the R-wave marker, and an end-systolic mask was selected by reference to the number of frames between end-diastole and end-systole on the direct left ventricular injection. Images for subtraction were processed without reference to the conventional contrast ventriculograms.

Data were analyzed using an off-line system of our own design. The selected cineangiographic frames were illuminated, placed under a video camera, digitized and displayed in a 512 by 256 pixel matrix with 256 gray levels (Grinnell Interactive Image Display, GMR-27, Grinnell Systems, San Jose, California), and stored using a PDP 11/55 computer (Digital Equipment Corporation, Marlboro, Massachusetts).

The intravenous mask and contrast frames were aligned for subtraction using system software and the radiopaque markers. Mask frames were subtracted from corresponding contrast-filled frames, and the results were displayed using either a linear or logarithmic display. Multiplying the mask image by a factor of 0.75 before subtraction produced optimal visual results. At this point, the quality of each end-diastolic and end-systolic image was judged. The image was classified as acceptable for analysis if definite borders could be seen along the left ventricular contractile perimeter.

The acceptable sets of images and the grid markings were traced onto clear plastic. The mitral and aortic valve planes were determined with reference to the subtracted images, the unsubtracted images, and to the results of (end-diastole minus end-systole) and (end-systole minus end-diastole) subtractions. Later, the digitized unprocessed frames from direct left ventricular injection were displayed and traced in similar fashion. The intravenous and direct-injection outlines were processed using a Numonics Digitizer (North Wales, Pennsylvania) having 0.01 inch resolution and a DEC-1099 computer that executed user-validated software and calculated left ventricular volumes by the area-length method.[17]

Regional left ventricular performance was determined with visual estimation of the area reduction in 45° polar sectors of the left ventricle. Eight sectors were constructed by placing a reference axis along the along axis of the left ventricle, and defining visually the center of the end-systolic ventricle.[18] Sectors 1 and 8, corresponding to the mitral and aortic valve regions, were excluded from analysis, and wall motion was estimated by judging the area reduction of the remaining 6 sectors corresponding to the contractile perimeter of the ventricle. A scale of 0 to 6 was employed, in which 0 represented akinesia/dyskinesia; 2, hypokinesia; 4, normokinesia; and 6, hyperkinesia. Similar methods for analyzing regional performance by area reduction have been validated using contrast ventriculography[19] and radionuclide ventriculography.[18] Also, we have demonstrated that visual estimates of area reduction correlate closely with measured area reduction on contrast ventriculography.[18]

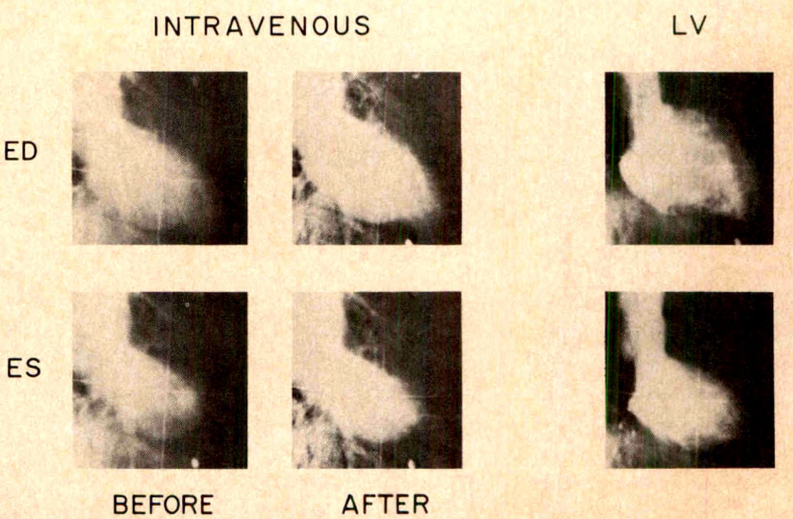

**FIGURE 1.** Images after intravenous and direct left ventriculography. The left ventricle (LV) is visible before subtraction at end-diastole (ED) and end-systole (ES), but the borders are more conspicuous after subtraction of mask images. The intravenous images are highly comparable to the direct left ventricular images.

Data were entered into a medical data base management system (CLINFO, supplied by Division of Research Resources, National Institutes of Health, Bethesda, Maryland). Results were compared by linear regression analysis and the Spearman rank correlation. Statistical significance was defined as $p < 0.05$.

**Protocol 2:** Left ventricular images and left ventricular performance were examined using small-volume direct left ventricular contrast injections that were processed by digital subtraction. In 10 subjects, 5 ml of contrast was injected at end-diastole using a power injector that delivered 12 or 15 ml/s. In 1 subject, 8 ml was injected and in 1, 10 ml was injected. Results were compared with those observed after conventional injections of 40 ml of contrast medium performed within 3 to 5 minutes of the small-volume injection. The details of data processing and analysis were identical to those in Protocol 1.

## Results

All studies were performed without complications. Of 12 intravenous injections, 9 left ventricular images were acceptable for analysis by the criteria described. Of 12 small-volume studies, 8 were acceptable for comparison. Four studies were rejected because of premature ventricular systoles seen with a 40 ml injection in 3 subjects and a very poor image seen with a 5 ml injection in 1 subject who had a very large, poorly contracting ventricle.

**Protocol 1:** Figure 1 demonstrates typical left ventricular images at end-diastole and end-systole before and after digital subtraction, compared with corresponding frames on direct left ventricular injection. The left ventricle was easily visible after intravenous injection, but the details were more conspicuous after subtraction. The images were highly comparable with those seen on direct left ventricular injection. Volume and ejection fraction comparisons for the 9 acceptable studies are shown in Figure 2. The ejection fraction correlation was close ($r = 0.89$, $p < 0.001$), and the correlation for the combined end-diastolic and end-systolic

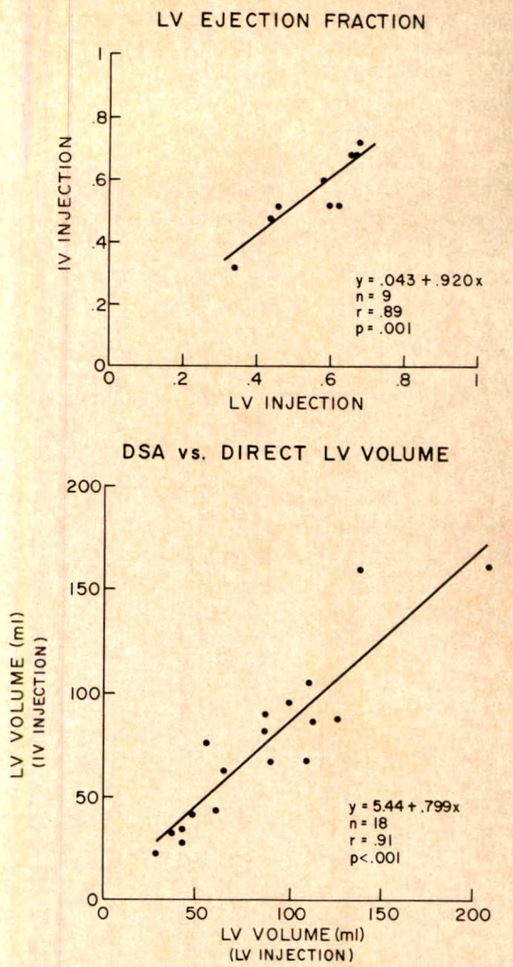

**FIGURE 2.** Comparison of left ventricular (LV) ejection fraction and volume by intravenous (IV) and direct injections. The results for intravenous digital subtraction angiography (DSA) are highly comparable to those for direct injection. However, the left ventricular volume was consistently lower on the intravenous study (see text for details).

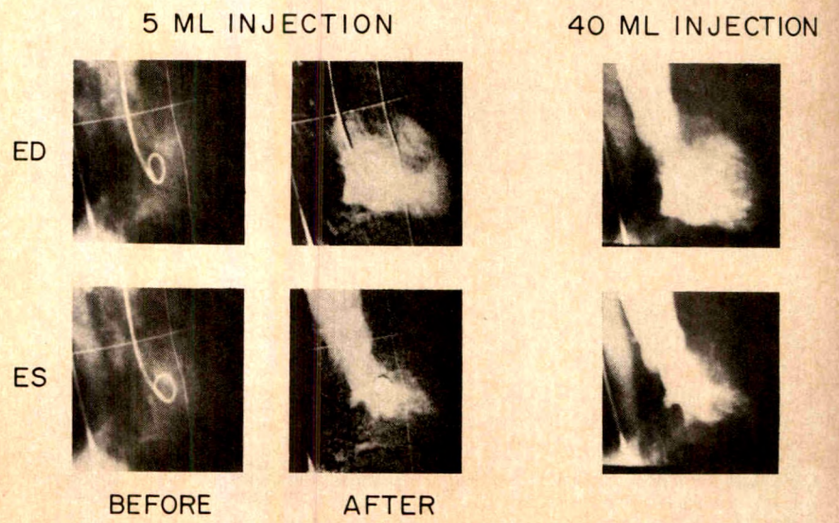

**FIGURE 3.** Images after small-volume (5 ml) and large-volume (40 ml) injections. Digital subtraction produced high quality left ventricular images that demonstrated considerable anatomic detail, including mitral valve prolapse seen on the end-systole (ES) frame in this subject. ED = end-diastole.

volumes was also strong ($r = 0.91$, $n = 18$, and $p < 0.001$), although the intravenous results showed a systematic error of 20% in underestimating the left ventricular volume on direct injection.

The visual estimates of regional ventricular performance were also accurate. Six sectors were graded for each of the 9 subjects. Scores for 45 of 54 sectors (83.3%) were accurate to within 1 grade, and all were accurate within 2 grades. Six of the 9 sectors with inaccuracies of 2 grades were located at the apex and 4 in the inferoapical sector. All grades for the anterior wall sectors were accurate to within 1 grade. There was no systematic error in the wall motion analysis.

**Protocol 2:** The comparison of the small- and large-volume left ventricular contrast injections is shown in Figure 3. In all subjects the left ventricles were barely visible during the 5 ml contrast injections, but their details were easily seen after digital subtraction. The images were highly comparable with those seen on conventional 40 ml contrast injection.

Ejection fraction and volume data for the 8 subjects with acceptable data are shown in Figure 4. For the ejection fraction, there was a close relationship ($r = 0.91$, $n = 8$, and $p = 0.002$). For the volume results, the regression equation demonstrates an x-y intercept near zero, a slope of nearly 1.0, and a strong correlation coefficient ($r = 0.96$, $n = 16$, and $p < 0.001$).

The visual estimates for regional performance showed close correspondence. Scores for 42 of 48 sectors (87.5%) were accurate to within 1 grade, and all scores except 1 were accurate to within 2 grades. Anterior wall sectors were analyzed more accurately than inferior wall sectors. Figure 5 shows the regional performance results.

## Discussion

Intravenous angiography for visualization of cardiac and arterial structures was attempted successfully more than 40 years ago, but the results were suboptimal because of technical limitations.[20–22] Improvements in image intensifiers, television cameras and rapid computer-based digital image processing[1,2] now provide excellent results for carotid, aortic, and renal intravenous angiography.[4–7]

Cardiac studies have been initiated recently. Technical refinements and limited descriptive data have been reported.[3,8,9,11–15] We undertook this study to evaluate left ventricular performance quantitatively. An off-line cineangiographic film-based system of our own design was used to process the ventriculograms.

Three fourths (9 of 12) of the intravenous images of the left ventricle were acceptable for analysis. The left ventricle target-to-background ratio was slightly greater for the acceptable images ($2.52 \pm 0.86$) (mean $\pm$ standard deviation) than for the hazy, unacceptable data ($2.36 \pm 0.29$, $n = 3$), but the differences were not statistically significant in this small number of studies. In the acceptable studies, it was usually possible to define the left ventricular borders before subtraction. However, the edges were more conspicuous after subtraction because of the contrast enhancement that digital angiography produces. The film-based system with a 256 by 512 image matrix produced images of higher resolution than present on-line systems for digital angiography.

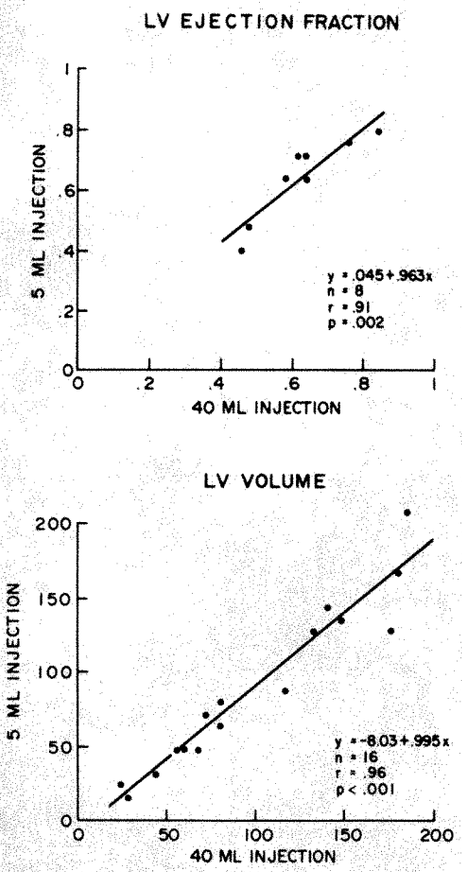

**FIGURE 4.** Comparison of left ventricular (LV) ejection fraction and volume by small-volume and large-volume direct left ventricular injection. Results were highly comparable, with no apparent systematic errors.

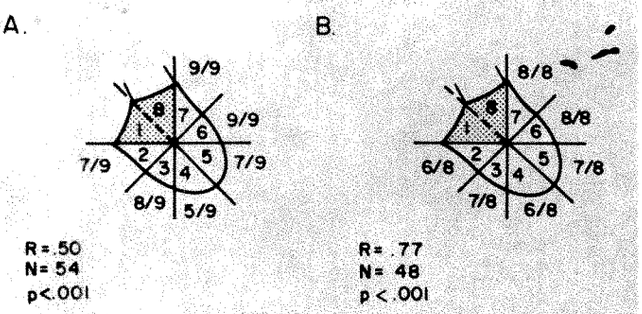

**FIGURE 5.** Comparison of regional performance by digital subtraction and conventional large-volume left ventricular injection. **A,** intravenous injection (9 subjects). **B,** small-volume left ventricular injection (8 subjects). The number of subjects with regional wall motion within 1 grade of that on conventional injection is shown for sectors 2 to 7, which comprise the contractile perimeter. Results of the Spearman rank correlation are listed. There was excellent correspondence in the anterior and anteroapical regions (sectors 5 to 7).

Our volume and ejection fraction data from intravenous injections correlated well with results from direct left ventricular injection, but the results after intravenous injection of contrast medium were systematically lower than those derived from direct injection. This may be due to the osmotic effects of contrast agents. Kloster et al[23] documented an average increase of 223 ml (4%) in blood volume 5 minutes after left ventricular contrast injection in human subjects. Also, Iseri et al[24] found an average increase of 170 ml in plasma volume 5 minutes after contrast left ventriculography (range 100 to 250 ml). In the present study, the direct left ventricular injection was performed 5 to 10 minutes after the intravenous injection. Thus, it is likely that the intravenous injection of contrast medium produced a moderate increase in intravascular volume, based on its osmotic effects. However, this cannot be confirmed because we did not measure blood volume. In addition, the rapid injection of this volume of contrast medium directly into the left ventricle could increase actual ventricular volume. This finding was reported by Sanmarco et al,[25] who documented an immediate, transient 5 to 15% increase in the ventricular volume of dogs after injection of 15 to 20 ml (1 ml/kg body weight) of contrast medium into the left ventricle. Intravenous contrast material is well mixed by passage through the right heart and lungs and does not constitute a bolus injection into the left ventricle. The intravenous injection of contrast medium is likely to have caused transient osmotic effects on the red blood cells[26], but it is unlikely to have greatly increased the total blood volume on its first passage through the central circulation. Thus, the intravenous volume measurements are probably accurate, although there could have been small errors in left ventricular border definition because of fainter borders seen on intravenous injection and errors in estimating valve plane location, or both.

Digital angiography greatly improved the visibility of small-volume direct left ventricular injections. Images that were barely visible before subtraction were easily seen afterward. Eleven of 12 small-volume injections were analyzable but 3 of twelve 40 ml injections were inadequate for comparison because of numerous premature ventricular systoles during these injections. The single subjects who received intraventricular injections of 8 and 10 ml had images that could be analyzed before subtraction; however, the images for those who received injections of 5 ml could not be analyzed without digital subtraction. After subtraction, the small- and large-volume results were highly comparable, without systematic differences. Left ventricular dilatation due to the larger 40 ml bolus of contrast medium was not apparent. There was no change in left ventricular end-diastolic pressure after the injections of 5 ml in the 3 subjects in whom this was measured. However, all 8 subjects had an increase in left ventricular end-diastolic pressure after the 40 ml injections.

The digital subtraction technique can lower the dosage of contrast needed for direct injection ventriculography. The potential physiologic benefits include a lower contrast load and a reduced chance of nephrotoxicity in susceptible patients.[27] It is also possible to study left ventricular performance more carefully by performing several small-volume ventriculograms rather than 1 or 2 conventional studies. Detectable volume and pressure alterations do not occur with small-volume injections. This freedom can allow accurate analysis of alterations in left ventricular loading or of drug therapy. Our data confirm the recent study of Sasayama et al[10] regarding the accuracy of data for small-volume left ventricular injections. Tobis et al[15] recently demonstrated excellent results using direct injections of 10 ml.

Regional wall motion analysis demonstrated accurate results in nearly all sectors, but the inferior and apical regions were more difficult to demarcate on the single static end-diastolic and end-systolic images we employed. Wall motion, volume, and ejection fraction results should improve considerably when moving, endless loop "playback buffers" are employed.

Our preliminary results with digital subtraction angiography are quantitative and encouraging. Problems can occur because of patient movement, slow circulation time, large cardiac volumes, and the intrinsic cardiac motion. Demonstration of left ventricular performance should improve considerably with future refinements in both radiographic hardware and image processing software.

**Acknowledgment:** We appreciate the technical assistance of Jenny James, John Norris, and Judy Sandlin. Some of the off-line processing software was written by Erol M. Breytas, MD.

# Evaluation of Intracardiac Thrombus With Computed Tomography

HARUO TOMODA, MD, MITSUMOTO HOSHIAI, MD, HIDEO FURUYA, MD, SACHIO KURIBAYASHI, MD, MAKOTO OOTAKI, MD, SEIYA MATSUYAMA, MD, SHIROSAKU KOIDE, MD, SHIAKI KAWADA, MD, and AKIRA SHOTSU, MD

**Left atrial (LA) and left ventricular (LV) thrombus was evaluated by computed tomography in 56 patients. The patients were divided into 2 groups: Group I, 28 patients with mitral valve disease, and Group II, 28 patients with myocardial infarction. Computed tomography and 2-dimensional echocardiography were performed in all the patients studied. Cineangiocardiography was performed in all Group I and in 13 Group II patients. Open heart surgery or autopsy was performed in all Group I and 4 Group II patients. The sensitivity in detecting LA thrombus was 100% with computed tomography, 70% with angiocardiography, and 60% with 2-dimensional echocardiography. The specificity in detecting LA thrombus was 91% with computed tomography, 86% with 2-dimensional echocardiography, and 88% with angiocardiography. Thrombi located at the LA appendage were associated with great difficulties in detection by other methods, but were well delineated with computed tomography. LV thrombus was also visualized by computed tomography with similar or greater accuracy than other diagnostic methods, although the sensitivity and specificity were not ascertained because surgery or autopsy was performed in only a minority of Group II patients. Therefore, as far as the detection of intracardiac thrombus is concerned, computed tomography has the advantage of offering uniform slices of the heart in an attempt to detect thrombi in unknown areas of cardiac chambers, including the LA appendage or LV apex, without being disturbed by the surrounding cardiac and noncardiac structures. Thus, computed tomography has excellent accuracy in the detection of intracardiac thrombus.**

The detection of intracardiac thrombus is significant in the treatment of patients with cardiac diseases. Evaluation of intracardiac thrombus, especially that of left atrial (LA) and left ventricular (LV) thrombus, has been attempted with angiocardiography,[1–5] M-mode echocardiography,[6,7] 2-dimensional echocardiography,[7–13] and radionuclide techniques.[14,15] Although there have been improvements in sensitivity and specificity in the detection of intracardiac thrombus, these methods still have limitations, depending on the size and location of the thrombus.[1–15] On the other hand, there have been sporadic reports on the detection of intracardiac thrombus with computed tomography; these preliminary experiences suggest the usefulness of computed tomography in the detection of intracardiac thrombus.[16–19] Therefore, the present study was undertaken to clarify the validity of computed tomography in evaluating LA and LV thrombi.

## Methods

**Patients:** Twenty-eight patients with mitral valve disease were classified as Group I patients. As shown in Table I, their ages ranged from 36 to 68 years (average 50.0 ± 8.4); 21 were women. The group consisted of 11 patients with mitral stenosis, 7 with mitral stenosis and regurgitation, and 10 with combined valvular disease; 24 of these patients had atrial fibrillation.

Twenty-seven of the 28 patients in Group I underwent open heart surgery (open mitral commissurotomy 13, valve replacement 14); a postmortem autopsy was performed on 1 patient to confirm left atrial thrombus. Computed tomography, 2-dimensional echocardiography, and cineangiocardiography were undertaken in all the patients in Group I. The interval from computed tomography to cardiac surgery ranged from 3 to 34 days (average 14.5 ± 9.5). The interval from 2-dimensional echocardiography to cardiac surgery ranged from

AL = anterolateral myocardial infarction; AS = anteroseptal myocardial infarction; E = equivocal; ECG = electrocardiogram; I = inferior myocardial infarction; − = not done; + = present; 0 = absent.

4 to 45 days (average 17.7 ± 10.6). The interval from angiocardiography to cardiac surgery ranged from 6 to 33 days (average 17.6 ± 9.6).

Twenty-eight patients with previous myocardial infarction, documented by prolonged precordial pain, typical electrocardiographic changes, and significant elevations of serum enzymes, were classified as Group II patients. As shown in Table II, the ages of the patients ranged from 36 to 77 years (average 56.9 ± 11.1); 25 were men. This group included 17 patients with anteroseptal myocardial infarction, 7 with anterolateral myocardial infarction, 1 with inferior myocardial infarction, and 3 with anteroseptal-inferior myocardial infarction. The mean interval between infarction and study was 9.4 ± 23.2 months, with a range of 1 month to 9 years.

Computed tomography and 2-dimensional echocardiography were performed in all patients in Group II. Angiocardiography was performed in 13 and cardiac surgery or autopsy was undertaken in 4. The interval from computed tomography to 2-dimensional echocardiography ranged from 2 to 18 days (average 9.2 ± 1.6) and that from computed tomography to angiocardiography from 2 to 19 days (average 8.3 ± 1.6).

**Computed tomography:** A computed tomographic whole body scanner that utilized a continuously rotating gantry and pulsed anode with x-radiation collimated to form a thin fan-shaped beam (Varian computed tomographic 3-second whole body scanner) was used.[20] A complete section scan was performed in 3 seconds. The scale for transparency was −1,000 for air, 0 for water, and +1,000 for bone. In this study, gated computed tomographic scanning to obtain "stop-action" image was not applied. Every computed tomogram (horizontal slice of the heart) was obtained at a thickness of 0.5 to 1 cm in the position of deep inspiration. Sustained enhancement was obtained with a rapid intravenous infusion of 100 ml of 60% meglumine iothalamate or 200 ml of 30% meglumine iothalamate.

**Two-dimensional echocardiography:** Two-dimensional echocardiographic studies were performed by a 90° Toshiba SSH-11A phase array sector scanner with a 2.5 MHz transducer. Recordings were undertaken with the patient in the supine or 30° left lateral decubitus position. The 2-dimensional echocardiographic findings were initially obtained from the left sternal border in the long- and short-axis planes. Apical and subxiphoid views were then taken, and 4-chamber and 2-chamber views were obtained.[21,22] The images were recorded on videotape, and photographs of single-frame findings were taken on Polaroid® or 35 mm black and white film.

Thrombus was defined by echocardiography as a distinct mass of echoes in the intracardiac cavity that was seen clearly throughout the cardiac cycle and that was contiguous with the endocardium.[11] LV aneurysm was defined as a distinct akinetic or dyskinetic bulge interrupting the normal ventricular configuration during systole and diastole.

**Cineangiocardiography:** In patients with mitral valvular disease (Group I), levophase pulmonary angiograms were obtained with the methods described by Parker et al.[1] An 8Fr National Institutes of Health angiographic catheter was inserted into the main pulmonary artery by way of the percutaneous femoral venous route, and 1 ml of 76% sodium meglumine diatrizoate per kilogram of body weight was injected over a 2.5-second period with a power injector. In patients with mitral valve disease (Group I) and those with myocardial infarction (Group II), LV cineangiocardiography was performed with a 7Fr pigtail catheter introduced into the left ventricle by way of the percutaneous femoral arterial route.

Forty milliliters of 76% sodium meglumine diatrizoate was injected into the left ventricle over a 2-second period with a power injector. The LA and LV angiographic studies were performed in the right anterior oblique position with 35 mm film exposed at 50 to 60 frames/s. Cineangiocardiographic criteria for LA thrombus were persistent fixed or mobile filling defects in the body of the left atrium or atrial appendage.[2] LV thrombus was diagnosed if there was evidence of a persistent filling defect in the LV cavity during both systole and diastole.[3]

**Interpretations and measurements:** The computed tomographic findings were interpreted by 3 of the authors (SK, MO, and SM), the 2-dimensional echocardiographic findings by 2 (MH and HF), the angiocardiographic findings by 1 (HT), and the surgical findings by 3 (SKo, SKa, and AS), independently. Measurements of the sizes of the thrombi were attempted as the largest long and short axes on the computed tomographic and 2-dimensional echocardiographic planes.

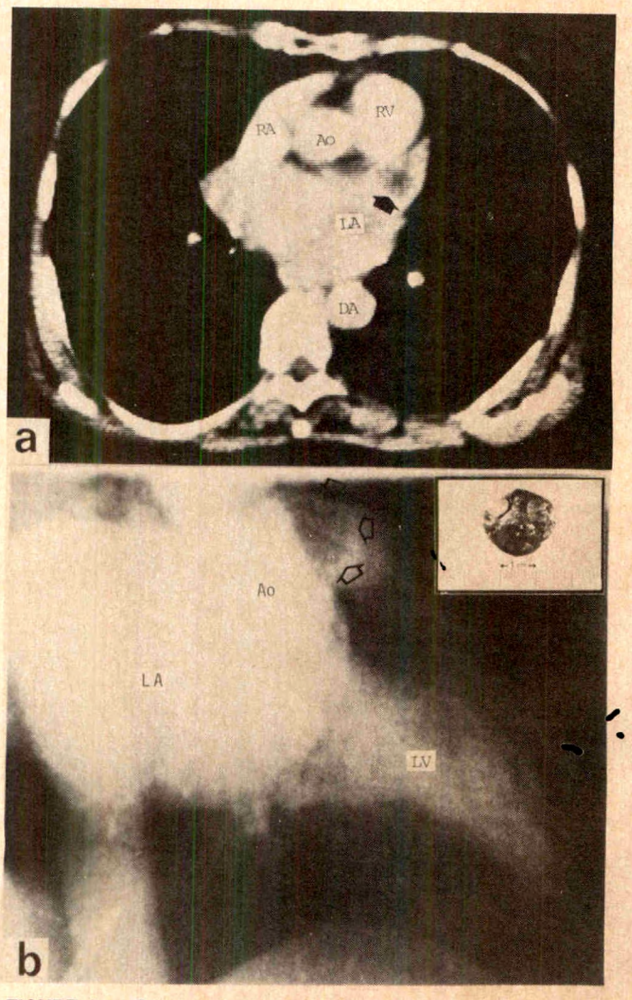

**FIGURE 1. a,** Computed tomogram of a patient with mitral stenosis (Case 2, Group I). There was a small filling defect (1.6 × 1.2 cm) (**arrow**) at the left atrial appendage, which was also identified by cineangiocardiography (**b**) (**arrows**). Open heart surgery later confirmed this to be an organized spherical thrombus 1.5 cm in diameter (**inset**). The thrombus was not revealed by 2-dimensional echocardiography. Ao = aorta; DA = descending aorta; LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

## Results

**Left atrial thrombus:** In 28 patients with mitral valve disease (Group I), 9 LA thrombi were confirmed in 7 patients by open heart surgery (Cases 1 to 5, 7, and 8), and a thrombus was identified in another patient by autopsy (Case 6). No LA thrombus was seen in the rest of the patients by open heart surgery (Table I).

All of the 10 LA thrombi confirmed by surgery or autopsy were delineated by computed tomography in each of the 8 patients. Six of the 10 thrombi in the 8 patients with LA thrombus were identified by 2-dimensional echocardiography. Three of the thrombi overlooked echocardiographically were located in the LA appendage (Cases 1 to 3), and 1 was attached to the lateral wall of the left atrium (Case 8) (Fig. 1 and 2). Three of the 10 thrombi in the 8 patients were not identified by cineangiocardiography. Two were located at the appendage (Cases 3 and 4), and 1 was present at the posterior wall of the left atrium (Case 1). Among 20 patients in whom LA thrombus was not detected by surgery, there was a positive diagnosis of LA appendage by computed tomography (Case 9) and a positive and an equivocal diagnosis was made at the posterior wall of the left atria by 2-dimensional echocardiography (Cases 13 and 14). A false-positive and 2 equivocal diagnoses were made at the LA appendage by angiocardiography (Cases 10 to 12).

Although the possibility of dissolution of the thrombi could not be ruled out completely, no patient received anticoagulant therapy, and the interval from the clinical evaluation to surgery was relatively short, ranging from 6 to 21 days; there was no systemic embolization during this period in these patients.

Thus, the sensitivity in detecting LA thrombus was 100% with computed tomography, 60% with 2-dimensional echocardiography, and 70% with cineangiocardiography. When both positive and equivocal study results were considered to indicate the presence of thrombus, the specificity in detecting LA thrombus was 91% with computed tomography, 75% with 2-dimensional echocardiography, and 70% with cineangiocar-

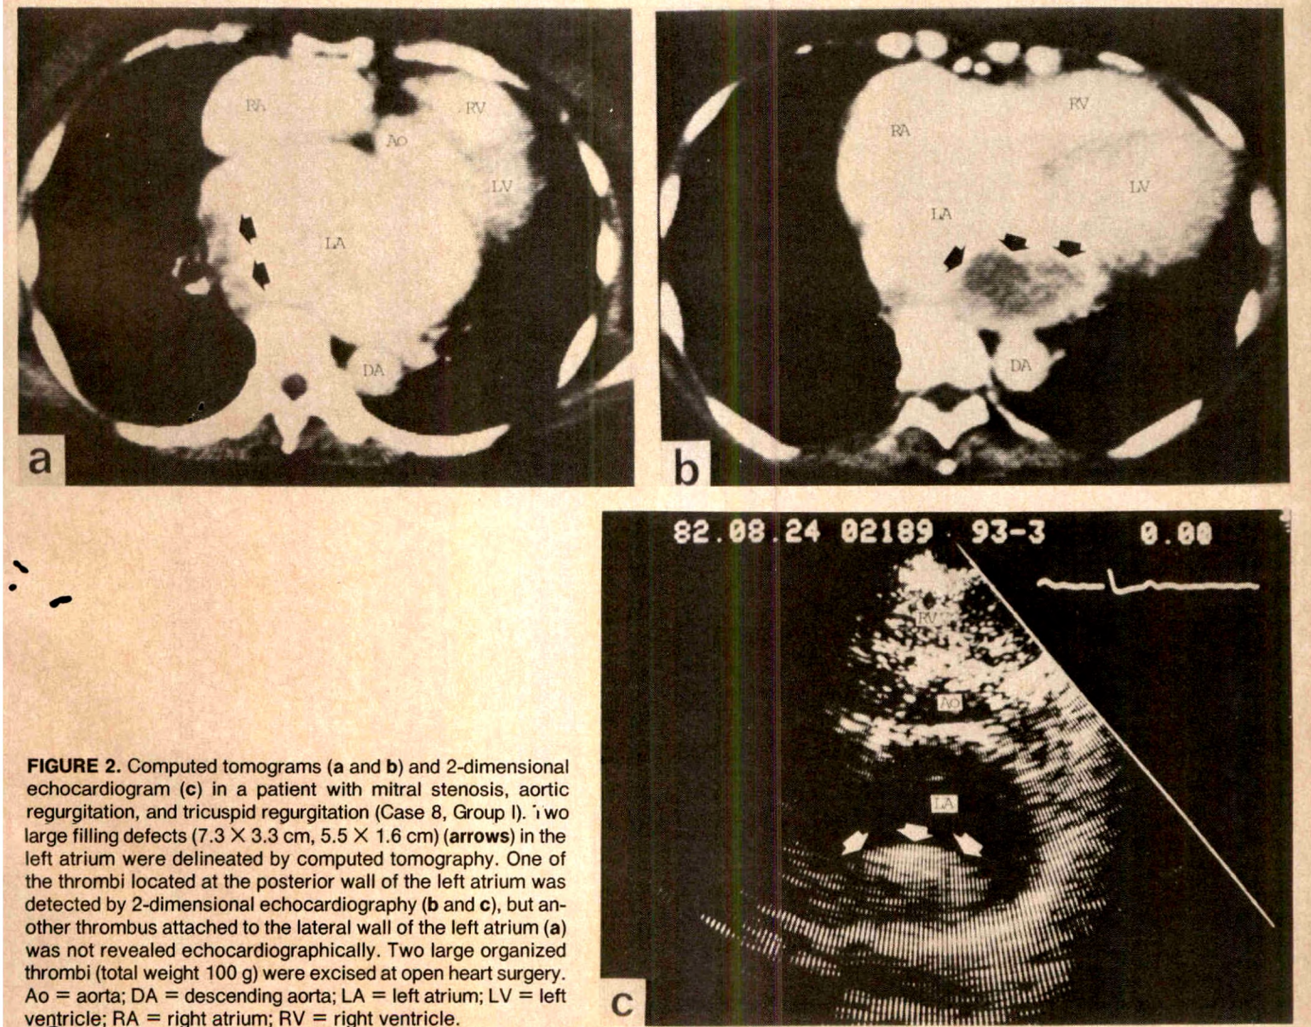

**FIGURE 2.** Computed tomograms (**a** and **b**) and 2-dimensional echocardiogram (**c**) in a patient with mitral stenosis, aortic regurgitation, and tricuspid regurgitation (Case 8, Group I). Two large filling defects (7.3 × 3.3 cm, 5.5 × 1.6 cm) (**arrows**) in the left atrium were delineated by computed tomography. One of the thrombi located at the posterior wall of the left atrium was detected by 2-dimensional echocardiography (**b** and **c**), but another thrombus attached to the lateral wall of the left atrium (**a**) was not revealed echocardiographically. Two large organized thrombi (total weight 100 g) were excised at open heart surgery. Ao = aorta; DA = descending aorta; LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

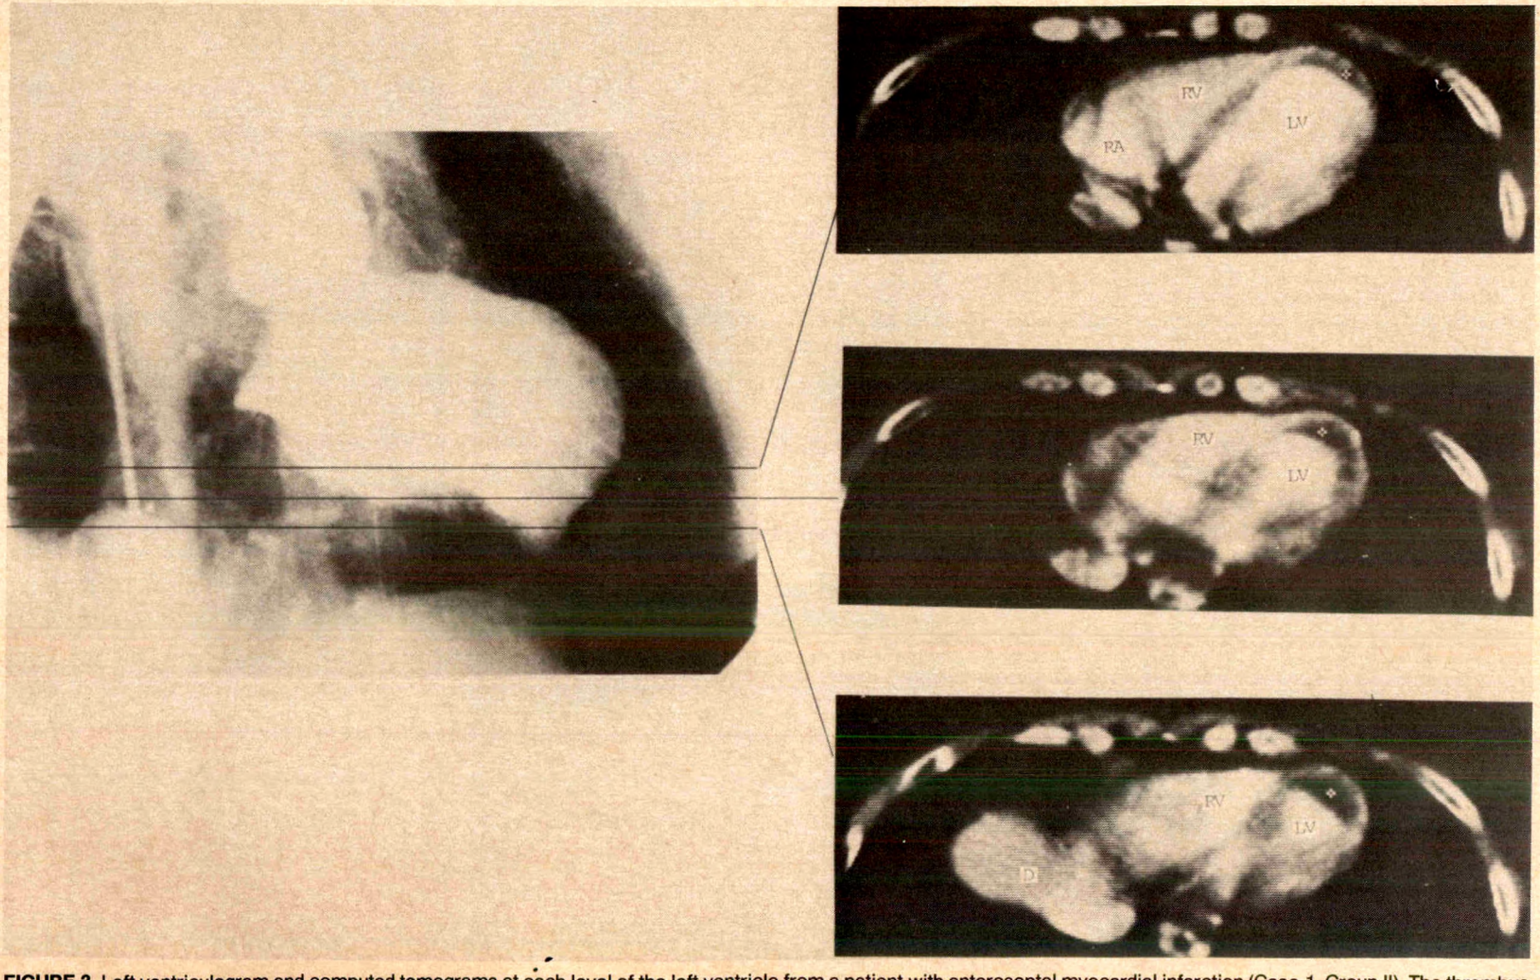

**FIGURE 3.** Left ventriculogram and computed tomograms at each level of the left ventricle from a patient with anteroseptal myocardial infarction (Case 1, Group II). The thrombus is indicated by **asterisks**. D = diaphragm; LV = left ventricle; RA = right atrium; RV = right ventricle.

diography. If equivocal study results were instead considered negative, the specificity in detecting LA thrombus was 91% with computed tomography, 86% with 2-dimensional echocardiography, and 87.5% with angiocardiography.

Five of the 8 patients with LA thrombus (62.5%) and 5 of the 20 patients without LA thrombus (25%) had a history of systemic embolization. The measurements of the thrombi were grossly similar with computed tomographic, echocardiographic, or surgical methods, although strict comparisons were not possible as the planes on which the measurements were attempted were not exactly the same with each method (Table I).

The values of x-ray transparency expressed as computed tomographic numbers ranged from +37 to +68 at the areas of the LA thrombi. The values, however, had no definitive correlation with the pathologic findings of the excised thrombi (Table I).

**Left ventricular thrombus:** There were 10 positive findings, that is, filling defects, compatible with LV thrombi and an equivocal finding by computed tomography (Fig. 3, Table II). There was 1 equivocal and 8 positive echocardiographic findings in the 10 patients with positive findings on computed tomography; satisfactory recordings were not obtained in 1 patient by echocardiography (Fig. 4). The LV filling defects were identified angiocardiographically in all 7 patients with positive computed tomographic findings in whom angiocardiography was performed; the thrombi were confirmed by open heart surgery in 2 patients (Cases 1 and 2) and by autopsy in 1 (Case 3). On the other hand, among the 18 patients in whom thrombus was not delineated by computed tomography, positive findings of LV thrombus were indicated in 1 patient (Case 12) and equivocal findings in another (Case 13) by 2-dimensional echocardiography.

LV aneurysms were noted echocardiographically in 7 of the 10 patients with thrombi proven by computed tomography and in 6 of the 18 patients without thrombus. There was no cineangiocardiographically positive finding in any of the 6 patients with negative computed tomographic findings who underwent LV angiocardiography.

The sizes of the thrombi were similar when measured by computed tomography and 2-dimensional echocardiography, although the comparisons may not be valid due to the differences in the planes at which the mea-

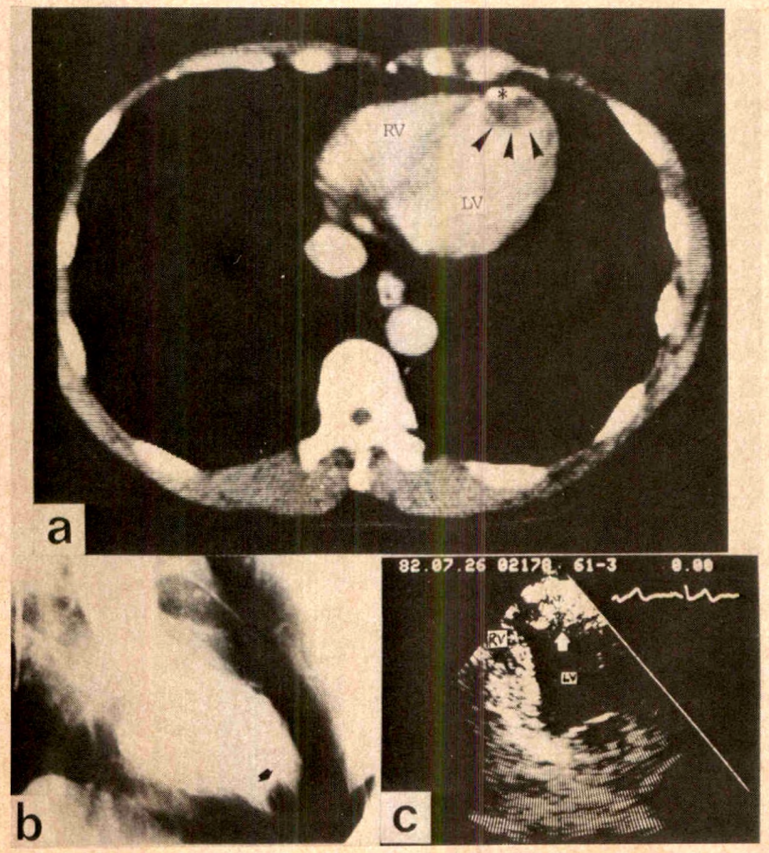

**FIGURE 4.** Computed tomogram (**a**), left ventriculogram (**b**), and 2-dimensional echocardiogram (**c**) of a patient with anteroseptal myocardial infarction (Case 7, Group II). There was a filling defect at the left ventricular apex (**arrows**) in the angiogram and computed tomogram; this was not clearly delineated by echocardiography most probably because of reverberations from the calcified infarct area (**asterisk**) as shown by computed tomography. LV = left ventricle; RV = right ventricle.

surements were attempted (Table II). No history of systemic embolization was detected in any patient in Group II.

## Discussion

The detection of intracardiac thrombus is important regardless of the size of the thrombi because the patients are exposed to the possibility of systemic embolization. Systemic embolization has been reported to originate from rheumatic heart disease in 26 to 40%[23–26] and from myocardial infarction in 22 to 36% of these patients.[23–26]

Thrombus formation was detected in 9 to 17% of patients with mitral valve disease[1,2] and in 14 to 33% of patients with myocardial infarction[11,13,27–29]; in our study, the incidence was higher in patients with mitral valve disease (29%) and similar in those with myocardial infarction (36%). Systemic embolization was encountered in 29 to 60% of patients with LA thrombosis[1,2] and in 5 to 45% of those with LV thrombosis.[11,27,28,30,31] The incidences are not necessarily compatible with those in the present study, which involves a relatively small number of patients: 62.5% of those with LA thrombosis and none of those with LV thrombosis.

**Detection of left atrial thrombus:** Although there has been no report on sensitivity and specificity in the detection of LA thrombus either by echocardiography or cineangiocardiography, the sensitivity and specificity were highest with computed tomography. Mikell et al[8] successfully detected a small LA thrombus 1 cm in diameter, which was located on an artificial valve. In our study, however, only 1 out of 4 LA thrombi lodged in the LA appendage was demonstrated echocardiographically, even though multiple acoustical windows with various sector orientations were used to provide complete imaging of the left atrium. On the other hand, there were also 2 false-positive diagnoses by echocardiography at the posterior wall of the left atrium, if we include an equivocal diagnosis as positive, which was most probably due to reverberations from the aorta or mitral apparatus.

With angiocardiographic methods, there were also 3 false-positive and 2 false-negative findings at the LA appendage. In 1 patient with a false-positive result (Case 10) with a defect at the LA appendage, surgery revealed that the appendage was shrunken without thrombus inside. In 2 other equivocal cases (Patients 11 and 12), thinly stained appendages could not exclude the possibility of atrial thrombus, which was denied at open heart surgery. According to Lewis,[2] the sensitivity in detecting LA thrombi by cineangiocardiography was 71%; this value is similar to that in the present study. However, the puncture of the interatrial septum is possibly associated with dislodgment of atrial thrombi[2]; as a result, we performed levophase pulmonary angiography instead. It is important to visualize the possible thrombi on multiple views to minimize the false-positive or false-negative results. However, angiographic procedures applied to mitral valve disease also include left ventriculography to evaluate coexistent mitral regurgitation or changes in the subvalvular apparatus. Thus, multiprojectional LA angiograms are usually not performed due to the limitation in the permissible volume of angiographic contrast material.

Computed tomography has the advantage of offering uniform slices of the left atrium in an attempt to detect thrombi in unknown areas of this chamber. Computed tomography is not disturbed by the lungs or bones, and slices of the entire atrium can be displayed on a plane including the appendage and lateral wall of the left atrium (Fig. 1 and 2). Although there was a false-positive result in 1 patient with computed tomography (Case 9), the suspected area showed low density (minus computed tomographic value) in a repeated study; this should have been identified as pericardial fat tissue.

In the present study, estimation of the characteristics of the thrombi based on the difference in computed tomographic numbers was unsuccessful. The most probable explanation for this result may be the artifacts in density with adjacent high-density structures such as the cardiac chamber filled with contrast material, as Godwin[16] noted.

**Detection of left ventricular thrombus:** In our study, LV cineangiocardiography, open heart surgery, or autopsy to confirm the existence of LV thrombus was performed in a limited number of patients. Therefore, evaluation of the sensitivity and specificity in detecting LV thrombus with computed tomography or 2-dimensional echocardiography is not possible.

In 7 patients with a positive computed tomographic diagnosis in whom angiocardiography was performed, the LV thrombi were identified angiocardiographically in all; the thrombi were also confirmed by surgery or autopsy in 3. On the other hand, in a patient in whom a small LV thrombus was suspected by computed tomography (Case 11), there was no positive finding by 2-dimensional echocardiography or left ventriculography. Thus, this case might be a false-positive computed tomographic finding, and the confusion was most probably caused by the papillary muscle. The possibility that the thrombus might have dissolved during the intervals between the different diagnostic procedures could not be denied, but this phenomenon is frequently encountered in recent myocardial infarction.[13] In the present study, however, only remote myocardial infarction of more than 1 month's duration was studied. The cardiac apex is the site of most LV thrombi[3,12,29] and, in this study, all of the left ventricular thrombi were located there. Hence, 2-dimensional echocardiographic apical views were valuable in detecting intraventricular thrombus, but an equivocal echocardiographic diagnosis (Case 7) was apparently due to reverberations from the calcified infarct focus (Fig. 4).

The sensitivity in detecting LV thrombus by 2-dimensional echocardiography has been reported as 50 to 95%[11,32,33] and the specificity as 86 to 95%.[10,11,33] The sensitivity in detecting LV thrombus angiocardiographically was reported as 41 to 50%[4,5] and the specificity as 75%.[4] Hence, the sensitivity and specificity of computed tomography in detecting LV thrombus are estimated to be similar to those with other methods, but the demarcation of the thrombus is usually outstanding with computed tomography (Fig. 3 and 4).

The reason for the absence of thromboembolic events

in our patients with LV thrombus is not known. Anticoagulant therapy was used in only 1 of the 10 patients with LV thrombus and in none of the 18 patients without thrombus. There is a possibility that embolic events were clinically silent. Cabin et al[30] reported the incidence of systemic embolization to be as low as 5% in patients with LV thrombus. According to Haugland et al,[34] the incidence of embolization was 24% with recent myocardial infarction and 9% with remote myocardial infarction (more than 3 weeks); all of our patients had remote myocardial infarction of more than 1 month's duration.

**Advantages and limitations of computed tomography:** Computed tomography demands the injection of contrast material by way of a peripheral vein and thus is not completely noninvasive, although we have found no anaphylactic reactions, heart failure, or renal insufficiency induced by this procedure. However, computed tomography avoids the insertion of a catheter into the LV cavity, and the information regarding the presence or absence of thrombus is important in preventing iatrogenic thrombotic events induced by angiographic procedures.

Echocardiography, on the other hand, is a completely noninvasive method. However, there is a definitive limitation in the projection of the echo beam due to surrounding structures such as the sternum, ribs, or lungs. Echocardiography demands high standards of proficiency and, even with a high level of technique, a small thrombus located at the LA appendage is difficult to detect echocardiographically. There is also some uncertainty as to whether newly formed thrombi that have an acoustic impedance similar to that of the blood or cardiac walls can be identified,[7] although it was suggested recently that thrombi can be imaged within days of their formation.[35]

However, in the detection of intracardiac thrombus, computed tomography has the advantage of offering uniform slices of the heart in an attempt to detect thrombi in unknown areas of cardiac chambers including the LA appendage, and the thrombus does not have to be projected in tangent to be detected because of its cross-sectional format.[16]

The stop-action method gated with echocardiography was not applied in the present study. Therefore, it should be noted that the configuration of the various cardiac structures obtained by computed tomography are influenced by the effects of cardiac movements. Fortunately, however, the cardiac movements are relatively limited in enlarged atria with fibrillation or LV aneurysms where intracardiac thrombi are located. In fact, the smallest thrombus detected by computed tomography was a LA thrombus weighing 3.5 g (Case 3, Group I), which was comparable to the smallest ventricular thrombus measuring 2 to 3 $cm^3$ detected with computed tomography by Godwin et al.[16]

**Implications:** The possibility of systemic embolization was 3 times greater in patients with LA thrombus than in those without thrombus (Table I). Therefore, to prevent tragedies connected with systemic embolization, detection of LA thrombus is crucial in determining the timing of open heart surgery or the indications for anticoagulant therapy. Although the effects of anticoagulant therapy for myocardial infarction are a controversial issue, the incidence of thromboembolism has been reported to be significantly reduced with the therapy[36,37]; the detection of intraventricular thrombus is also important in determining the indications for such treatment. As the data presented in this study indicate, computed tomography is useful for the detection of intracardiac thrombus, and we believe this technique is the best one for detecting LA thrombus. Moreover, combined applications of computed tomography with other noninvasive or invasive methods will improve the accuracy of diagnosing intracardiac thrombus.

# Absolute Left Ventricular Volume From Gated Blood Pool Imaging With Use of Esophageal Transmission Measurement

ALAN H. MAURER, MD, JEFFRY A. SIEGEL, PhD, BARRY S. DENENBERG, MD, BLASE A. CARABELLO, MD, ARNOLD K. GASH, MD, JAMES F. SPANN, MD, and LEON S. MALMUD, MD

**A new method for determining absolute left ventricular (LV) volume from equilibrium gated blood pool images was validated in 36 patients by comparing gated blood pool (GBP) imaging with contrast ventriculography (CV) using both Simpson's rule (SR) and area-length (AL) calculations. The technique is geometry-independent and is the first to correct for tissue attenuation with use of an in vivo point source. An orally administered capsule containing 1 to 2 mCi of technetium-99m (Tc-99m) sulfur colloid is used for this purpose. Left ventricular volumes are determined by dividing attenuation and background-corrected count rates obtained from semiautomated LV regions of interest by the count rate per milliliter from a blood sample. The correlation between GBP and CV (SR) was 0.96 (CV [SR] = 0.99 GBP + 1.32 ml; standard error of the estimate [SEE] = 21.2 ml) for diastole and 0.97 (CV [SR] = 0.93 GBP − 0.03 ml; SEE = 11.9 ml) for systole. The correlation between GBP and CV (AL) was 0.92 (CV [AL] = 0.90 GBP + 16.72 ml; SEE = 27.8 ml) for diastole and 0.95 (CV [AL] = 0.87 GBP + 4.56 ml; SEE = 14.4 ml) for systole. The method is noninvasive and can be performed easily as part of routine gated blood pool imaging and analysis.**

Contrast ventriculography is the most frequently used clinical method for measuring absolute left ventricular (LV) volume. However, contrast ventriculography is invasive and requires geometric assumptions regarding the shape of the ventricle.[1–4] Several studies[5–7] have reported that geometry-independent LV volumes can be measured from radionuclide gated blood pool imaging by comparing a background-corrected count rate from the left ventricle with that obtained from a blood sample. However, none of these early reports attempted to correct for tissue attenuation.

Recently, Links et al[8] used gated blood pool imaging to measure absolute LV volume by calculating an attenuation factor for each patient after measuring the depth of the left ventricle and assuming an average linear attenuation coefficient. We have developed a new technique for measuring absolute LV volume which is geometry-independent and corrects for tissue attenuation with use of an in vivo point source.

## Methods

Thirty-six consecutive patients referred for cardiac catheterization were studied. All patients underwent precatheterization radionuclide gated blood pool imaging after giving written informed consent to swallow a small capsule containing a calibrated dose of technetium 99-m (Tc-99m) sulfur colloid and to have a venous blood sample drawn at the conclusion of the radionuclide study. Twenty-eight male and 8 female patients, ranging in age from 34 to 81 years (mean 59), were studied.

Before beginning the gated blood pool study, a #4 gelatin capsule is prepared by placing a 2.9 mm diameter circular piece of filter paper in one half of the capsule and saturating it with a precalibrated dose of 1 to 2 mCi of Tc-99m sulfur colloid. The capsule is then closed and wrapped in a piece of paraffin paper (Parafilm "M"). At the end of the sealed capsule, a 50 cm length of sewing thread is tied to the capsule. A mark is made on the thread at 40 cm from the end of the capsule.

A capsule count rate is then acquired behind a 9.85 cm thick phantom of tissue-equivalent material using a scintillation camera fitted with a low-energy parallel hole collimator and interfaced to a commercial nuclear medicine computer. The camera is peaked for technetium at 140 keV with a 20% window. The phantom is employed to avoid saturation of the camera count rate, which could occur if the capsule were counted in air.

The patient is then positioned in front of the same camera for a standard left anterior oblique 40° view and instructed

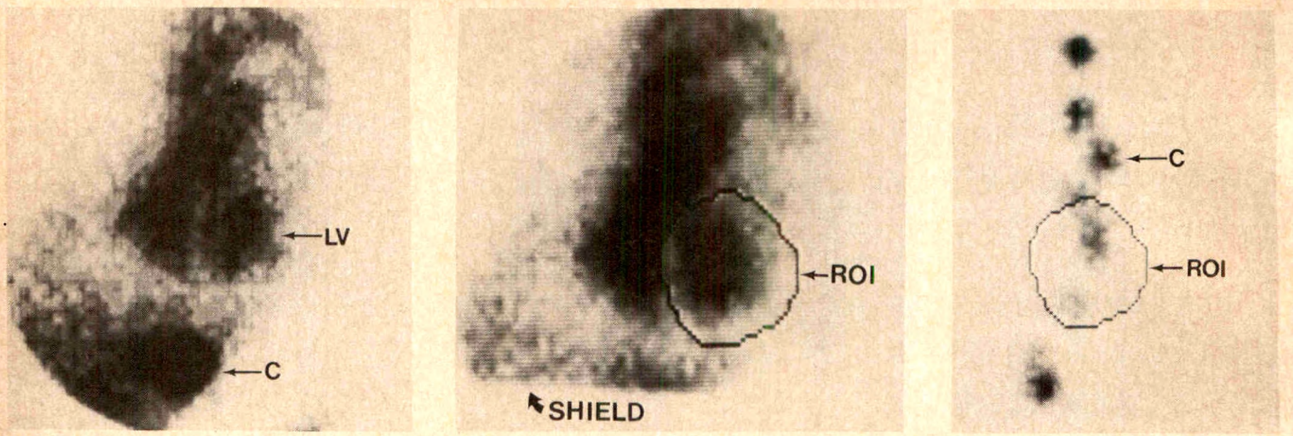

**FIGURE 1. Left,** left anterior oblique image after capsule swallow. The capsule (C) which was swallowed before labeling the patients' red blood cells is shown as it appears in the stomach below the left ventricle (LV). **Center,** left anterior oblique image with shield. A lead shield is placed over the stomach to eliminate counts from the capsule, and gated blood pool imaging is performed without moving the patient. A manual region of interest (ROI) is drawn around the left ventricle. **Right,** esophageal transit study. Several frames from the capsule swallow study are shown to illustrate how the capsule passes through the LV region of interest as it goes behind the left ventricle.

to swallow the capsule. The thread is swallowed with the capsule so that the rate of descent of the capsule can be controlled. As the capsule is swallowed, the esophageal transit is recorded for up to 400 consecutive frames of 0.3 second each. If the esophageal transit takes longer than the allotted time, a remote switch is used to reset the start of computer acquisition. The capsule is observed on the persistence scope until it is positioned behind the left ventricle. This is easily recognized as the intensity of the capsule dims when it reaches the left ventricle. During acquisition the capsule position can also be approximated by the location of the string marker as the distance to the lower esophageal sphincter averages 40 cm. The capsule swallow is considered complete when the capsule enters the stomach.

The patient is kept in the same position and the patient's red blood cells are labeled in vivo with 20 mCi of Tc-99m pertechnetate 20 minutes after previous intravenous administration of stannous pyrophosphate.[9]

After blood pool equilibration, the patient is imaged in the same left anterior oblique 40° position. A lead shield is placed over the stomach (Fig. 1, center). Data are acquired on a magnetic disk in a 64 by 64 matrix until 300,000 counts are collected in at least 1 of 16 frames of the cardiac cycle. After completion of the left anterior oblique image the patient can be moved for acquisition of other views.

When imaging of the patient is completed, a 10 ml venous blood sample is withdrawn into a heparinized syringe from a previously unused venipuncture site. The blood sample is placed in a 100 mm diameter by 15 mm deep petri dish, and the petri dish is counted in air at 10 cm from the collimator face of the camera. Finally, a point source of 200 to 300 $\mu$Ci of Tc-99m pertechnetate is counted in air and behind the 9.85 cm tissue-equivalent phantom in order to derive a build-up factor (see Appendix).

To determine the capsule count rate behind the left ventricle, a LV region of interest at end-diastole is manually drawn from the left anterior oblique 40° gated blood pool study (Fig. 1, center). This region of interest is drawn slightly greater in size than the area of blood pool activity to include the thickness of the left ventricular wall which appears as a halo of decreased activity surrounding the blood pool. If the halo is not easily identified, the thickness of the septum is used to outline the blood pool.

The esophageal transit study is reviewed, and a count profile is generated as the capsule passes through the LV region of interest (Fig. 1, right). A capsule count rate from behind the left ventricle is determined by integrating the count profile curve between points which correspond to the time the capsule is within the LV region of interest (Fig. 2).

End-diastolic and end-systolic count rates from the gated blood pool images of the left ventricle are then obtained from semiautomated regions of interest generated around the left ventricle. We use the same regions generated for routine ejection fraction calculation from a program provided with our nuclear medicine computer system (MUGE, Medical Data Systems). This program uses a combination second derivative and count-threshold algorithm.[10]

The end-diastolic and end-systolic LV counts are corrected for background by using an automatically generated background region which is drawn lateral to the left ventricle in the end-systolic frame. During the processing of the ejection fraction program the computer pauses and allows the operator to accept or reject the automatically generated background. The background region is visually inspected to ensure that it does not include an area of increased activity from adjacent vascular structures (aorta or spleen) or decreased activity from an area such as a fluid- or gas-filled stomach. If the automatically generated region of interest is not considered representative of average background, the operator can manually select a region from the end-systolic image which is adjacent to the left ventricle. In 10 cases the automatically drawn background was rejected because it included increased activity from adjacent vascular structures. In these cases a manual background was selected.

The total time for acquisition of the end-diastolic and systolic images is derived from the average time per frame and the number of cardiac cycles acquired. The mathematical basis for calculation of the transmission factor and ventricular volumes is given in the Appendix.

All patients had contrast ventriculography performed within 24 hours of the gated blood pool study. Cardiac catheterization was performed using either the brachial or per-

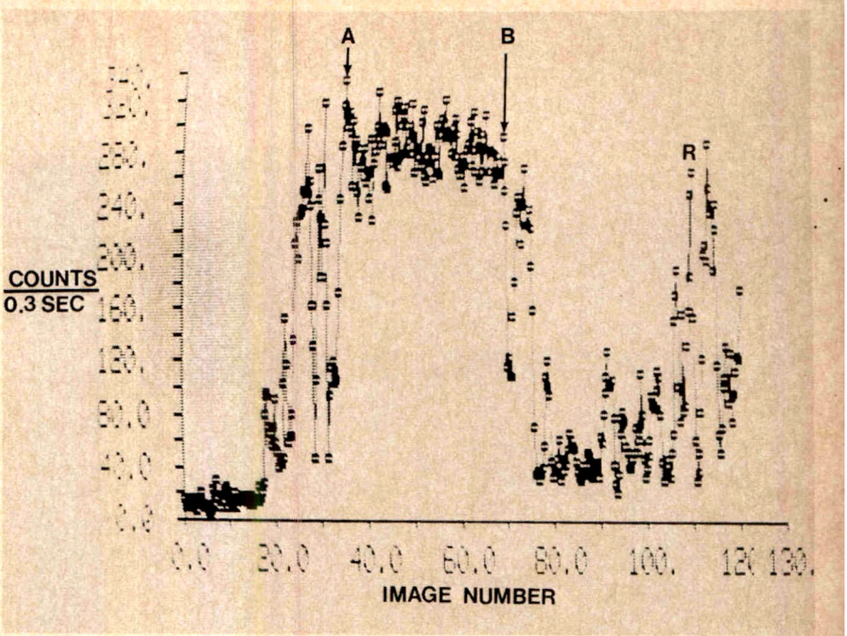

**FIGURE 2.** Capsule count curve from the LV region of interest. The capsule swallow study is used to generate a capsule count curve. Points are chosen (**arrows A and B**) to identify when the capsule is within the LV region of interest. The capsule count rate (total counts from A to B/time from A to B) is derived by integrating the curve between A and B. In the example shown, the study was terminated after 120 images had been collected when reflux (R) of the capsule up the esophagus was noted.

**TABLE I Contrast Angiographic and Radionuclide Volumes**

| | End-Diastolic Volume (ml) | | | End-Systolic Volume (ml) | | | |
|---|---|---|---|---|---|---|---|
| | Contrast Ventriculography | | | Contrast Ventriculography | | | |
| Patient | Simpson's Rule | Area-Length | Radionuclide | Simpson's Rule | Area-Length | Radionuclide | Transmission Factor (T) |

cutaneous femoral technique. Left ventricular end-diastolic and end-systolic volumes were obtained from monoplane or biplane cine films using both the Dodge area-length formula and Simpson's rule and a semiautomatic computer processing system which has previously been described.[11]

The volumes from gated blood pool imaging were compared with the contrast angiographic volumes using a paired $t$ test.

## Results

Of the 36 patients studied, 5 with chest pain were found to have no evidence of coronary artery disease and were otherwise considered normal. Twenty-three had significant coronary artery disease involving either 1 vessel (n = 2), 2 vessels (n = 12), or 3 vessels (n = 9). Eight had regional wall motion abnormalities or an aneurysm. Ten patients had either aortic (n = 6) or mitral (n = 4) valve disease. Of those with valvular disease, 2 also had significant coronary artery disease.

The volumes and transmission factors determined from the radionuclide studies are given together with the volumes obtained by contrast ventriculography in Table I. The correlations for the end-diastolic and end-systolic volumes are shown in Figures 3 and 4.

A paired $t$ test at the $\alpha = 0.01$ level revealed no significant difference between scintigraphic and angio-

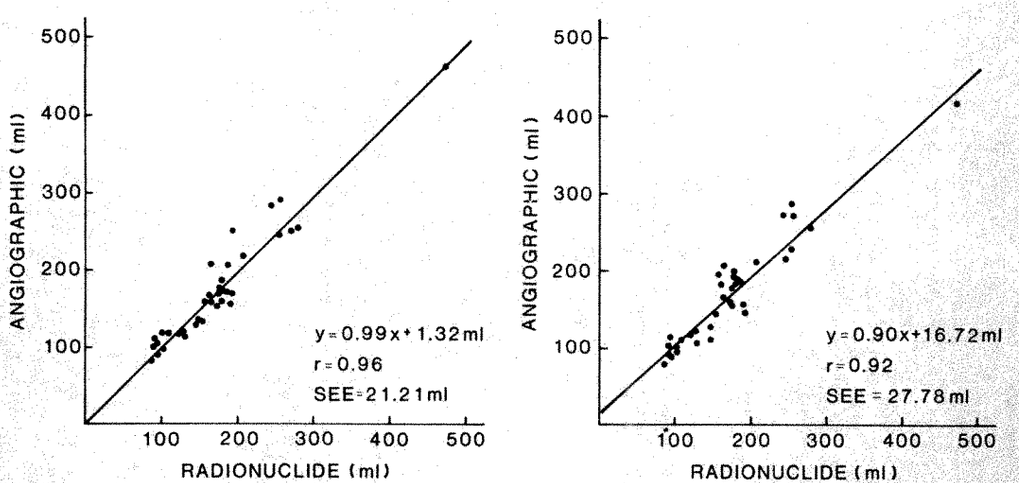

**FIGURE 3.** Correlation of contrast ventriculography with radionuclide end-diastolic volumes. **Left,** Simpson's rule calculation. **Right,** area-length calculation. SEE = standard error of the estimate.

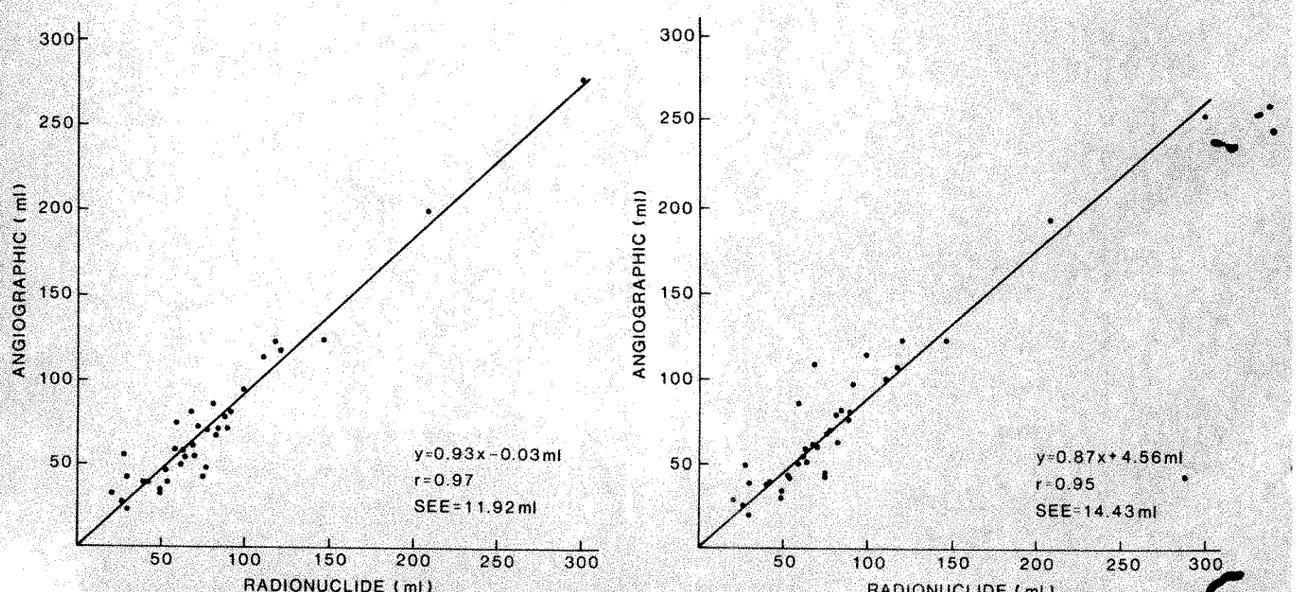

**FIGURE 4.** Correlation of contrast ventriculography with radionuclide end-systolic volumes. **Left,** Simpson's rule calculation. **Right,** area-length calculation. SEE = standard error of the estimate.

graphic end-diastolic volumes using either Simpson's rule (SR) or an area-length (AL) calculation ($p > 0.80$). For the end-systolic volumes the p values were $0.02 < p < 0.05$ for scintigraphy versus contrast ventriculography (CV) using the area-length calculation and $0.001 < p < 0.01$ using Simpson's rule.

There was 1 patient in our series with a very large (465 cc) left ventricle. If this patient were eliminated, there would be little change in the correlation coefficients or standard error of the estimate. Eliminating this patient, the correlation between gated blood pool imaging (GBP) and CV (SR) was 0.93 (CV [SR] = 1.01 GBP − 0.49 ml; standard error of the estimate [SEE] = 21.5 ml) for diastole and 0.94 (CV [SR] = 0.91 GBP + 0.89 ml; SEE = 12.8 ml) for systole. Similarly the correlation between GBP and CV (AL) was 0.88 (CV [AL] = 0.96 GBP + 6.6 ml; SEE = 27.8 ml) for diastole and 0.92 (CV [AL] = 0.91 GBP + 211 ml; SEE = 14.5 ml) for systole.

In 10 randomly selected patients the calculation of the transmission factor was repeated by 2 independent observers. Using a paired $t$ test there was no significant difference at the $\alpha = 0.01$ level between the 2 observers' values ($0.6 < p < 0.8$).

## Discussion

The ability to measure absolute LV volumes using equilibrium gated blood pool imaging has many advantages over contrast ventriculography. The radionuclide method is noninvasive and can be performed at rest and with exercise. Because gated blood pool imaging is geometry independent, it can be used reliably in patients with regional contraction abnormalities.

Previous studies[5–7] have shown that the radionuclide method can give a reliable index of LV volume. However, these early studies required regression equations to convert a volume index to an absolute volume. Links et al[8] were the first to attempt to measure absolute volumes by taking into account attenuation. To do this, however, they assumed a uniform linear attenuation coefficient and had to measure the distance from the chest wall to the center of the left ventricle.

We have developed a new technique which makes no assumptions about attenuation or geometry. We directly measure a transmission factor in each patient. This is done in the same position in which the left anterior oblique gated blood pool image is acquired.

The individual transmission factors measured in our patients ranged from 0.11 to 0.35 with an average of 0.21 ± 0.06. These transmission measurements varied by as much as a factor of 3. If we express the regression curves, as reported by Dehmer et al[6] and Slutsky et al,[5] in the general form $y = mx + b$, where y = contrast ventriculographic volume, x = radionuclide volume index (net ventricular counts/[blood sample counts/ml]), b = y intercept, and m = slope of the line, we see that the slope is the same as 1/T, where T is our measured transmission factor (equation 4, Appendix). Therefore, we can calculate a transmission factor that equals the reciprocal of the slope of the regression line. The regression data from Slutsky,[5] Dehmer,[6] Links,[8] and their co-workers yield transmission factors of 0.13, 0.16, and 0.29, respectively. These values represent average transmission factors which result from grouping their patient data into 1 regression equation. These values are compatible with the range of values we have measured directly. It is evident from the wide range of values we have observed that it is necessary to measure a transmission factor individually for each patient.

Several potential sources of error exist with the radionuclide method. The first is the method of edge detection used to define the systolic and diastolic borders of the left ventricle. The previous studies cited used either manually drawn regions[6,8] or computerized edge detection.[5,7] We have used a semiautomated edge detection program. The reproducibility of this program was previously validated[9] and the use of automated regions of interest makes the technique more reproducible.

A problem common to any radionuclide study is the determination of background. We have used a region of interest drawn adjacent to the left ventricle. Significant differences in volume could be expected if there were large variations in the determination of background.

When the left atrium is enlarged, it may be difficult to separate LV activity from left atrial activity in the standard left anterior oblique image. Counts from the left atrium could affect the accuracy of the LV volume determination. If necessary, a caudal tilt of the collimator can be used to better separate the left atrium and left ventricle. In this series of patients, we did not attempt to systemically evaluate the contribution from left atrial counts.

A large left atrium can also displace the esophagus posteriorly. If the left atrium is enlarged and positioned between the esophagus and left ventricle, it could lead to an underestimation of the transmission factor. We had only 4 patients in this series with large left atria. Atrial enlargement did not appear to be a significant problem in these patients.

In our laboratory the determination of LV volume using this technique adds approximately 45 minutes to the time required for acquisition and processing of a routine resting gated blood pool study. To date, we have found that the capsule swallow is well tolerated by all patients. We have observed much variability in the time needed to complete the swallow. Most younger patients with normal heart size can complete the swallow within 30 to 60 seconds. Older patients with normal heart size may take as much as 5 to 10 minutes for the capsule to reach the stomach. This difference most likely reflects age-related changes in esophageal motility. A large left atrium or left ventricle can also slow esophageal transit. We have found it very helpful to feed the patient a small cracker followed by sips of water when esophageal transit is slow or the heart is enlarged. Little technical skill is required to perform the capsule swallow, but patience is needed when esophageal transit is slow. We have now begun to use the method routinely in our laboratory and are applying the technique to an even larger population of patients.

In summary, we have developed a new technique for determining absolute LV volume from gated blood pool images using an in vivo point source to correct for tissue attenuation. Our early experience with the technique shows a good correlation with contrast ventriculography.

## Appendix

Left ventricular volumes at end-diastole and end-systole were computed for each patient. The basis of these determinations is as follows:

1. *Point source calibration.* A 200 to 300 $\mu$Ci source of Tc-99m is used to determine the build-up factor (B)[12] according to

$$B = \frac{I'}{I'_0} e^{\mu d} \quad (1)$$

where $I'$ = count rate (counts/s) behind phantom from the point source, $I'_0$ = count rate in air from the point source, $\mu$ = linear attenuation coefficient = 0.15 $cm^{-1}$, and d = phantom thickness = 9.85 cm.

2. *Transmission factor for capsule.* Because the capsule is counted behind the phantom, the capsule count rate in air ($I_0$) is given by

$$I_0 = \frac{I_p}{B} e^{\mu d} \quad (2)$$

where $I_p$ = measured capsule count rate behind phantom and B = value obtained from Equation 1. The transmission factor (T) is given as

$$T = e^{-\mu d} = \frac{I_{LV}}{I_0} \quad (3)$$

where $L_{LV}$ = capsule count rate behind the left ventricle and $I_0$ = value obtained from Equation 2.

3. *Left ventricular volumes.* The absolute LV end-diastolic volume (LVEDV) can be calculated as follows:

LVEDV = count rate from left ventricle in the end-diastolic frame (LVED)/ (count rate [counts/s]/ml from blood sample × T) (4)

where LVED = total counts in left ventricle in end-diastolic frame-background counts/ time per frame × number of cardiac cycles. (5)

The count rate for all blood samples was corrected for isotope decay by

$$A_0 = A_t e^{0.693(t-t_0)/T_{1/2}} \quad (6)$$

where $A_0$ = activity of the blood at the midpoint of acquisition of the gated blood pool study (time, $t = t_0$), $A_t$ = activity of the blood sample at midpoint of counting the blood in the petri dish (time, t), and $T_{1/2}$ = half-life of technetium-99m = 6.02 hours.

The left ventricular end-systolic volumes are similarly derived using the end-systolic counts.

**Acknowledgment:** Our cardiac nuclear medicine technologists, Kenneth M. Blasius and Zehra Travis, both made many helpful suggestions and spent much time and effort perfecting the techniques developed here. Milne Hewish did our photography and graphics and Maxine Blob and Carol Barnette helped with the typing.

# Effect of Exercise Protocol on the Left Ventricular Response to Exercise

CARL FOSTER, PhD, DUNCAN S. DYMOND, MD, JAMES D. ANHOLM, MD, MICHAEL L. POLLOCK, PhD, and DONALD H. SCHMIDT, MD,
*With the technical assistance of* JOHN G. CARPENTER, CNMT

**The purpose of this study was to determine whether the left ventricular response during exercise radionuclide angiography would be influenced by exercise protocol. One hundred twenty healthy volunteers (aged 18 to 40 years) performed upright bicycle exercise using 1 of 5 protocols. Ejection fraction was measured using first-pass radionuclide angiography. Exercise protocols were as follows: (1) graded exercise (25 W increase every 2 minutes) to fatigue, heart rate >85% of age-predicted maximum, n = 53; (2) graded exercise to 85% of age-predicted maximal heart rate or to fatigue with heart rate <85% of age-predicted maximum, n = 26; (3) graded exercise to fatigue, with "exercise" imaging performed immediately after exercise, n = 15; (4) abrupt presentation of a supermaximal work load (400 W), n = 10; (5) graded exercise to a work load of 75 W preceding the abrupt presentation of a supermaximal work load (300 to 400 W), n = 16. Protocols 2 and 3, representing less than maximal stress, yield higher ejection fractions than Protocol 1 and may reduce the sensitivity of exercise radionuclide angiography. Protocols 4 and 5, representing supermaximal stress, yield lower ejection fractions than Protocol 1 and may reduce the specificity of exercise radionuclide angiography. Thus, exercise protocol has a significant influence on the left ventricular response during exercise radionuclide angiography.**

Graded exercise testing (GXT) is important in the noninvasive evaluation of patients with known or suspected cardiovascular disease. Hemodynamic and electrocardiographic data obtained during GXT are sensitive and specific markers of coronary artery disease.[1,2] Radionuclide techniques including myocardial perfusion studies with thallium-201 and ventricular function studies with technetium-99m have been shown to improve the diagnostic accuracy of GXT.[3–6]

Interpretation of the exercise radionuclide angiogram depends upon an understanding of the normal and abnormal left ventricular responses to exercise, as well as of the influence of a variety of technical factors. Reports from this and other laboratories have suggested that factors related to exercise protocol may influence the left ventricular response to exercise and, accordingly, the interpretation of diagnostic radionuclide angiography. These include adequacy of exercise,[7] temporal sequence of imaging,[8,9] and degree to which the exercise is graded.[10,11] The present investigation was designed to evaluate the influence of exercise protocol on the left ventricular response during exercise radionuclide angiography. Healthy volunteer subjects were used as subjects for this investigation in order to remove the potentially confounding effect of patients with chest pain and normal coronary arteries who have often been used as control patients in studies of this nature.

## Methods

**Subjects:** The subjects for this investigation were 120 healthy male volunteers aged 18 to 40 years (Table I). All subjects were normotensive, asymptomatic for cardiovascular disease, and demonstrated normal electrocardiographic, hemodynamic, and symptomatic responses during screening

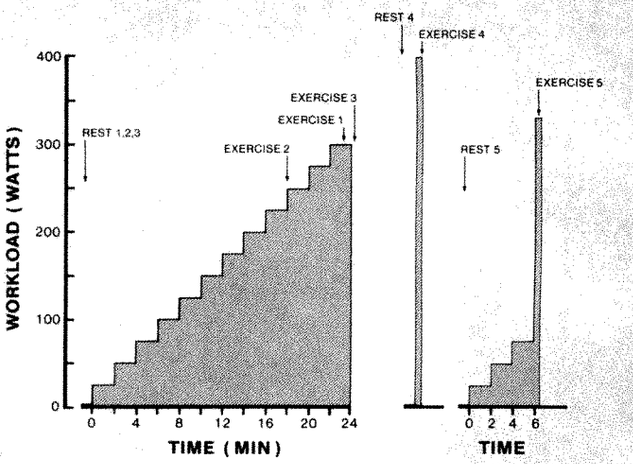

**FIGURE 1.** Schematic presentation of the exercise protocols employed in this investigation. Protocols 1 to 3 were accomplished during or after graded (25 W every 2 minutes) incremental bicycle exercise beginning at a work load of 25 W. Protocols 4 and 5 represent abrupt increases in work load from rest (Protocol 4) or graded submaximal exercise (Protocol 5).

symptom-limited GXT. On the basis of age, lack of symptoms, and normal exercise test results, the likelihood of significant coronary artery disease in this population is very low.[12] Ninety of the subjects (75%) were regular exercisers while the remaining 30 (25%) were sedentary. Twenty-six (22%) had a family history of cardiovascular disease and 18 (15%) were smokers. None were taking medications at the time of study. All subjects provided informed consent before participation.

**Protocol:** Each subject was assigned to 1 of 5 exercise protocols, or was placed in a particular protocol on the basis of responses during the exercise test (Protocol 1 versus Protocol 2). All exercise was performed with the patient in the upright posture on an electrically braked bicycle ergometer (W. E. Collins, Braintree, Massachusetts) at a pedal frequency of 60 to 80 rpm. Resting radionuclide angiograms were obtained before exercise with the subject seated on the ergometer in a position identical to that employed in the subsequent exercise study.

Protocol 1 represented symptom-limited GXT with the subject attaining >85% of the age-predicted maximal heart rate. The exercise radionuclide angiogram was obtained during exercise while the subject continued to pedal the ergometer at the peak work load attained. The work load was 25 W initially and was increased by 25 W increments every 2 minutes. The electrocardiogram ($V_5$) and blood pressure were obtained at the end of each stage of exercise. Fifty-three subjects completed this protocol.

Protocol 2 was identical to Protocol 1 except that the subjects stopped secondary to fatigue before the heart rate reached 85% of the age-predicted maximum (n = 11) or were studied during submaximal exercise when the heart rate reached 85% of the age-predicted maximal heart rate (n = 15). A total of 26 subjects completed this protocol.

Protocol 3 was identical to Protocol 1, except that in addition to the study performed during maximal exercise, an additional study was obtained immediately after exercise. Injection of the radionuclide for the postexercise study coincided with the cessation of exercise. The results of this study have been previously reported.[8] For purposes of comparison with Protocol 1, the postexercise study was taken as the "exercise" study. Fifteen subjects completed this protocol.

Protocol 4 represented the abrupt (<1 second) presentation of a supermaximal work load (400 W) which was continued for 30 seconds. This represents sudden strenuous exercise and has been previously reported from this laboratory.[10] The exercise radionuclide angiogram was during the last 15 seconds of the 30-second work bout. The electrocardiogram was monitored throughout the exercise and blood pressure was measured during the last 15 seconds of exercise. Ten subjects completed this protocol.

Protocol 5 represents the effects of warm-up on the response to sudden strenous exercise and has, in part, been previously reported.[11] Each subject performed 6 minutes of incremental exercise to a work load of 75 W according to Protocol 1. The work load was then rapidly increased to a work load calculated to represent approximately 125% of the subject's previously determined maximal working capacity. This work load was continued for 30 to 60 seconds and the exercise radionuclide angiogram was obtained during the last 15 seconds of exercise. Ten of the 16 subjects in this protocol were also studied at the end of the warm-up period. The electrocardiogram and blood pressure were measured at the end of each stage of warm-up and during the last 15 seconds of exercise.

The structures of Protocols 1 to 5 are depicted schematically in Figure 1. Protocol assignment was not entirely random in that Protocols 3 to 5 were performed as separate studies during a longer period of time in which Protocols 1 and 2 were completed; only physically active subjects were assigned to Protocol 4 (out of concern for subject safety); and subjects completing Protocol 3 were also included in Protocol 1.

**Radionuclide technique:** First-pass radionuclide angiograms were obtained with a computerized multicrystal scintillation camera (Baird System 77, Bedford, Massachusetts). The technique employed has been described previously.[10,11,13,14]

**Statistical methods:** Mean values of heart rate, double product, and left ventricular ejection fraction (LVEF) at rest and during exercise, as well as rest to exercise changes in these variables, were compared using analysis of covariance with exercise protocol as the main effect and age and resting parameters as covariants. When significant differences were noted, individual comparisons were made using either paired or unpaired $t$ tests as appropriate. A p value $\leq 0.05$ was accepted as statistically significant. Comparisons of the serial responses within Protocols 3 and 5 were made using repeated measures analysis of variance and $t$ tests as indicated.

## Results

The mean values and responses of heart rate, double product, and LVEF for each of the protocols are presented in Table II. Analysis of covariance indicated significant main effect (protocol) differences in the comparisons for heart rate ($F = 26.46$, $p < 0.01$), double product ($F = 16.74$, $p < 0.01$), and LVEF ($F = 26.10$, $p < 0.01$), even when the resting values for these param-

eters and age were entered as covariates. Mean values for these variables were tested using $t$ tests for paired and group comparisons. These are presented in Table II. The response of LVEF from rest to exercise during each of the protocols is depicted in Figure 2. No electrocardiographic abnormality was observed during any protocol except in 1 subject who developed inverted T waves during Protocol 4. Blood pressure responses generally conformed to accepted standards for normality.

During Protocol 1, the heart rate increased to 90.2 ± 7.4% of the age-predicted maximal heart rate. This value was significantly ($p < 0.01$) lower than the heart rate attained during the screening test on the treadmill (187.0 ± 12.1 beats/min) and is representative of the difficulty inherent in pedaling the ergometer while seated in front of the scintillation camera as well as the tendency for bicycle exercise tests to be limited by local muscular fatigue. LVEF did not change significantly from rest to peak exercise during Protocol 1. In 21 cases (40%) ejection fraction decreased from rest to exercise. The greatest rest to exercise decrease in LVEF was 18% (76 to 58%) and was associated with normal symptomatic, blood pressure, and regional wall motion responses. The lowest absolute value for peak exercise LVEF observed during Protocol 1 was 54%. Individuals demonstrating increased or decreased LVEF from rest to exercise were compared (Table III). Only the resting LVEF was different between these groups. The change in ejection fraction from rest to exercise was significantly correlated ($r = -0.51$) with the resting ejection fraction and could be described by the following regression equaton: Protocol 1: $\Delta LVEF = 38.6 - 0.52$ (rest LVEF).

During Protocol 2 the heart rate increased to 79.6 ± 6.7% of the age-predicted maximal heart rate. LVEF increased significantly ($p < 0.05$) from rest to exercise. Although the absolute value of the LVEF during exercise (72.7 ± 8.7%) was not significantly ($p = 0.29$) different than in Protocol 1 (70.6 ± 7.3), the rest to exercise change in LVEF (+5.6 ± 9.4%) was significantly ($p < 0.05$) greater than in Protocol 1 (+0.8 ± 7.4%). LVEF decreased from rest to exercise in 5 of 21 cases (24%) and

**TABLE III Comparison of Protocol 1 Subjects Demonstrating Increased or Decreased LVEF From Rest to Exercise***

| | Decreased LVEF (n = 21) | Increased LVEF (n = 32) | p |
|---|---|---|---|
| Age (yr) | 29 ± 9 | 28 ± 7 | 0.61 |
| Height (cm) | 176 ± 8 | 178 ± 5 | 0.21 |
| Weight (kg) | 74 ± 11 | 76 ± 10 | 0.61 |
| Resting heart rate (beats/min) | 71 ± 13 | 69 ± 11 | 0.52 |
| Resting double product (mm Hg × beats/min × $10^2$) | 81 ± 22 | 75 ± 15 | 0.30 |
| Resting LVEF (%) | 74 ± 6 | 67 ± 7 | 0.01 |
| Maximal heart rate (beats/min) | 177 ± 10 | 178 ± 12 | 0.83 |
| Maximal double product (mm Hg × beats/min × $10^2$) | 339 ± 38 | 340 ± 44 | 0.97 |
| Maximal LVEF (%) | 68 ± 7 | 72 ± 7 | 0.06 |

* Mean ± standard deviation.

the lowest absolute value observed was 50%. As in Protocol 1, the resting LVEF was significantly related to the change in LVEF with exercise ($r = -0.52$) ($\Delta LVEF = 45.1 - 0.59$ [rest LVEF]).

During Protocol 3 the heart rate was 89.6 ± 8.2% of the age-predicted maximal heart rate during the immediate postexercise imaging period used for comparison to Protocol 1. This was not significantly different from that observed during Protocol 1. The LVEF increased significantly from rest to immediately after exercise. Both the absolute value of the postexercise LVEF as well as the rest to postexercise change in LVEF were significantly different from Protocol 1. A comparison of the LVEF responses at rest, peak exercise, and immediately after exercise is presented in Figure 3. Heart rate decreased significantly from peak to immediately after exercise although the absolute magnitude of the decrease (5 beats/min) was small. LVEF did not change significantly from rest (67.9 ± 4.1%) to peak exercise (69.2 ± 3.4%), then increased significantly during the postexercise period (80.4 ± 5.2%).

During Protocol 4 there was a significant decrease in

LVEF after the abrupt presentation of sudden strenuous exercise. This response was significantly different than observed in Protocol 1 and occurred despite a comparatively small increase in heart rate and double product.

During Protocol 5 the ejection fraction was decreased during peak exercise relative to the resting studies. This also occurred despite a lower response of heart rate and double product compared to Protocol 1. The serial responses of the 10 subjects studied at rest, during submaximal exercise control studies, and during peak exercise are presented in Figure 3. LVEF increased from the resting (66.0 ± 5.2%) to control exercise studies (70.5 ± 6.3%), then decreased significantly during supermaximal exercise (64.8 ± 8.2%). The decrease in ejection fraction from the submaximal exercise control study to supermaximal exercise was significantly lower than observed without warm-up during Protocol 4.

## Discussion

The general principles of GXT have evolved greatly since Master and Jaffe[16] first introduced the concept of exercise electrocardiography and a standard exercise protocol. These principles are well summarized by Bruce.[15] Protocol 1 conforms to these principles in several important ways: (1) exertion is initially submaximal, (2) increments of work output are small, (3) each stage is of sufficient duration to allow physiologic adaptation, (4) functional capacity is related to exercise duration, (5) the work is familiar to most adults, and (6) exercise is terminated for patient specific factors. Protocol 1, accordingly, represents the reference standard for this investigation. Other studies have demonstrated that various factors may exert a significant influence on the interpretation of diagnostic GXT. These include the adequacy of exercise,[7,17,18] the temporal sequence of imaging,[8,9] and resting LVEF.[18–21]

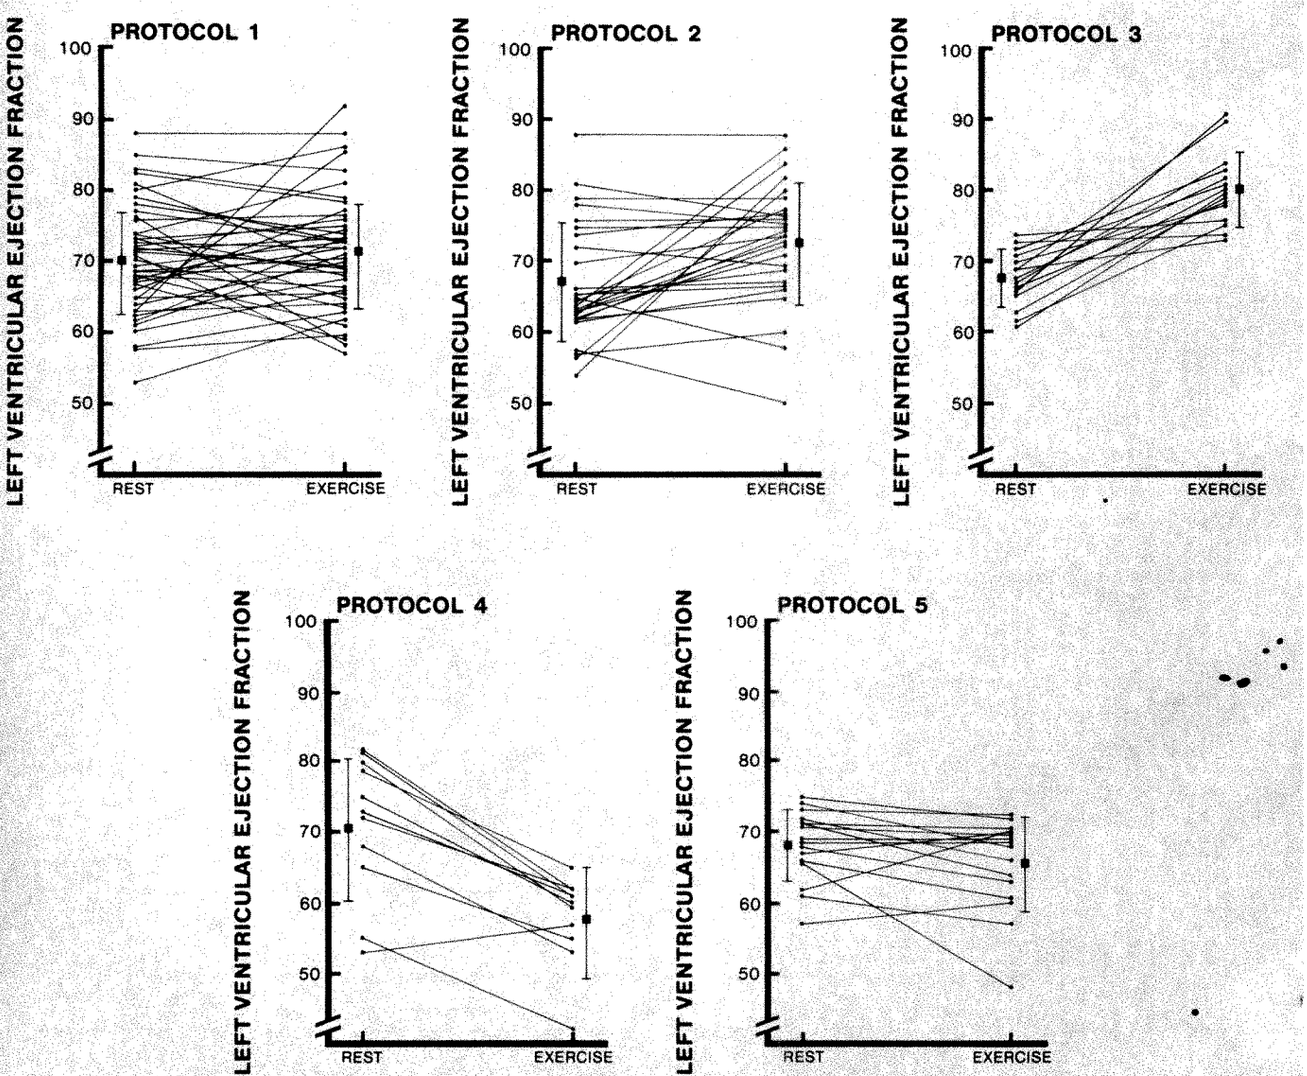

**FIGURE 2.** Rest to exercise changes in LVEF in each protocol. The ejection fraction response was significantly different in Protocols 2 to 5 from that in Protocol 1, which represents the reference standard for this investigation.

During Protocol 2 exercise was stopped either during submaximal exercise when 85% of the age-predicted heart rate had been attained or secondary to fatigue but with a low (<85% age-predicted maximal heart rate) heart rate response. Failure to achieve an adequate heart rate response has been shown to reduce the yield of electrocardiographic abnormalities during treadmill testing,[17] and failure to attain adequate levels of either heart rate[18] or double product[7] has been shown to reduce the diagnostic sensitivity of exercise radionuclide angiography. The same absolute values for heart rate and double product cannot be applied to the present data because of the difference in age between this group of young normal subjects and other series using middle-aged subjects.[7,18] Nevertheless, the results from Protocol 2 suggest that expectations of the LVEF response to exercise based on symptom-limited GXT with a good heart rate response may not be valid with a less satisfactory heart rate response. This observation is of particular importance, since termination of GXT at a fixed percentage of the age-predicted maximal heart rate is a relatively common practice in laboratories employing radionuclide angiography.[18–20] In the context of the less-than-maximal exercise test is the issue of functional capacity. Gibbons et al[20] demonstrated that the LVEF response in patients with chest pain and normal coronary arteries is related to functional capacity. Likewise, reports on exercise testing are replete with observations that good effort tolerance minimizes the prognostic significance of positive electrocardiographic findings,[22] whereas poor effort tolerance is a negative prognostic factor independent of electrocardiographic responses.[23,24]

Protocol 3 represents a common procedural variant in the conduct of exercise radionuclide angiography.[25,26] It allows for adequate levels of exercise but takes advantage of the reduced body motion after exercise to achieve technically better images. The results of the present investigation indicate, however, that the hemodynamic state inferred from radionuclide angiographic studies during the immediate postexercise period may not be representative of that actually occurring during peak exercise. This is true despite only modest differences in peak heart rate and double product. The marked increase in LVEF during the first few seconds after exercise may serve to mask abnormal left ventricular function which occurs during peak exercise.[9] Accordingly, this variant of the technique may reduce the diagnostic sensitivity of first-pass radionuclide angiography. However, as recently demonstrated by Rozanski et al,[27] postexercise imaging may be useful for predicting which patients are likely to demonstrate hemodynamic improvement after myocardial revascularization surgery.

Protocol 4 represents an extreme violation of GXT principles 1 to 3 enumerated earlier. This protocol, which was previously reported,[10] was initially accomplished in order to evaluate a potential model of subendocardial ischemia. It demonstrates that even the normal left ventricle can behave abnormally under certain circumstances. While no clinician would consider initiating an exercise protocol at 400 W, patients

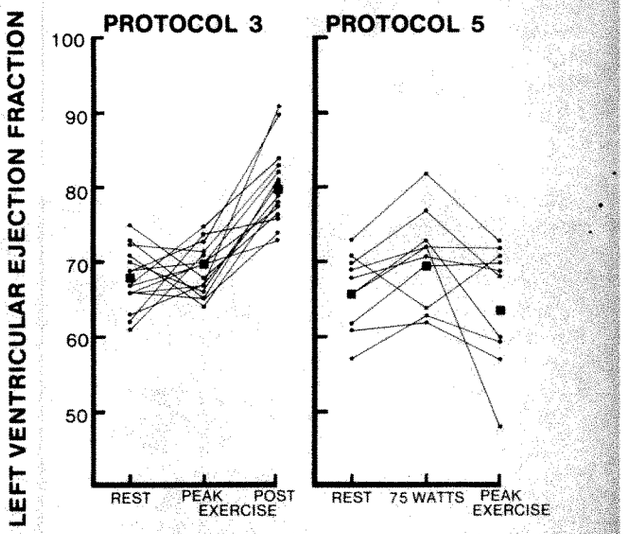

**FIGURE 3.** Serial ejection fraction responses during Protocols 3 (rest, peak exercise, immediately after exercise) and 5 (rest, 75 W exercise, peak exercise).

with very low work capacity may inadvertently start exercise protocols at supermaximal work loads. For example, completion of the first stage of Protocol 1 requires an oxygen uptake of about 600 ml/min. For a 70 kg patient, this represents about 2.5 multiples of the resting metabolic rate. Functional capacity will be lower than this in a small but significant number of patients. Thus, for these patients even the first stage of a well-designed GXT protocol may be functionally equivalent to sudden strenuous exercise in young athletes. Interpretation of the exercise radionuclide angiogram in patients with very low exercise tolerance should, accordingly, be tempered by these findings.

Protocol 5 was accomplished as a follow-up[11] to our published findings in Protocol 4 and, like Protocol 4, represents a somewhat contrived example that, regardless, may be of clinical significance. The results of this protocol suggest that warm-up exercise does not completely normalize the response to abruptly presented supermaximal exercise. The serial studies (Fig. 3) indicate, in concurrence with the findings in Protocol 3, that LVEF can change dramatically during very short time periods and can significantly affect the interpretation of the exercise radionuclide angiogram. As with Protocol 4, the exercise pattern employed in Protocol 5 is unlikely to be intentionally employed clinically. However, if an exercise protocol involves relatively large increments between stages, the work load could go from clearly submaximal to clearly supermaximal and create a situation similar to Protocol 5.

The importance of the resting LVEF on the LVEF response to exercise has been previously discussed.[18–21] The present results confirm these findings. The slope of the regression line between resting LVEF and the change in LVEF (−0.52 in Protocol 1, and −0.59 in Protocol 2) is similar to that described previously and suggests the great importance of resting LVEF to the results of exercise radionuclide angiography. It also

suggests that the LVEF response cannot be viewed outside the context of the total left ventricular response, including changes in left ventricular volume,[18] resting LVEF,[18–21] age,[28] heart rate response,[7,18] and functional capacity.[20] It suggests the utility of a multivariate approach to defining the LVEF response to exercise.[29] It also indicates the importance of accurate measurement of left ventricular volumes during exercise. We have chosen not to report left ventricular volumes in the present series because we, unlike Upton et al,[30] have found left ventricular end-diastolic volume to be poorly reproducible using the angiographic silhouette method and because attempts to develop a geometry-independent method similar to that employed with gated blood pool angiography[31] are not complete.

The results of this investigation obviously suggest that the LVEF response is related to how the exercise load is presented. This suggests that considerable standardization is necessary before literature values can be used to define the "normal" LVEF response and, thereby, provide the reference standard for diagnostic testing. It is pertinent to point out that regardless of the exercise protocol, the LVEF never fell below 48%. This suggests that the absolute value of LVEF may be as important diagnostically as the pattern of LVEF response. This remains an interesting problem for future study since it suggests that a single radionuclide angiogram may be effective, thus minimizing the cost, radiation exposure, and processing time for these studies.

The implications of the present investigation to clinical exercise testing using first-pass radionuclide angiography are clear. The present results indicate that comparatively minor variations in exercise test protocol can yield considerable variations in the LVEF response to exercise. Accordingly, laboratories using this procedure should ensure that the technical aspects of GXT are comparable before relying upon literature-based values for normal and abnormal responses with this procedure. The lack of correlation between the behavior of heart rate-double product and LVEF during the serial studies in Protocols 3 and 5 further suggests that the hemodynamic situation implied by changes in heart rate-double product should not lead to unwarranted assumptions regarding other indexes of left ventricular function. In the context of previous studies relating to the LVEF response[7–11,18–21,28] and of studies demonstrating multiple factors influencing the interpretation of clinical exercise testing,[22–24] the present results indicate that the overall utility of exercise radionuclide angiography in the diagnosis of cardiovascular disease may also depend on compliance with the principles of GXT.

# Influence of Aortic Stenosis on the Hemodynamic Importance of Coronary Artery Narrowing in Dogs Without Left Ventricular Hypertrophy

ROBERT L. FELDMAN, MD, WILMER W. NICHOLS, PhD, JAMES R. EDGERTON, MD, C. RICHARD CONTI, MD, and CARL J. PEPINE, MD

**Coronary hemodynamic effects of controlled left ventricular outflow obstruction simulating aortic valve stenosis were studied in 20 open-chest dogs, with and without graded coronary artery diameter narrowing. Aortic stenosis was regulated so that a mean left ventricular-aortic pressure gradient of 46 ± 20 mm Hg (mean ± standard deviation) was created as both heart rate and stroke volume were unchanged. In addition, during aortic stenosis, mean aortic pressure (105 ± 17 to 84 ± 15 mm Hg, p <0.05) and diastolic pressure time index/systolic pressure time index ratio (1.2 ± 0.3 to 0.6 ± 0.2, p <0.05) decreased and end-diastolic left ventricular pressure (7 ± 4 to 14 ± 6 mm Hg, p <0.05) increased. With no coronary narrowing, mean coronary flow increased during aortic stenosis (53 ± 23 to 62 ± 23 ml/min) as the percentage of diastolic flow increased (83 ± 6 to 89 ± 4) and endocardial/epicardial ratio decreased (1.14 ± 0.16 to 0.95 ± 0.24) (all p <0.05). Peak reactive hyperemic flow also decreased (168 ± 85 to 125 ± 73 ml/min, p <0.05). This value with no coronary narrowing was similar to peak hyperemic flow with 60% narrowing without aortic stenosis. With 90% coronary narrowing, mean coronary flow decreased with or without aortic stenosis. Transmural flow distribution also decreased but was lower during aortic stenosis (0.86 ± 0.19 to 0.61 ± 0.25, respectively; p <0.05).**

**These data suggest that although mean coronary flow is increased during aortic stenosis, endocardial flow may be limited, and coronary reserve exposed during reactive hyperemia appears decreased. When a coronary artery is narrowed, aortic stenosis has an even more important hemodynamic influence on the coronary circulation.**

Aortic stenosis is often accompanied by clinical, electrocardiographic, and histologic findings that suggest myocardial ischemia.[1] These findings usually imply valvular obstruction of hemodynamic importance but do not necessarily indicate accompanying severe coronary artery disease.[1,2] Although most patients with important coronary artery disease and aortic stenosis have angina, in some series approximately 75% of middle-aged patients with aortic stenosis and normal coronary angiograms also have angina. Patients with aortic stenosis have both left ventricular hypertrophy and changes in aortic and left ventricular pressures. Either or both of these factors would conceivably alter left ventricular perfusion at rest and during stress.

The problem of aortic stenosis and myocardial ischemia has been evaluated previously, but results have often conflicted. In patients with aortic stenosis, both normal and reduced left ventricular blood flow per unit mass has been reported.[3–6] A seemingly appropriate increase during isometric or exercise stress has been reported.[4,5] In contrast, reduced flow responses after pharmacologic or ischemic induced vasodilation were also reported.[6,7] The diastolic pressure time index/systolic pressure time index (DPTI/SPTI) ratio was reduced in many patients with aortic stenosis.[4] In short-term animal models, studies usually suggested an increase in basal coronary flow.[8–10] Some studies have also indicated changes in transmural myocardial blood flow and metabolism, whereas others have not.[10–13]

We investigated coronary hemodynamic responses due to acute aortic stenosis in an animal model without left ventricular hypertrophy. This model of aortic stenosis was chosen to allow evaluation of the coronary hemodynamic effects of changes in aortic and left ventricular pressure that occurred during aortic stenosis, separate from changes related to left ventricular hypertrophy. Results were obtained with and without coronary artery narrowing.

## Methods

**Animal preparation:** Twenty large healthy dogs (average weight 29 kg, range 20 to 40) were studied. After premedication (1 mg/kg of morphine), dogs were anesthetized (either 100 mg/kg of alpha-chloralose or 30 mg/kg of pentobarbital) and intubated. Respiration was controlled to maintain arterial blood gases and pH within the physiologic range. A left thoracotomy was performed in the fifth intercostal space, and the heart was supported by a pericardial cradle. Both carotid arteries, the ascending aorta, and either the left circumflex or anterior descending artery were isolated.

**Instrumentation:** Electromagnetic flow probes were positioned on the proximal coronary artery and ascending aorta. Use and calibration of these probes in our laboratory has been described previously.[14–16] Catheter tip micromanometers (Millar) were positioned in the left ventricle from the right carotid artery and left atrial appendage. After confirmation of equally sensitive calibration, the catheter positioned from the right carotid artery was withdrawn to the ascending aorta.

**Creation of coronary narrowings:** Two techniques were used to create controlled reduction of coronary diameter. In 8 dogs, a calibrated snare was used.[14–16] In 12 dogs, narrowings were created with 1 mm long plastic occluders chosen to produce estimated narrowings of 60, 80, and 90%.[14–16]

**Creation of reversible subvalvular obstruction:** Reversible subvalvular obstruction was created using a balloon catheter positioned in the left ventricle (Fig. 1).[10,12] Magnitude of outflow obstruction was controlled by manipulating catheter position or balloon size with fluoroscopic or pressure monitoring or both. The aortic flow signal was monitored to detect the presence or absence of aortic insufficiency.[15,17] In 3 experiments the left ventricular-aortic obstruction was released simultaneously with release of the 10-second coronary occlusion. The purpose of these additional studies was to verify that the coronary bed was at least as responsive during the aortic stenosis period as during control periods.

**Endocardial/epicardial ratio:** The endocardial/epicardial ratio was determined by radioactive microsphere (8 to 10 $\mu$m) technique in 12 experiments.[18] Approximately 3 million spheres were injected into the left atrium. Injections were done when a 90% narrowing was applied to either the proximal anterior descending or the circumflex artery. Thus, either the anterior or posterior region was perfused by an artery with a 90% narrowing, and the other left ventricular region was perfused by an artery without narrowing.

At the conclusion of the experiment, the heart was removed and placed in formalin for 72 hours. The left ventricle was "bread-loafed" into 4 slices. Samples from the anterior and posterior papillary muscle regions of the middle 2 slices were divided into endocardial, midwall, and epicardial pieces and weighed. The number of radioactive counts/gram in the endocardial and epicardial pieces were used to estimate transmural flow distribution. In experiments in which endocardial/epicardial ratios were measured, coronary narrowings were created with plastic occluders. Ratios were combined according to whether perfusion was through an artery with no narrowing or a 90% narrowing.

**Experimental sequence:** Each experiment consisted of 3 periods beginning with a *first control period.* Each period consisted of a "sequence" of duplicate recordings at fast trace (100 mm/s) and slow trace (2.5 mm/s) of flow, and pressure signals before and after a 10-second complete coronary occlusion. This was repeated after a 60 and 80% coronary narrowing had been applied for 5 minutes. The 10-second coronary occlusion was omitted after a 90% coronary narrowing was applied. During the *aortic stenosis period*, the balloon was inflated, positioned, and fixed. Flow and pressure stabilization (±5%) occurred in <5 minutes, and approximately 10 minutes was allowed before measurements were repeated. During the *second control period*, the balloon was deflated. Five minutes after pressure and flow stabilized, recordings were repeated again according to sequences outlined for the first control period.

If differences between repeated responses within a period were >10%, the sequence was not used in this report. When differences ≤10% were found between paired reactive hyperemic responses, the higher value was used. However, if small differences (≤10%) were found comparing systemic or coronary hemodynamic values from the 2 control periods, the value closest to that during aortic stenosis was used for comparison.

**Measurements and calculations:** All measurements were made over at least 10 heart beats and averaged during control and aortic stenosis periods with no coronary diameter reduction and with narrowings estimated at 60, 80, and 90%.

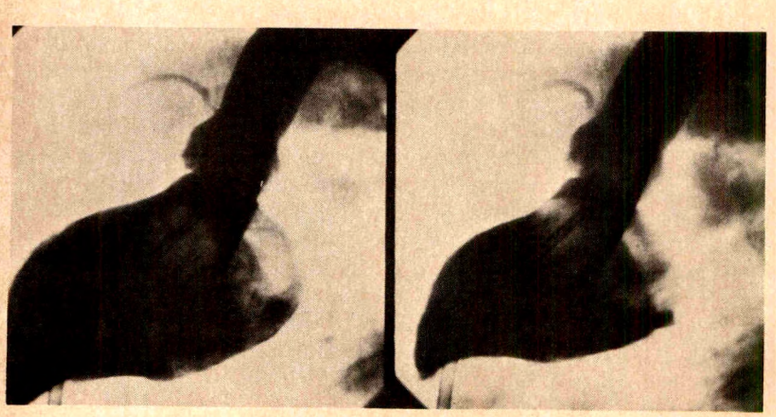

**FIGURE 1.** Left ventriculogram end-diastolic (**left**) and end-systolic (**right**) frames (left lateral projection) showing the balloon catheter positioned in the left ventricle below the aortic valve. No mitral regurgitation was seen.

Total coronary blood flow before 10-second occlusion was used as an index of basal flow. Peak reactive hyperemic flow was used as an index of flow reserve. Indexes of coronary artery resistance were calculated as ratios of mean aortic pressure and mean coronary flow, mean aortic pressure minus left ventricular end-diastolic pressure and mean coronary flow, and late diastolic aortic pressure minus left ventricular end-diastolic pressure and late diastolic coronary flow. Systolic and diastolic phasic coronary and aortic flows were quantified by cutting these areas out and weighing them on an analytic balance. The DPTI/SPTI ratio and the mean systolic pressure gradient were calculated from the left ventricular and aortic pressure signals by weighing the respective portion of the tracing and correcting for calibration. This technique yields a coefficient of variation <1%. Stroke volume was calculated from aortic flow. The systolic ejection period was measured from the initial upstroke of the aortic velocity signal to the point where it crossed the zero baseline. The aortic flow signal position at end-diastole, defined from the left ventricular pressure trace, with the balloon deflated in the left ventricle was taken as zero aortic flow.[15,17]

**Analysis of results and definitions:** Mean values and standard deviations were calculated. An analysis of variance for repeated measures, Duncan's multiple comparison procedure, and a paired $t$ test were used for statistical comparisons. A multiple regression analysis was performed to test the following variables for a relation with the endocardial/epicardial ratio during control and aortic stenosis and the change in each variable from control to aortic stenosis: mean coronary flow, left ventricular systolic and end-diastolic pressure, mean aortic and aortic diastolic pressure, DPTI/SPTI, and mean left ventricular-aortic pressure gradient. A p value ≤0.05 was considered statistically significant.

## Results

Evaluation of recordings with the balloon catheter "fixed" did not suggest variable left ventricular outflow obstruction in any dog. Specifically, no additional changes in either aortic pulse pressure or flow were observed during monitoring. In addition, when the left ventricular micromanometer was moved within the left ventricular cavity, no intraventricular gradients were detected.

In some dogs certain variables were not obtained, and in 2 dogs 2 complete experiments were done. Acceptable aortic velocity signals were not obtained in 5 experiments. In 5 experiments, hemodynamic instability developed during aortic stenosis when the coronary artery was transiently occluded with or without coronary narrowing. Values at these times were excluded from analysis. Because hemodynamic measurements were stable at other times during these experiments, paired data were included.

**Hemodynamic findings (Table I):** During aortic stenosis, the left ventricular-aortic pressure gradient averaged 46 ± 20 mm Hg (range 18 to 122 mm Hg), whereas heart rate and stroke volume were similar to control period values. Left ventricular systolic and end-diastolic pressures increased, and mean aortic pressure decreased during aortic stenosis. The systolic ejection period increased and the DPTI/SPTI ratio (1.2 ± 0.3 to 0.6 ± 0.2) decreased during aortic stenosis. These values were not significantly changed during coronary narrowing.

**TABLE I Summary of Hemodynamic Findings in Acute Aortic Stenosis**

*$p = <0.05$ comparing control and aortic stenosis values.
AS = aortic stenosis; C = control; CBF = coronary blood flow; SD = standard deviation; — = data not obtained.

**Coronary hemodynamic responses (Tables II and III):** Mean coronary flow with no narrowing was higher during aortic stenosis. As the coronary diameter was reduced by 60 and 80%, there was no significant change in coronary flow with or without aortic stenosis. With a 90% diameter reduction, coronary flow was similar with and without aortic stenosis as both decreased compared with values with a lesser amount of coronary narrowing (both $p < 0.05$). The diastolic fraction of coronary flow increased during aortic stenosis. The endocardial/epicardial ratio was reduced during aortic stenosis with no coronary narrowing. With a 90% narrowing, the endocardial/epicardial ratio decreased during the control period and during aortic stenosis compared with their respective values with no coronary narrowing (both $p < 0.05$). The endocardial/epicardial ratio with the 90% coronary narrowing was lower during aortic stenosis ($p < 0.05$).

Coronary artery resistance was lower during aortic stenosis. Resistance calculated as the ratio of mean aortic pressure to mean coronary flow was 2.41 ± 1.27 during control and 1.61 ± 0.70 mm Hg/ml/min during aortic stenosis; resistance calculated as the ratio of mean aortic pressure minus left ventricular end-diastolic pressure to mean coronary flow was 2.27 ± 1.20 and 1.36 ± 0.65 mm Hg/ml/min; and resistance calculated as the ratio of late diastolic aortic pressure minus left ventricular end-diastolic pressure to late diastolic coronary flow was 1.19 ± 0.82 and 0.68 ± 0.35 mm Hg/ml/min (all $p < 0.05$).

In each experiment peak reactive hyperemic flow with no coronary narrowing was reduced during aortic stenosis (Fig. 2). Even in the 5 experiments (Numbers 7, 9, 11, 16, and 20) in which mean aortic pressure was similar during control and aortic stenosis periods, peak reactive hyperemic flow decreased. In general, this decrease was greater in experiments with a larger left ventricular-aortic pressure gradient. A significant ($p < 0.05$) decrease in both control and aortic stenosis reactive hyperemic responses was observed with a 60% narrowing compared with no narrowing and with the 80% narrowing compared with the 60% and no narrowing values during control or aortic stenosis, respectively. Peak hyperemic flow values with a 60 or 80% coronary narrowing were consistently lower during aortic stenosis.

Coronary artery resistance calculated at peak reactive hyperemia was similar during control and aortic stenosis. Resistance calculated as the ratio of mean aortic pressure to mean coronary flow was 0.81 ± 0.47 mm Hg/ml/min during control and 0.88 ± 0.44 mm Hg/ml/min during aortic stenosis; resistance calculated as the ratio of mean aortic pressure minus left ventricular end-diastolic pressure to mean coronary blood flow was 0.76 ± 0.44 and 0.73 ± 0.35 mm Hg/ml/min; and resistance calculated as the ratio of late diastolic aortic pressure minus left ventricular end-diastolic pressure to late diastolic coronary flow was 0.48 ± 0.22 and 0.49 ± 0.23 mm Hg/ml/min, respectively (all $p$ = NS [not significant]).

When the left ventricular-aortic obstruction was released simultaneously with the release of the 10-second coronary occlusion (Fig. 3), peak flow was usually higher (316, 160, and 92 ml/min) than during aortic stenosis

(277, 120, and 76 ml/min) and during control (316, 150, and 84 ml/min), respectively.

During the control period there was no significant relation between the endocardial/epicardial ratio and the coronary and left ventricular hemodynamic variables tested. During aortic stenosis, a lower endocardial/epicardial ratio was usually associated with a lower aortic pressure and DPTI/SPTI ratio and higher values of the left ventricular-aortic pressure gradient and of coronary flow (all $p < 0.05$). When the change in endocardial/epicardial ratio, control to aortic stenosis, was correlated against changes in coronary and left ventricular hemodynamics comparing the 2 periods, no significant relations were observed. However, a trend toward an important relation was found for decreases in mean and diastolic aortic pressures (both $p = 0.08$) from control values to those during aortic stenosis.

## Discussion

Creation of aortic stenosis altered coronary hemodynamic function and increased the coronary hemodynamic importance of a coronary narrowing. These changes occurred in a model without left ventricular hypertrophy. In this model aortic stenosis increased left ventricular systolic and end-diastolic pressures and decreased aortic pressure. Heart rate and stroke volume were unchanged. During aortic stenosis when no coronary narrowing was present, total coronary flow increased and coronary resistance decreased. The endocardial/epicardial ratio was lower during aortic stenosis.

*$p = <0.05$ comparing control and aortic stenosis values.
AS = aortic stenosis; C = control; SD = standard deviation.

With a high-grade coronary narrowing, total coronary flow and the endocardial/epicardial ratio decreased with or without aortic stenosis. However, endocardial/epicardial values remained lower during aortic stenosis.

Coronary flow reserve as measured by reactive hyperemia was reduced during aortic stenosis with no coronary narrowing. This value was similar to that

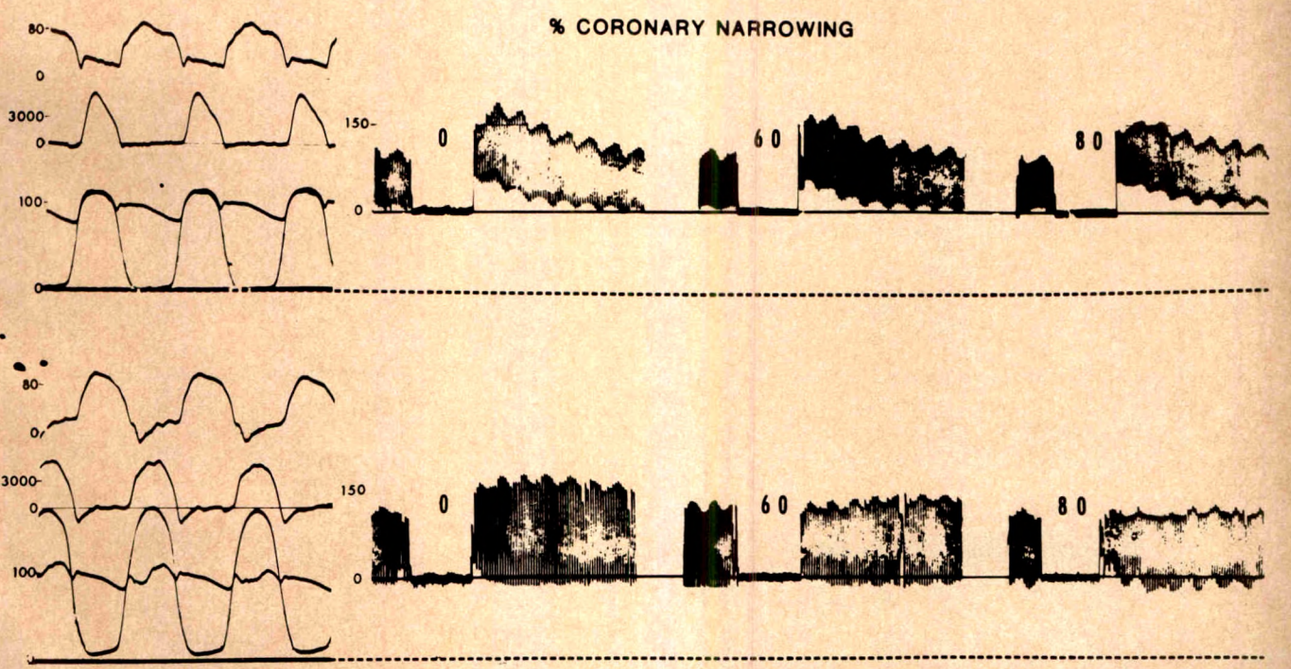

**FIGURE 2. Left,** at fast paper speed, coronary flow, aortic flow, and aortic and left ventricular pressure signals during control (**top**) and aortic stenosis (**bottom**). **Right,** at slow paper speed, phasic coronary flow signals before and during reactive hyperemia after a 10-second coronary occlusion for no coronary narrowing and for 60 and 80% coronary narrowings (control, **top;** aortic stenosis, **bottom**). Reactive hyperemic coronary flow values during aortic stenosis were similar to those during the control period with higher degrees of coronary narrowing. This example was chosen because mean aortic pressure was similar with and without aortic stenosis.

caused by a 60% coronary narrowing without aortic stenosis. Furthermore, aortic stenosis with 60% narrowing caused reductions in coronary reserve similar to those caused by an 80% narrowing without aortic stenosis. Thus, besides potentially inadequate transmural myocardial perfusion during rest and stress, coronary flow reserve could also be limited. The decrease in aortic pressure certainly contributed to the reduction in peak reactive hyperemic flow.[19] However, in the 5 experiments when aortic pressure was similar during the control and aortic stenosis periods, reactive hyperemia was still lower during aortic stenosis (Fig. 2).

Inspection of the phasic coronary flow signal revealed that most dogs had a reversal of flow during early systole during aortic stenosis so that little or no forward systolic flow occurred. This has been observed in dogs with congenital subaortic stenosis[20] and during coronary angiography in patients with aortic stenosis.[21] These changes in phasic coronary flow pattern during aortic stenosis were probably mediated through alterations in aortic and left ventricular pressures.

Results of previous experimental studies of acute aortic stenosis disagreed on the adequacy of endocardial perfusion.[10–12] We found lower endocardial/epicardial ratios during acute aortic stenosis. The reasons disagreements have been reported on the effect of acute aortic stenosis on this value were unclear because experimental models and the magnitude of left ventricular-aortic pressure gradient were similar.[10–12] During aortic stenosis, the increased left ventricular systolic and end-diastolic pressures reflected an increase in demand, whereas the decreased aortic pressure reflected a reduced coronary perfusion pressure. Thus, the DPTI/SPTI ratio decreased, and the value was sufficiently low to predict a reduction in endocardial perfusion even in a model without left ventricular hypertrophy.[22] In a model of chronic subcoronary valvular aortic stenosis accompanied by compensatory left ventricular hypertrophy, Attarian et al[13] found decreases in endocardial perfusion.

In 3 experiments, we released the left ventricular-aortic obstruction simultaneously with the beginning of reactive hyperemia. Peak coronary flow was usually higher than with left ventricular-aortic obstruction maintained or during control (Fig. 3). This seemed to indicate at least 2 things: One was that the reactive hyperemic response would have been higher but was limited during aortic stenosis. The other was that myocardial oxygen demands were probably higher during aortic stenosis, and the reactive hyperemic response after release of the left ventricular-aortic obstruction unmasked increased oxygen demand during aortic stenosis.[23]

These observations were made in an animal model of acute aortic stenosis and conclusions drawn may not apply to animals with chronic aortic stenosis or to patients with aortic stenosis. Although rare, acute aortic stenosis can occur in patients (for example, aortic valve thrombosis or aortic valve replacement with too small a valve in patients with previous aortic insufficiency). Several other factors deserve further comment: (1) These dogs did not have left ventricular hypertrophy. The presence of both left ventricular hypertrophy and changes in aortic and left ventricular pressure that occur during aortic stenosis would probably have additive effects on coronary hemodynamic function. In addition, changes in transmural flow distribution have reportedly been found in some but not all models of left ventricular hypertrophy.[13,24–27] (2) The central-occlusion type of outflow tract obstruction caused by the balloon tech-

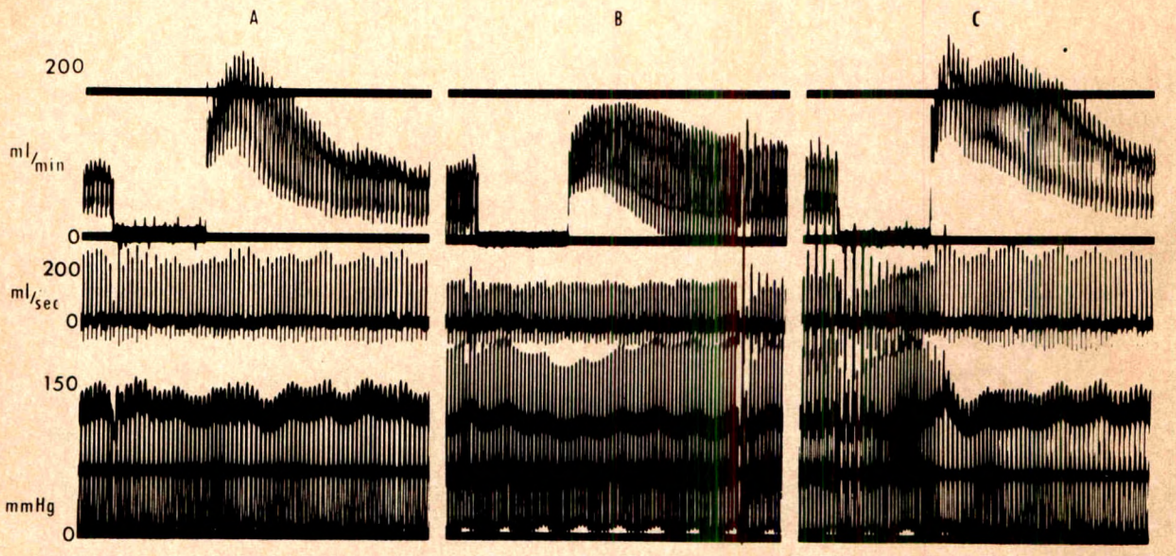

**FIGURE 3.** Example of phasic coronary flow and left ventricular and aortic pressures before and during reactive hyperemia occurring after a 10-second coronary occlusion. Control (**A**), aortic stenosis (**B**), and aortic stenosis with balloon deflation coincident with release of coronary occlusion (**C**) are shown. The reactive hyperemic response was least during aortic stenosis (**B**), intermediate during the control period (**A**), and greatest during aortic stenosis when the balloon was deflated coincident with release of coronary occlusion (**C**).

**TABLE IV Schematic Summary of Effects of Aortic Stenosis and Coronary Narrowing on the Endocardial/Epicardial Flow Ratio and on Total Coronary Flow During Reactive Hyperemia After Coronary Occlusion**

| Animal Model | Coronary Blood Flow | |
|---|---|---|
| | Endocardial/ Epicardial Ratio | Peak Reactive Hyperemic Flow |
| Coronary narrowing | ↓ | ↓ |
| Aortic stenosis | ↓ | ↓↓ |
| Aortic stenosis + coronary narrowing | ↓↓ | ↓↓↓ |

nique differs from the central-open orifice type associated with stenosis of the aortic valve. Although the aortic velocity signal had a normal shape, changes in flow and turbulence near the coronary ostia probably differ in central-occlusion and central-open left ventricular outflow obstruction. (3) Both the left ventricular outflow obstruction and coronary narrowings were maintained for relatively short periods of time. Compensatory left ventricular or coronary circulatory alterations occurring over longer periods could not be assessed. (4) We have shown previously that the length of a coronary stenosis,[14,16] as well as number of stenoses in a vessel,[16] has important coronary hemodynamic effects. (5) Although the calibrated snare technique to create coronary narrowing has been used by several investigators,[14–16,28,29] the precise percentage of narrowing and the ability to precisely reproduce each percentage of narrowing is open to question. Because of possible limitations of the snare technique relative to being able to precisely reproduce a coronary narrowing in the dogs, we used plastic occluders to create coronary narrowings where endocardial/epicardial ratios were measured.

*In summary*, changes in aortic and left ventricular pressures that accompany aortic stenosis can potentially cause decreases in the portion of coronary flow perfusing the endocardium and in total coronary flow during stress (for example, mimicked by reactive hyperemia after coronary occlusion). The coronary hemodynamic effects of coronary narrowing and aortic stenosis seem additive because endocardial perfusion and total flow during reactive hyperemia decreased more in the presence of both, than with either alone (Table IV). These coronary hemodynamic changes occurred even in a model without left ventricular hypertrophy which has an additional effect on coronary flow.

# Topographic Changes in the Left Ventricle After Experimentally Induced Myocardial Infarction in the Rat

CHARLES S. ROBERTS, BA, DEREK MACLEAN, MD, EUGENE BRAUNWALD, MD, PETER R. MAROKO, MD, and ROBERT A. KLONER, MD, PhD

**The factors that determine the thickness of transmural myocardial infarcts are unknown. Therefore, the relation between the size and thickness of transmural infarcts in 67 rats 21 days after occlusion of the left main coronary artery was studied. On examination of histologic sections, infarct size was determined by planimetry and expressed as a percentage of the left ventricular (LV) area, and thickness was expressed as a percentage of noninfarcted ventricular septal wall thickness. The circumferential length of the infarcted ventricle was measured in millimeters, as well as the circumferential length of the noninfarcted ventricular septum. Septal wall thickness was similar in rats with transmural infarcts and in sham-operated rats. No significant correlation was observed between infarct size and thickness ($r = 0.10$) or between circumferential length of the infarct and infarct thickness ($r = 0.17$). However, large ($\geq 20\%$ of the left ventricle, $n = 37$) and small ($<20\%$ of the left ventricle, $n = 30$) infarcts which were similarly thin ($37 \pm 1\%$ and $34 \pm 2\%$ of septal wall thickness, respectively) affected LV topography differently. Large infarcts resulted in a 23% greater loss of myocardium ($p < 0.001$), greater expansion of the LV cavity ($18 \pm 9$ mm$^2$ compared with $14 \pm 1$ mm$^2$ in small infarcts, $p < 0.005$), and lengthening of the septal wall ($7.2 \pm 1.1$ mm and $6.7 \pm 1.0$ mm in large and small infarcts, respectively [$p < 0.05$], and $6.3 \pm 0.1$ mm in shams). Increase in cavity area and septal length in infarcted ventricles suggested a volume overload hypertrophy, which at 3 weeks was nonetheless inadequate to provide as much normal muscle as was present in sham-operated rats. In an additional 9 rats with subendocardial infarctions (involving $<75\%$ of the LV wall from endocardium to epicardium), the LV walls were thicker ($94 \pm 5\%$ of septal wall thickness, compared with $35 \pm 1\%$ for transmural infarcts, $p < 0.001$) and an inverse correlation was observed between infarct size and thickness. In conclusion, neither the size of a transmural infarct in rat nor the circumferential length of infarction determines the thickness of the infarct; however, infarct size does affect LV topography by increasing LV cavity area and the length of the noninfarcted septal wall. Subendocardial infarcts result in less myocardial thinning than do transmural infarcts.**

It is now appreciated that the left ventricular (LV) topography after myocardial infarction is not static but that this chamber may undergo varying degrees of thinning of the infarcted area, hypertrophy of the noninfarcted walls, and dilatation of the cavity. It has been suggested that thinning and expansion of the infarct may be associated with poor cardiac function, increased mortality rates, and ventricular wall rupture.[1,2] Little information is available concerning the determinants of these topographic changes. This study assesses whether the size (percentage of LV area) or circumferential length of a transmural infarct are important factors in determining the ultimate transmural thickness of the myocardial scar and in the development of hypertrophy of the remaining normal myocardium. Hearts in 76 rats were examined 21 days after coronary occlusion, a time when scar formation is complete.[3] In this animal model, the free anterior wall of the left ventricle is infarcted and the ventricular septum is spared.[3,4]

## Methods

A retrospective analysis was performed on the hearts of 76 rats that had been subjected to coronary occlusion and 35 rats that had been subjected to a sham operation. Some rats had been used as nontreated controls in a previous study.[3] The operative techniques are described elsewhere,[3,4] but, briefly, thoracotomies were performed in male albino Sprague-Dawley rats, weighing 250 to 300 g, under ether anesthesia, and the left main coronary artery was occluded 1 to 2 mm from its origin. Other than anesthesia, these rats received no pharmacologic agents. The chests were closed and the rats allowed

to recover. Twenty-one days after occlusion, the rats were reanesthetized and the hearts were excised. Sham-operated rats, without coronary occlusion, also were killed at 21 days after thoracotomy and served as controls. After fixation in 10% phosphate-buffered formalin for ≥48 hours, the ventricles were cut into 4 transverse slices 2 to 2.5 mm thick in a plane parallel to the atrioventricular groove. The slices were dehydrated, cleared, embedded, and cut into sections 5 μm thick, which were mounted on 5 × 5 cm glass slides and stained with hematoxylin-eosin and Mallory's stain for connective tissue.

**Measurement of extent of infarction:** The 2 largest sections from each heart which traversed the infarct were projected onto a screen and the following 3 areas were traced separately on paper: (1) the area of the infarct, which was clearly visible as darkly staining blue tissue, (2) the area enclosed by the LV endocardial circumference, and (3) the area enclosed by the LV epicardial circumference (Fig. 1). The areas were measured by videoplanimetry as described elsewhere.[5] The LV area in each section was calculated by subtracting the area enclosed by the endocardial circumference (LV cavity area) from that enclosed by the epicardial circumference. The viable LV myocardial area was determined by subtracting the infarct area from the LV tissue area. The extent of the infarct within the endocardial and epicardial ventricular rings (infarct size) was calculated as the ratio of infarct area to LV area and expressed as a percentage. Values were first determined for each section; the 2 sections of each heart were then averaged. Therefore, in this report the term *infarct size* is used to represent the percentage by area of the LV rings which developed necrosis.

The extent of infarction was also analyzed in another fashion. The circumferential lengths of the infarcts and of the noninfarcted septal wall were measured approximately midway between endocardium and epicardium from enlarged projections and expressed in millimeters (Fig. 2). The values for the 2 sections of each heart were averaged.

**Measurement of anterior free wall thickness containing infarct:** The same 2 histologic sections utilized for the measurement of infarct size were projected onto a screen and magnified 12.5 times. The transmural thickness, from endocardium to epicardium, of the anterior free wall containing infarct and of the septal wall was measured every 1.6 mm along these circumferences (Fig. 2). The thickness was measured along an axis perpendicular to the endocardial and epicardial outlines. These multiple measurements of thickness were averaged to arrive at a single anterior free wall thickness and septal wall thickness for each section. LV free wall thickness containing infarct was expressed as a percentage of noninfarcted ventricular septal thickness. Values were first determined for each section, then averaged to obtain a single value for each heart.

The sham-operated rats were analyzed in a similar fashion. Since none had infarcts, an infarct size ratio could not be determined and only LV muscle area was calculated. In addition, rather than infarct thickness, the anterior LV free wall thickness was measured to allow calculation of the ratio of free wall to septal wall thickness.

**Statistical methods:** The data are presented as mean ± standard error of the mean and compared using Student's *t* test. To determine whether there was a correlation between infarct size and thickness (ratios), the family regression test was used to provide a coefficient of correlation.

## Results

In 67 rats that developed transmural myocardial infarcts (Table I), septal wall (noninfarcted tissue) thickness (2.6 ± 0.1 mm) was similar to that in 35 sham-operated rats (2.7 ± 0.1 mm, difference not significant [NS]). Transmural infarcts resulted in the following significant alterations in LV topography when compared with the sham-operated controls: (1) LV free wall thickness was markedly reduced in the infarcted region (ratio of infarcted to noninfarcted septal wall was 35 ± 1% compared with 112 ± 2% in sham-operated controls ($p < 0.001$); (2) total LV tissue area was reduced by approximately 30% (38 ± 1 $mm^2$ compared with 53 ± 1 $mm^2$, $p < 0.001$); viable LV myocardium was reduced by 42% (31 ± 1 $mm^2$ compared with 53 ± 1 $mm^2$ in shams, $p < 0.001$), (3) the area enclosed by the endocardial circumference was approximately 250% greater (16 ± 1 $mm^2$ in infarcted rats compared with 6 ± 0 $mm^2$

Circum = circumferential; NA = not applicable.

in sham-operated controls, $p < 0.001$); and (4) the circumferential length of the noninfarcted septal wall was greater (7.0 ± 0.1 mm in infarcted compared with 6.3 ± 0.1 mm in sham-operated rats, $p < 0.001$). No significant correlation was observed between infarct size and thickness ($r = 0.10$). No correlation was observed between the circumferential length of the infarct and infarct thickness ($r = 0.17$).

When the 67 rats with transmural infarcts were divided into 37 with large infarcts (≥20% of LV muscle area) and 30 with small infarcts (<20% of LV muscle area), the ratio of infarct to septal wall thickness was similar (37 ± 1% and 34 ± 2%, p = NS) (Fig. 3, top and center), and neither group showed a significant correlation between infarct size and infarct thickness ($r = 0.14$ for both groups). Large and small infarcts, however, differed in their effect on LV topography. Larger infarcts resulted in larger LV cavity areas (18 ± 1 $mm^2$ in large compared with 14 ± 1 $mm^2$ in small infarcts, $p < 0.005$), and greater circumferential length of the septal wall (7.2 ± 1.1 mm compared with 6.7 ± 1.0 mm in small infarcts, $p < 0.05$). The septal wall thickness was similar in both groups (2.6 ± 0.1 mm and 2.7 ± 0.1, $p > 0.2$). Viable LV myocardial area was less in larger compared with smaller transmural infarcts (27 ± 1 $mm^2$ and 35 ± 1 $mm^2$).

Nine rats had subendocardial myocardial infarcts involving <75% of the LV wall from endocardium to epicardium. In these rats, the thickness of the anterior LV free wall in the subendocardium was significantly greater (2.3 ± 0.1 mm) than in those with transmural infarcts (0.9 ± 0.0 mm, $p < 0.001$). Consequently, the ratio of the thickness of the infarcted LV free wall to that of the noninfarcted subendocardial wall in the 9 rats with subendocardial infarcts (94 ± 5%) (Fig. 3 bottom), was significantly greater than in the 67 rats with transmural infarcts (35 ± 1%, $p < 0.001$) (Table I). Unlike transmural infarcts, a moderate negative correlation was observed between subendocardial infarct size (percentage of LV area) and wall thickness (percentage of septal wall thickness) (wall thickness = −1.45 infarct size + 117.8, $r = -0.70$, $p < 0.05$). There was a weak negative correlation between circumferential length of infarction and anterior wall thickness in these 9 rats ($r = -0.41$). Subendocardial infarcts were associated with significant lengthening of the septal wall compared with the sham-controls. A significant increase was observed in LV cavity area compared with shams and a trend toward a smaller cavity area compared with transmural infarcts. Viable LV myocardial area was significantly greater in subendocardial (38 ± 3 $mm^2$) compared with transmural myocardial infarctions (31 ± 1 $mm^2$, $p < 0.01$). The thickness of the septal wall was similar between transmural and subendocardial infarcts (2.6 ± 0.1 mm and 2.5 ± 0.1 mm, p = NS), and the circumferential length of the infarcted LV wall was similar between transmural and subendocardial infarcts (8.1 ± 2.3 mm and 9.9 ± 0.9 mm, p = NS).

## Discussion

This study suggests that in transmural myocardial infarcts in the rat, LV free wall thickness containing infarct is not a function of the amount of myocardium

infarcted, measured as a percentage of LV area or measured circumferentially. A transmural infarct involving only a small portion of the LV free wall may be as thin as one which involves the entire LV free wall (Fig. 3, top and center). Twenty-one days after coronary occlusion in our rats, transmural infarcts were approximately one-third the thickness of the LV free wall in sham-operated rats.

Transmural infarcts did not cause an increase in thickness of the ventricular septal wall but did cause a circumferential lengthening of the septum, which was not infarcted in any animals. The lengthening of the septum without an increase in septal thickness suggests a volume overload-type of hypertrophy in the nonischemic myocardium, that is, an increase in cell length without an increase in cell diameter. Since the viable LV myocardium was smaller in area in infarcted ventricles compared with sham-operated animals, the degree of hypertrophy was inadequate at this time. Whether the muscle eventually hypertrophies to equal that in sham-operated animals remains to be determined. This increase in septal length coupled with an increase in LV cavity area initially may serve to compensate for depressed LV function through operation of the Frank-Starling mechanism. Long-term volume overload may result in deleterious changes within the myocardium. It remains to be determined whether agents which reduce preload (diuretics), LV cavity area (digitalis), or afterload (vasodilators) administered shortly after infarction would prevent cavity dilatation and the lengthening of the septum, and perhaps improve long-term LV function.

Although there was no difference in anterior free wall thickness or septal wall thickness between large and small transmural infarcts, the 2 did differ in some respects. Larger infarcts were associated with greater lengthening of the noninfarcted septum, a larger LV cavity area, and greater loss of viable myocardium compared with smaller infarcts. The profound increase in the size of the LV cavity in rats with large infarcts may be due to several factors including loss of tissue, volume overload hypertrophy of the viable septum, and the process of myocardial infarct "expansion." A recent study suggests that this latter process occurs within the first week of infarction in rats.[6]

Subendocardial infarcts resulted in anterior free LV walls which were only slightly thinned compared with the noninfarcted septal wall or the thickness of the LV free wall in sham-operated rats. In subendocardial, but not transmural infarcts, a correlation between infarct size and infarct wall thickness was observed. Subendocardial infarcts did not cause an increase in thickness of the noninfarcted ventricular septal wall, but, similar to transmural infarcts, did cause lengthening of the noninfarcted septum. Subendocardial infarcts resulted in an increase in LV cavity area compared with shams; the degree of dilatation was less than that observed with large transmural infarcts.

Our observations may be relevant to new clinical approaches in treating patients with evolving myocardial infarction. Recently, coronary reperfusion has been shown to be both safe and feasible in the early phases of acute myocardial infarction.[7,8] Previous animal studies have shown that early reperfusion may interrupt the normal evolution of an infarct and result in a subendocardial rather than a transmural infarct.[9] Thus, it is possible that early coronary reperfusion will result in less wall thinning and possibly less LV cavity dilatation.

**FIGURE 3.** Photomicrographs of transverse sections of rat left ventricles subjected to coronary occlusion for 21 days. **Top,** large transmural infarction of the entire free wall showing considerable thinning of the infarct compared with the septal wall. **Middle,** small transmural infarction of the anterior free wall showing an equivalent amount of infarct thinning compared with the top panel. **Bottom,** subendocardial infarction showing very little free wall thinning compared with the top and middle panels. (Approximate magnification ×5.6, reduced 50%.)

Recent studies in man[1,2] suggest that after infarction the necrotic tissue may thin and stretch. This process termed *infarct expansion* has clinical significance as it may predispose to increased congestive heart failure, ventricular rupture, and aneurysm formation. Therefore, measures which would limit such topographic alterations in the left ventricle might reduce the incidence of these complications of infarction.

The present study suggests that the primary process of infarction may cause long-term secondary changes within the noninfarcted tissue. Noninfarcted septal lengthening and cavity dilatation may have been a manifestation of volume overload hypertrophy. It is conceivable that some patients with so-called ischemic cardiomyopathy, who have had remote infarcts and then present with the clinical picture of congestive heart failure in the absence of active ischemia or new infarction, may have an element of LV dysfunction due to chronic volume overload.

# Scar Thinning Due to Ibuprofen Administration After Experimental Myocardial Infarction

EDWARD J. BROWN, Jr., MD, ROBERT A. KLONER, MD, PhD, FREDERICK J. SCHOEN, MD, PhD, HAIM HAMMERMAN, MD, SHARON HALE, BS, and EUGENE BRAUNWALD, MD

**Although much attention has been directed toward interventions which reduce myocardial infarct size, the effect of such agents on the healing phase of myocardial infarction is not well understood. The present study examines the effect of the nonsteroidal anti-inflammatory agent ibuprofen, previously demonstrated to be able to reduce infarct size, and of aspirin on the healing of experimentally produced myocardial infarcts. Thirty-nine anesthetized, open-chest dogs were subjected to proximal left anterior descending coronary artery occlusions for 6 weeks. Four groups of dogs were studied: (1) a control (untreated) group: (2) ibuprofen, 12.5 mg/kg intravenously 15 minutes and 6, 12, 18, and 24 hours after occlusion (high dose); (3) ibuprofen, 12.5 mg/kg intravenously 15 minutes and 3 hours after occlusion (low dose); (4) aspirin, 30 mg/kg intravenously 15 minutes and 3 hours after occlusion. The average thickness of the transmural scar and of the noninfarcted left ventricular wall was determined from multiple measurements of formalin-fixed left ventricular slices. The ratio of transmural scar to noninfarcted wall thickness was determined.**

**In control animals the ratio was 0.87 with only 1 of 15 animals having a ratio <0.60. High-dose ibuprofen-treated animals had an average ratio of 0.59 (difference not significant [NS] compared with control values), with 6 of 9 animals having a ratio <0.60 ($p < 0.02$ compared with control values). Low-dose ibuprofen-treated animals had an average ratio of 0.66 ($p < 0.05$ compared with control values), with 4 of 8 animals having a ratio <0.60 (p = NS compared with control values). In the aspirin-treated animals, the ratio was 0.88 (p = NS compared with control values), with 0 of 7 animals having a ratio <0.60 (p = NS compared with control values). Although 1 of 22 animals had ratios <0.60 in the control and aspirin groups, 10 of 17 had ratios <0.60 in the ibuprofen-treated groups ($p < 0.001$). Scars in treated animals did not differ from those in control animals histologically or by analysis of hydroxyproline content per unit weight. Thus, ibuprofen, a nonsteroidal anti-inflammatory agent which reduces infarct size, is shown to increase the incidence of scar thinning after myocardial infarction.**

Although many investigations have been directed toward the study of interventions which reduce myocardial infarct size,[1,2] there is little information concerning the effect of such interventions on the healing phase of myocardial infarctions. The healing phase has been viewed as a process which follows a predictable morphologic course.[3,4] That this may not be true was demonstrated when multiple doses of glucocorticoids were shown to retard the rate of wound healing,[5–8] cause myocardial scar thinning in animals subjected to coronary occlusion,[9] and possibly lead to formation of left ventricular aneurysms in patients with myocardial infarction.[10] We investigated the effect of 2 nonsteroidal anti-inflammatory agents on myocardial scar formation: ibuprofen, a cyclooxygenase inhibitor, which has been shown to reduce experimental myocardial infarct size[11,12] and aspirin, also a cyclooxygenase inhibitor but one which has no effect on infarct size,[13] and which is widely used for the treatment of postmyocardial infarction pericarditis.

## Methods

**Experimental preparation:** Mongrel dogs of either sex weighing 10 to 26 kg were sedated with acepromazine maleate (1.0 mg/kg subcutaneously), anesthetized with pentobarbital (30 mg/kg intravenously), intubated, and placed on a Harvard respirator (Harvard Apparatus, Millis, Massachusetts). A thoracotomy was performed in the left fifth intercostal space under sterile conditions. The proximal left anterior descending coronary artery was dissected free from surrounding tissue and a silk ligature was placed around the artery in a location which resulted in epicardial cyanosis during temporary 15-second occlusions. Generally, the tie was immediately distal to the first diagonal branch, approximately 2 cm from the origin of the left anterior descending coronary artery.

**Experimental protocol:** After the administration of lidocaine (1.5 mg/kg intravenously), the left anterior descending coronary artery was permanently occluded with a silk ligature. A second similar dose of lidocaine was administered 5 minutes after coronary artery occlusion. The dogs were assigned at random, although not in equal numbers, into a control group or 1 of 3 treated groups. In the initial phase of the study, dogs were randomly assigned to control versus high-dose ibuprofen. Later in the study, low-dose ibuprofen and aspirin groups were added and dogs were randomized to control or one of these groups. Group 1 was the control group; these animals received 50 ml of saline solution infused over 5 minutes. Group 2, high-dose ibuprofen, received sodium ibuprofen (UpJohn, Kalamazoo, Michigan) (12.5 mg/kg intravenously) in 50 ml of normal saline solution infused over 5 minutes, at 15 minutes and 6, 12, 18, and 24 hours after occlusion (total dose 62.5 mg/kg). Group 3, low-dose ibuprofen, received sodium ibuprofen (12.5 mg/kg intravenously) in 50 ml of normal saline solution infused over 5 minutes, at 15 minutes and again 3 hours after occlusion (total dose 25 mg/kg). Group 4 received aspirin (30 mg/kg intravenously) in 50 ml of normal saline solution infused over 5 minutes, 15 minutes and 3 hours after occlusion. The thoracotomy wounds were closed, the air was evacuated from the thoracic cavity, and the animals were returned to the kennel. At the end of a 6-week period the animals were reanesthetized with thiamylal sodium (30 mg/kg intravenously) and killed with an overdose of potassium chloride, and the hearts were excised. Potassium chloride injection allowed all hearts to be arrested in diastole.

**Assessment of wall thickness:** After removal of the hearts, the left ventricle was isolated by dissecting away the right ventricle and structures above the atrioventricular ring, packed with gauze to prevent collapse of the left ventricular cavity, and allowed to fix in 10% neutral buffered formalin for 3 days. After fixation, the heart was sectioned into 3 to 5 mm transverse sections from base to apex. Measurements of the wall and scar thickness were made on each section as shown in Figure 1; all measurements were made along a line which passed through the center of the ventricular cavity. Normal wall thickness was measured in 3 to 5 widely separated locations and an average scar thickness was determined for each slice. In order to take into account variability in heart size, the thickness of the scar was compared with that of the noninfarcted left ventricular wall, and a ratio of scar thickness to noninfarcted wall thickness was determined. An average ratio in each dog was determined by averaging the ratios in each slice containing infarcted tissue.

**Analysis of infarct (scar) size:** After fixation, the heart was sectioned into 3 to 5 mm transverse sections from base to apex. The normal and infarcted myocardium was traced onto a clear acetate sheet placed over the slices. The extent of infarct (scar) at 6 weeks was determined by 2 methods. In the first method, area of the normal and infarcted (scar) myocardium was measured by planimetry and the area of infarcted tissue was expressed as a percentage of the area of the entire left ventricle. In the second method, endocardial circumference occupied by infarcted tissue and entire endocardial circumference of each of the slices was measured. The endocardial circumference occupied by the infarcted tissue was expressed as a percentage of the total endocardial length for all slices of the left ventricle.

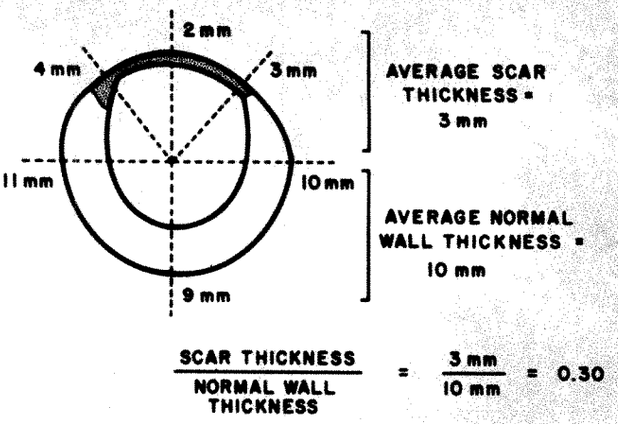

**FIGURE 1.** Schematic diagram demonstrating the technique used to determine the ratio of scar to normal wall thickness.

**Analysis of hydroxyproline content:** Tissue samples weighing between 100 and 200 mg were obtained from the endocardial and epicardial halves of normal and scarred myocardium and oven dried to a constant weight. Samples were then hydrolyzed in 6 N hydrochloric acid at 110°C for 12 hours. After neutralization and decolorization of the hydrolyzate, hydroxyproline was measured by the method of Newman and Logan.[14] Hydroxyproline concentration was expressed as $mg \cdot g^{-1}$ dry weight of the original sample.

**Histologic analysis:** Formalin-fixed transmural, transverse sections of noninfarcted and infarcted myocardium measuring 25 × 10 × 2 mm were conventionally processed and embedded in paraffin. Two to 3 sections, each stained with hematoxylin and eosin and Masson's trichrome, were examined from each heart by an investigator who had no knowledge of treatment. The following histologic features of necrosis and healing were assessed and graded from 0 (not present) to 4 (most prominent), as previously described,[3,4] with respect to (1) necrosis,

**TABLE 1 Fate of Experimental Animals**

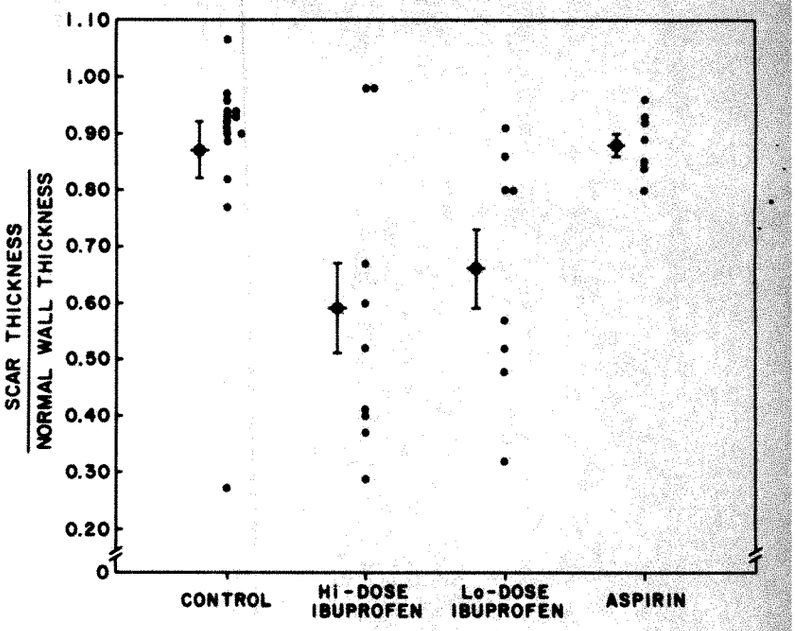

**FIGURE 2.** Ratio of scar thickness to normal wall thickness in control high-dose (Hi-Dose) ibuprofen, low-dose (Lo-Dose) ibuprofen, and aspirin treated dogs. **Closed circles** represent ratios for individual animals in all 4 groups. **Circles and bars** represent mean ± standard error of the mean for each group of animals.

(2) vascular proliferation, (3) neutrophil infiltration, (4) fibroblast deposition, and (5) collagen deposition. The histologic score for each animal was averaged over several slices.

**Statistical analysis:** Because the distribution of the ratios of scar to normal wall thickness was nonnormal (Fig. 2), we compared the 4 treatment groups by the Kruskal-Wallis test based on the ranks of the ratios in the combined sample for each group. Pairwise comparison of treatment groups were based on the Wilcoxon test, with p values interpreted using Bonferroni's method.[15]

We determined the number of dogs showing severe thinning, defined by the ratio of scar thickness to normal wall thickness of <0.6. The number 0.6 was chosen since a recent study showed that canine hearts with myocardial infarct expansion and thinning of the ventricular wall had a mean ratio of scar thickness to normal wall thickness of 0.66.[16] We compared exact p values by using Fisher's exact test and multiplied these p values by 4 to correct for multiple comparisons using Bonferroni's method.[15] Differences in hydroxyproline content between the 4 groups were determined by the analysis of variance.

Differences in infarct size among the 4 groups were determined by analysis of variance and Sheffe's method for multiple comparison. Differences in infarct size calculated as percent area and percent endocardial circumference within each group were determined by Student's $t$ test for paired data.

## Results

Seventy-six dogs were entered into the protocol. Ventricular fibrillation developed in 12 dogs within 30 minutes; these dogs were excluded. Nineteen dogs died suddenly after 30 minutes (range 12 hours to 12 days; mean 3.7) after occlusion. These 19 dogs consisted of 7 in the control group, 12 dogs in the ibuprofen-treated groups, and none in the aspirin-treated group (Table I). Six dogs did not have a transmural myocardial infarction at the time of examination and were excluded. This trend toward a lower incidence of sudden death in the aspirin-treated group was not statistically significant. None of these 19 dogs had evidence of myocardial rupture on postmortem examination. The remaining 39 dogs (51.3%) lived for 6 weeks and had transmural myocardial infarction; the observations in these animals form the basis for the reported results.

**Measurements of wall and scar thickness:** Figure 2 shows the distribution of the ratio of scar thickness to normal wall thickness in the 4 treated groups. The distributions were significantly different in the 4 treatment groups based on the Kruskal-Wallis test ($p < 0.02$). The median ratios of scar thickness to normal wall thickness were 0.92 (control), 0.68 (low-dose ibuprofen), 0.52 (high-dose ibuprofen), and 0.84 (aspirin). The control and low-dose ibuprofen groups were significantly different by the Wilcoxon test after correcting for multiplicity ($p < 0.05$). The control group did not significantly differ from high-dose ibuprofen group because 2 animals in the high-dose group had a thinning index higher than the median value in the control group. In the control group, only 1 of 15 dogs had a ratio of scar thickness to noninfarcted wall thickness of <0.60. In the high-dose ibuprofen–treated animals, 6 of 9 dogs exhibited severe wall thinning with ratios <0.60 ($p < 0.02$ compared with control values) (Fig. 3). However, only 4 of 8 animals in the low-dose ibuprofen group had severe thinning with ratios <0.60 ($p = 0.13$, NS compared with control values); the other 4 animals had little or no thinning and appeared similar to control animals (Fig. 3). The ratio in the aspirin-treated animals did not differ significantly from that in controls, and none of these dogs had ratios <0.60. The number of dogs in the aspirin-treated group with ratios <0.60 differed significantly from that in high-dose ($p < 0.05$) but not the low-dose ($p$ = NS) ibuprofen-treated animals. While 1 of 15 control animals had ratios <0.60, in pooled ibuprofen-treated animals 10 of 17 had thinning ratios <0.60 ($p$

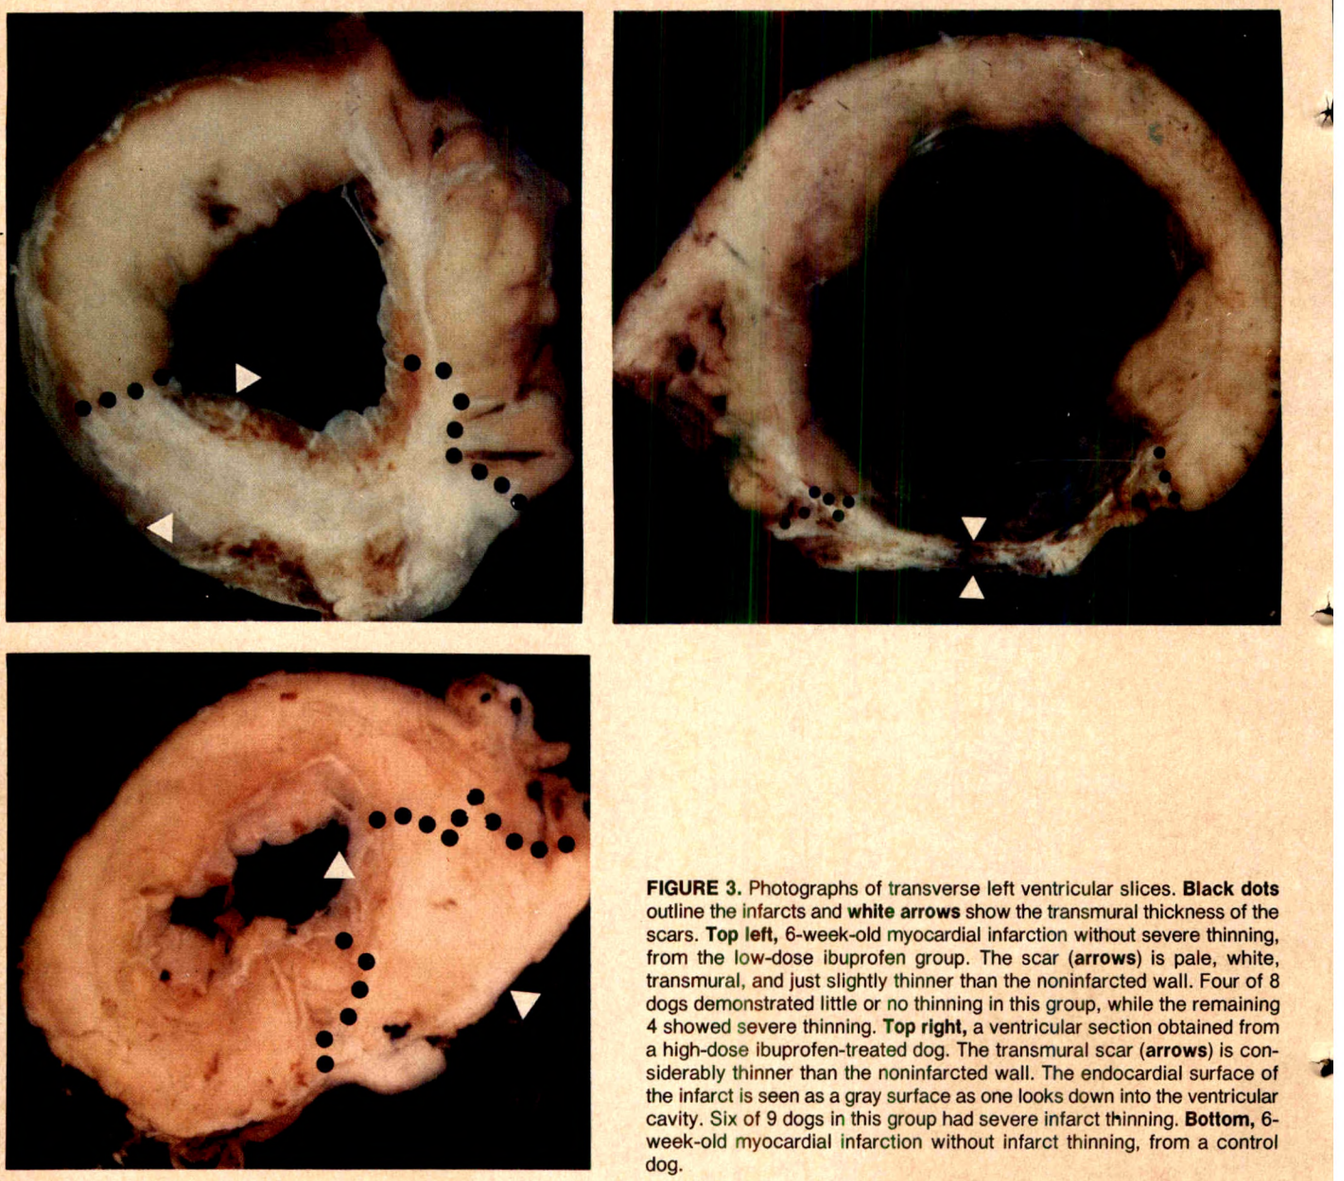

**FIGURE 3.** Photographs of transverse left ventricular slices. **Black dots** outline the infarcts and **white arrows** show the transmural thickness of the scars. **Top left,** 6-week-old myocardial infarction without severe thinning, from the low-dose ibuprofen group. The scar (**arrows**) is pale, white, transmural, and just slightly thinner than the noninfarcted wall. Four of 8 dogs demonstrated little or no thinning in this group, while the remaining 4 showed severe thinning. **Top right,** a ventricular section obtained from a high-dose ibuprofen-treated dog. The transmural scar (**arrows**) is considerably thinner than the noninfarcted wall. The endocardial surface of the infarct is seen as a gray surface as one looks down into the ventricular cavity. Six of 9 dogs in this group had severe infarct thinning. **Bottom,** 6-week-old myocardial infarction without infarct thinning, from a control dog.

<0.01). In combined aspirin and control dogs only 1 of 22 animals showed severe thinning, while in pooled ibuprofen-treated animals 10 of 17 showed severe thinning ($p < 0.001$). Absolute noninfarcted wall thickness was similar in all groups: (8.8 ± 0.4 mm in the low-dose ibuprofen group, 9.7 ± 0.2 mm in the high-dose ibuprofen group, 9.3 ± 0.2 mm in the control group, and 8.9 ± 0.2 mm in the aspirin-treated group; p = NS among groups).

**Myocardial infarct size:** Myocardial infarct size expressed as percent area of the left ventricle and as percent endocardial circumference of the left ventricle is shown in Table II. There were no significant differences among the 4 groups when infarct size was expressed as a percentage of either endocardial circumference or of left ventricular area. There was a trend toward larger circumferences of the scars in the high-dose ibuprofen-treated animals; this most likely represents infarct expansion.

In the control group, infarct size determined as percentage of endocardial circumference (14 ± 2) was not significantly different when compared with infarct size determined as percentage of area (12 ± 1). Similarly, in the aspirin group, infarct size as percentage of endocardial circumference (11 ± 2) was not significantly different when compared with infarct size as percentage of area (10 ± 1). Neither control nor aspirin-treated animals had myocardial scar thinning. However, in both high-dose and low-dose ibuprofen-treated animals, infarct size measured as a percentage of endocardial circumference was significantly larger than infarct size measured as a percentage of area. In the high-dose ibuprofen group, infarct size as a percentage of endocardial circumference was 21 ± 3 while infarct size as a percentage of area was 15 ± 1 ($p < 0.05$). In the low-dose ibuprofen group, infarct size as a percentage of endocardial circumference was 15 ± 2 while infarct size as a percentage of area was 12 ± 1 ($p < 0.05$). It is likely that

**TABLE II Myocardial Infarct (Scar) Size (Mean ± Standard Error of the Mean)**

| | Control | Ibuprofen | | |
|---|---|---|---|---|
| | | High Dose | Low Dose | Aspirin |
| Infarct (scar) size (% endocardial circumference) | 14 ± 2 | 21 ± 3* | 15 ± 2* | 11 ± 2 |
| Infarct (scar) size (% area) | 12 ± 1 | 15 ± 1 | 12 ± 1 | 10 ± 1 |

* Larger than infarct size determined as % area, $p < 0.05$. There were no significant differences among any of the 4 treatment groups by Sheffe's method for multiple comparison.

**TABLE III Hydroxyproline Concentration in Normal Myocardium and in Scar (μg/mg Dry Weight, Mean ± Standard Error of the Mean)**

| | Normal | | Scar | |
|---|---|---|---|---|
| | Epicardium | Endocardium | Epicardium | Endocardium |
| Control | 4.3 ± 0.2 | 3.9 ± 0.2 | 25.3 ± 1.2 | 35.6 ± 2.4 |
| High-dose ibuprofen | 4.5 ± 0.3 | 4.7 ± 0.7 | 30.9 ± 3.6 | 31.7 ± 3.3 |
| Low-dose ibuprofen | 4.9 ± 0.4 | 4.5 ± 0.5 | 33.0 ± 3.7 | 37.1 ± 2.7 |
| Aspirin | 4.6 ± 0.5 | 4.5 ± 0.2 | 29.0 ± 2.8 | 37.8 ± 4.3 |

the circumferential determination of infarct or scar size in the ibuprofen groups was greater than that determined by area because of circumferential expansion and transmural thinning of the infarcts.

**Hydroxyproline assay:** Normal subepicardial and subendocardial tissue, made up primarily of myocardial cells, contained very little collagen, as reflected in hydroxyproline concentration <5.0 μg/mg dry weight. Large quantities of collagen were contained within the subepicardium and subendocardium of the scar, with hydroxyproline concentrations five- to sixfold greater than in noninfarcted tissue (Table III). Treatment with ibuprofen or aspirin did not affect the hydroxyproline concentrations, either in scar or normal tissue.

**Histologic analysis:** As might be expected in 6-week-old scars, there was minimal necrosis and few if any neutrophils; however, extensive vascular proliferation, collagen, and fibroblasts were noted. The findings were similar in all 4 groups (Table IV).

## Discussion

Traditionally, myocardial healing has been viewed as an unalterable process that follows a predictable course. Observations on the effect of glucocorticoids on myocardial healing suggest that this may not always be the case. Glucocorticoids have been shown to reduce infarct size in animals with experimental infarcts,[17–23] to be useful in the treatment of complete heart block,[24,25] to decrease mortality after infarction,[26–28] and to control the pain of Dressler's syndrome in patients not responding to aspirin.[29,30] However, despite

**TABLE IV Histologic Summary (6 Weeks)**

| | Control (n = 15) | Ibuprofen | | |
|---|---|---|---|---|
| | | High Dose (n = 9) | Low Dose (n = 8) | Aspirin (n = 7) |
| Necrosis score (mean) | 0.2 | 0.1 | 0.4 | 0 |
| Neutrophil score (mean) | 0.1 | 0.6 | 0.5 | 0.1 |
| Vascularity score (mean) | 2.8 | 2.9 | 3.2 | 2.1 |
| Macrophage score (mean) | 1.8 | 1.7 | 1.9 | 1.9 |
| Fibroblast score (mean) | 2.8 | 3.0 | 3.4 | 2.4 |
| Collagen score (mean) | 3.5 | 3.4 | 3.5 | 3.3 |
| Dogs (n) with necrosis | 1 | 1 | 2 | 0 |
| Dogs (n) with neutrophils | 1 | 2 | 3 | 2 |

these suggested salutary effects, there is evidence that multiple doses of glucocorticoids adversely affect the healing of myocardial infarctions.[7–10] Administration of multiple doses of methylprednisolone delays removal of necrotic myocardium with reduced phagocytosis, resulting in large sheets of dead but architecturally preserved cells (mummification) and in scar thinning.[9,31] One or 2 doses of methylprednisolone administered early in the course of infarction does not appear to have this effect.[9] There is also suggestive evidence that glucocorticoids interfere with scar formation in patients with myocardial infarcts. In a patient treated with multiple doses of steroids for Dressler's syndrome,[10] the histology of the infarcted myocardium 63 days after myocardial infarction revealed persistent necrosis, inflammatory cells, and small foci of loose fibrous tissue, findings which one would expect 10 to 14 days after myocardial infarction.[3,4] An association between the development of postmyocardial infarction left ventricular aneurysms and treatment with glucocorticoids has also been noted.[10]

Ibuprofen, an agent which has been shown to reduce myocardial infarct size in some animal models,[11,12] initially appeared to be an attractive agent because of its low incidence of adverse effects. Because, like glucocorticoids, ibuprofen is an anti-inflammatory agent, we designed the present investigation to look for any adverse effects on healing. We chose dose schedules of ibuprofen which were similar to the doses which have previously been shown to reduce infarct size.[11] In the present study we chose to examine the healing process at its completed stage. Complete myocardial healing occurs in 3 weeks in the rat,[31] 6 to 8 weeks in humans,[3,4] and approximately 6 weeks in dogs,[32] the time selected for this study.

Marked scar thinning, defined as a ratio of the thickness of the scar to the uninvolved myocardium as <0.60, occurred in 10 of 17 (59%) animals treated with ibuprofen; however, the response was not uniform. In the control and aspirin-treated animals significant thinning was observed in only 1 of 22 dogs. However, both the collagen content, as reflected in the hydroxyproline concentration, and histologic examination results were similar in control and treated animals, suggesting that while the scars were thinner in ibuprofen-treated dogs, the scar tissue was qualitatively similar in all 4 groups. A recent study by Cannon et al[33] actually showed improved collagen deposition in rats

with experimental myocardial infarction treated with ibuprofen.

The mechanism of ibuprofen's action on myocardial healing is unknown. Because aspirin did not alter the healing process, the explanation for ibuprofen's action may lie in differences between aspirin and ibuprofen. Both drugs are nonsteroidal anti-inflammatory agents exhibiting analgesic, antipyretic, and anti-inflammatory properties. Both drugs inhibit prostaglandin biosynthesis in vitro and in vivo, presumably by inhibiting cyclooxygenase, the enzyme which generates the cyclic-endoperoxides from arachidonic acid. Aspirin and ibuprofen are approximately equipotent as to their effect on the inhibition of cyclooxygenase.[34] In addition to their effect on prostaglandin synthesis, these drugs exert inhibitory effects on a variety of enzymes and cellular systems such as oxidative phosphorylation, stabilization of protein, and enzyme release from lysosomes.[34] However, several differences exist in the mechanism of action of these 2 agents. Ibuprofen suppresses prostaglandin synthesis by competitive inhibition of cyclooxygenase activity, compared with the noncompetitive inhibition by aspirin. Aspirin has the unique property of acetylating the active site of cyclooxygenase. In platelets, which cannot synthesize protein, this action is irreversible for the life of the cell.[12] In a study on the effect of anti-inflammatory drugs on leukocyte migration in carrageenan-induced inflammation, it was shown that aspirin significantly increases leukocyte migration, while ibuprofen does not.[35] Ibuprofen is capable of affecting stimulated granulocytes by inhibiting their ability to aggregate, to generate radical oxygen, or to damage the endothelial wall. These effects were not demonstrated by aspirin.[36] It is not clear which if any of these mechanisms was responsible for the difference in scar thickness between ibuprofen and aspirin-treated animals in the present study.

Measurement of infarct or scar size after 6 weeks of healing would not necessarily correlate well with infarct size measured within a few hours to days of the myocardial infarction. Over a period of weeks it is possible and even likely that topographic changes in the infarct occur. In this study there were no significant differences in infarct size among groups when measured as a percentage of the area or circumference of the left ventricle. When comparing the size of infarct by the 2 different methods, percent area and percent endocardial circumference, we detected differences in both ibuprofen groups, while no difference in infarct size measured by these 2 methods was noted in either the control or aspirin groups. We believe a possible explanation for the above difference in infarct size when using the 2 methods is infarct expansion and thinning.

Infarct expansion was first recorded by Tennant and Wiggers[37] and the concept was developed by Bulkley, Hutchins, and co-workers.[16,38–40] They described infarct expansion as a thinning and dilatation of infarcted myocardium. Postmortem studies revealed that this process occurred not only in animals with experimentally induced infarcts[16] but also in approximately one third of patients with transmural myocardial infarctions.[39] If expansion occurred early in the ibuprofen groups, before the deposition of collagen, scar tissue would then be deposited onto a thinned and elongated area of necrotic myocardium. It is possible that the mechanical explanation for scar thinning is early infarct expansion. The similar hydroxyproline content in thinned and nonthinned scars is evidence that thinning or expansion does occur early, before collagen is deposited.

The clinical significance of our observations is not clear. Although reduction in the amount of infarcted tissue after coronary occlusion continues to be a major clinical concern, it is possible that the final prognosis of a patient with myocardial infarction depends also on the outcome of the healing phase.

# Effects of Flurbiprofen in Altering the Size of Myocardial Infarcts in Dogs: Reduction or Delay?

DAVID E. CHAMBERS, BS, DEREK M. YELLON, PhD, DAVID J. HEARSE, PhD, and JAMES M. DOWNEY, PhD

**Anti-inflammatory agents such as flurbiprofen have been claimed to reduce infarct size in a number of models of coronary artery occlusion. However, several of the studies are controversial and also do not allow the critical distinction between reducing and delaying injury. In the present study, a closed chest method of coronary occlusion was used to generate small areas of regional myocardial ischemia in dogs. The method involved cannulation of the coronary ostium by way of the carotid artery and coronary embolization with 2.5 mm diameter beads. Flurbiprofen (1 mg/kg) was given immediately after occlusion and thereafter every 6 hours. Groups of dogs were subjected to either 6 or 24 hours of elapsed ischemia, after which time the hearts were removed and sectioned. Frozen-tissue slices were stained with triphenyl tetrazolium in order to delineate infarct size. After staining the tissue slices were subjected to autoradiography in which microspheres given immediately after occlusion were visualized to delineate the perfusion bed served by the occluded coronary artery (zone at risk). Risk zone to infarct size ratios for drug treated and control animals revealed that flurbiprofen treatment had no effect upon infarct size as determined 24 hours after occlusion. Despite significant residual coronary flow in the ischemic area, virtually all of the risk zone deteriorated to necrotic tissue. By contrast, after 6 hours of elapsed ischemia, infarct size was considerably reduced in the flurbiprofen-treated group. With the proviso that the drug might have affected only the sensitivity to tetrazolium staining, these results indicate that in severe ischemia, flurbiprofen can greatly delay but not prevent tissue necrosis.**

Numerous studies have aimed to identify interventions which protect the myocardium during ischemia.[1] Unfortunately, no single intervention has gained widespread acceptance and controversy persists, not only over the efficacy of certain drugs, but over the entire concept of infarct size reduction itself.[2,3,4] Most studies have failed to distinguish between a sustained *reduction* versus a *delay* of injury.[2] This problem is particularly relevant when infarct size is assessed soon (for example, 6 hours) after occlusion. Another major problem has been the variability of injury arising from a standard occlusion.[5] This variability makes it difficult to perform statistical comparisons in small groups of animals, even when the amount of salvage is great. The variability has recently been reduced by expressing the eventual zone of necrotic myocardium as a percentage of the zone at risk, that is, the perfusion field of the affected coronary artery.[6–13] Any discordance between the necrotic and the risk zones would reflect either tissue salvage or infarct extension.

The anti-inflammatory agents ibuprofen and flurbiprofen have been reported to be extremely potent in promoting salvage.[10,12,13] However, several methodologic aspects of these studies prevent a definitive claim of infarct size reduction.

In the present study, we endeavored to overcome these problems by developing a method of risk-zone analysis in which radiolabelled microspheres are used to mark the region at risk at the *time of occlusion* rather than after the infarct has evolved.[9] This is important since it is known that there are time-dependent changes in blood flow in and around infarcting tissue.[14,15] We visualized the flow distribution patterns and infarct zones by autoradiography of microspheres and tetrazolium staining of tissue sections either 6 or 24 hours after the onset of ischemia in both control and flurbiprofen-treated dogs.

## Methods

**Occlusion model:** Thirty-nine greyhounds of either sex, weighing 20 to 32 kg, were anesthetized with sodium pentobarbital 30 mg/kg intravenously. Each dog also received penicillin $1 \times 10^6$ $\mu$m intramuscularly at the time of an-

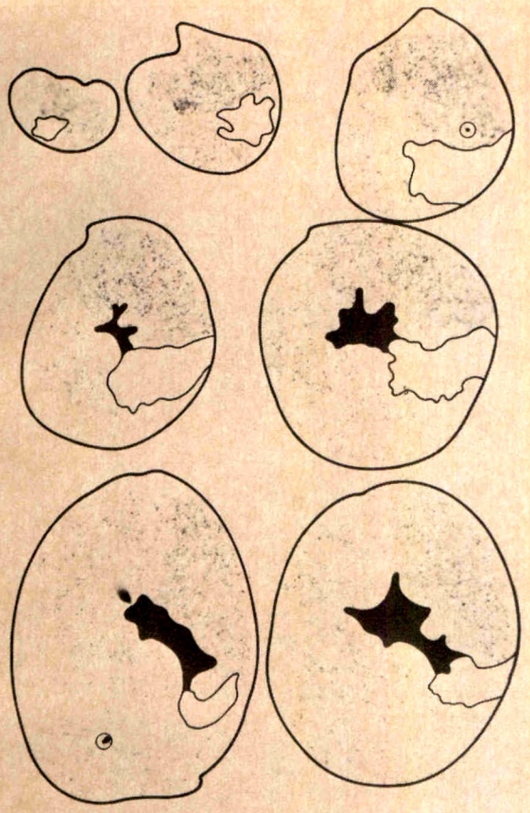

**FIGURE 1.** Typical autoradiogram matched to dye tracing. Autoradiogram of transverse myocardial sections; each small spot corresponds to a single cerium-141–labelled microsphere. Well-perfused, nonischemic areas exhibit a high density of spots, whereas the area served by the occluded coronary contains very few, thus producing a "window." The infarct is indicated by the **solid outline,** and the ventricular lumen is indicated by the **solid black area.**

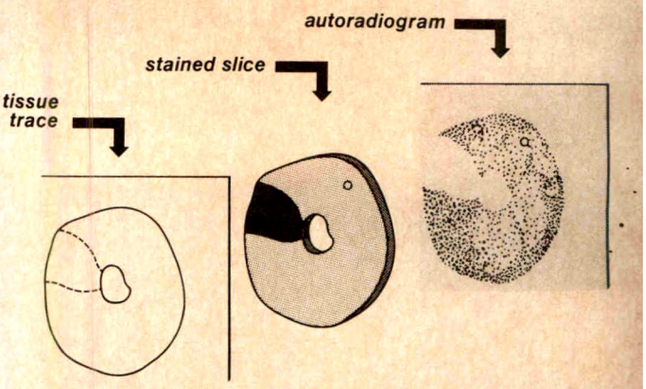

**FIGURE 2.** Delineation of risk zones and infarct zones. Each stained tissue section (**center**) reveals the zone of necrosis (**black shaded area**); the viable tetrazolium positive tissue adjacent to this and surrounding the lumen is the **lightly shaded area.** From this tissue section a tracing on acetate sheet (**left**) can be prepared to record the outline of the necrotic tissue. An autoradiogram (**right**) is also prepared from the tissue section and this indicates the risk zone (no silver grains). Superimposition of the acetate trace and autoradiogram allows the detection of tissue salvage or infarct extension relative to the original zone at risk.

esthetization. A femoral cutdown was performed and a catheter was placed in the femoral artery for withdrawal of a calibration blood sample during microsphere infusion. The left carotid artery was exposed by way of a midline cervical incision and a special cannula[16] with a pressure transducer attached to a side arm was inserted into the carotid artery. The cannula was then advanced into the coronary ostium. Insertion of the cannula was confirmed by a decrease in pressure from aortic to a distal coronary value of about 20 mm Hg. Two plastic beads, 2.5 mm in diameter, followed by 10 ml of saline solution each, were sequentially administered through the cannula so as to embolize the coronary vasculature. Our experience with this technique in open-chest dogs indicates that the beads lodge firmly in place and cause a permanent occlusion. The cannula was then withdrawn from the coronary ostium and advanced past the aortic valve into the left ventricle. Twenty million microspheres labelled with cerium-141 and having a 15 $\mu$m diameter were then injected into the left ventricle. Just before microsphere administration, a 90-second withdrawal of arterial blood from the femoral artery was initiated. This blood sample served as a reference for calculation of regional blood flow.[17] The cannula was then removed. Dogs were randomly divided into 4 groups: Group I was subjected to 24 hours of untreated ischemia. Group II experienced 24 hours of ischemia with flurbiprofen (1 mg/kg) after microspheres and thereafter every 6 hours. Group III was subjected to 6 hours of ischemia with no drug, and Group IV experienced 6 hours of ischemia with a single dose of flurbiprofen (1 mg/kg) immediately after microspheres. The cutdowns were then reconstructed and the animals returned to the recovery room. All surgery was carried out under sterile conditions. To prevent thrombus formation behind the emboli, heparin (5,000 units intravenously) was given every 6 hours. Blood samples for serum drug level determinations were also removed every 6 hours in 3 dogs. Heart rate, electrocardiograms, and blood pressure were recorded throughout each experiment.

**Tissue processing procedures:** At the end of each experimental period, dogs were reanesthetized and the chests opened. The hearts were removed, weighed, and frozen. Once frozen, the hearts were sliced transversely into 5 mm thick sections.

**Infarct visualization:** The slices were placed in 1% weight/volume triphenyl tetrazolium in phosphate buffer at 37°C and were incubated for 20 minutes.[18] The contour of the interface between stained and unstained tissue in each section was marked with a fine line of disulphine blue dye using an artist's brush. The necrotic tissue within the blue boundary line was painted with fluorescein dye. This step was necessary because the triphenyl tetrazolium stain, although plainly visible in warm tissue, was not readily seen once the tissue was frozen as was required in the subsequent step.

**Autoradiographic risk zone visualization:** After staining, tissue slices were placed on an acrylic sheet (20 × 25 × 4 mm). A layer of plastic film was then placed over the tissue slices and on top of this was placed a sheet of x-ray film (Kodak no screen NS-ZT). A second acrylic sheet was then placed on top of the x-ray film and the 2 sheets were held tightly together in a specially made wooden press. The press was placed in a light-proof box and stored at −20°C for a suitable exposure period. Fresh microspheres require a 24-hour exposure period. The exposure period must then be doubled for each half-life which elapses. The film was then removed and developed. Figure 1 shows a typical autoradiogram. Care was taken not to let the tissue, which was firmly frozen to the lower acrylic sheet, thaw. Just before developing, the exact position of the

tissue section in relation to the film was recorded by driving a sharpened probe through 2 predrilled holes in the acrylic sheets, thus piercing both the film and the tissue (Fig. 2).

**Data analysis:** A clear acetate sheet was placed over the slices and the outline of the sections, the ventricular lumens, the 2 register holes, and the infarcts were traced. This tracing could then be superimposed on the autoradiogram using the 2 register holes for precise alignment. The x-ray film revealed the blood flow pattern around the area served by the occluded artery and thus defined the risk zone. A tracing and its autoradiogram are shown in Figure 1. The cerium-141–labelled microspheres produce sharp spots in the autoradiogram. Studies with specially prepared phantoms indicate that the spots identify individual microspheres in the tissue and that there is little exposure of the film between the spots. This is unlike technetium-99m–labelled microspheres, which produce a blurred autoradiographic image.[7] In Figure 1, the field of the occluded artery is easily identifiable as the region of the autoradiogram which is devoid of spots. This is designated the region at risk. The volume of the region of risk was calculated by planimetering the area of the risk zone for each slice and multiplying this by the thickness (5.0 mm) of the section. The values for sequential slices were summed to provide the total volume for each heart. Using a similar procedure, the total volume of the necrotic tissue was calculated.

**Blood flow measurements:** In order to quantitate regional myocardial blood flow, 4 samples (approximately 250 mg each) were taken from each heart. Using the triphenyl tetrazolium stain as a guide, 2 samples were taken from the center of the infarcted region (1 from the epicardium and 1 from the endocardium) and 2 samples were taken from the epicardial and endocardial regions of normal myocardium well-remote from the infarct. The tissue samples were then weighed and counted using a gamma counter. Blood flow was then calculated.[17]

**Animal numbers and subdivision:** A total of 39 dogs were taken for study. Six of these died from aortic rupture or aneurysm (a hazard of the "blind" coronary cannulation procedure) before or just after embolization. An additional 2 dogs died from ventricular fibrillation soon after coronary embolization. Of the remaining animals, 17 were randomly assigned to the 24 hour series (8 drug treated and 9 controls); however, 1 of the latter group died 4 hours after embolization, probably as a result of injury sustained during cannulation or a lethal arrhythmia. Fourteen were assigned to the 6-hour series (7 drug-treated and 7 controls).

**TABLE II Bead Locations for the 4 Groups of Animals Studied**

| Group | First Branch LAD | Terminal LAD | First Branch Circumflex | Second Branch Circumflex | Terminal Circumflex |
|---|---|---|---|---|---|
| 24 hour control | 2 | 2 | 0 | 0 | 4 |
| 24 hour drug | 0 | 3 | 0 | 1 | 4 |
| 6 hour control | 0 | 5 | 0 | 0 | 2 |
| 6 hour drug | . . . | 3 | . . . | 2 | 2 |

The numbers refer to the incidence of an embolus in that location for each group. LAD = left anterior descending.

## Results

Two series of studies were carried out. In 1 series, infarct sizing and risk-zone analyses were carried out 24 hours after embolization. In the second series, measurements were taken after only 6 hours of ischemia. The second series was carried out: (1) to ascertain whether our procedures and results agreed with those reported by Darsee et al,[10,12] and (2) to attempt to dissociate delaying injury from reducing injury.

**Twenty-four hours of elapsed ischemia (absolute measurements):** Table I shows the infarct size and risk-zone size for the drug-treated and control animals in this group. In both groups relatively small infarcts were produced (about 5% of the ventricular mass) and, as is common with the dog heart, considerable variability between individuals was observed. In the drug-treated group, the mean infarct size was $7.98 \pm 1.76$ $cm^3$. In the control group, the value was $12.22 \pm 2.10$ $cm^3$. There was no statistically significant difference between these values ($p = 0.110$). Table I also reveals a wide individual variability in risk zone with a lower mean value in the drug group; however, as with infarct size, this difference was not statistically significant. Since the selection of animals for drug treatment or control was a random process undertaken before the size of the infarct was

known, then this difference between groups must reflect the large individual variation between animals and not the consequence of drug treatment. This point is reinforced by the range of the sizes of zones at risk (5.5 to 30.3 $cm^3$), which are, of course, determined before the administration of the drug. Table I also shows the heart rate and blood pressure measurements for the 2 groups. These figures serve to further confirm that only 1 population existed. Table II shows the locations of the emboli in these dogs.

The lefthand panel of Figure 3A shows the infarct sizes expressed as a fraction of region at risk. Note that the variability in the 2 groups is small and that no significant differences exist between the drug treatment and the control. One interesting observation was that, unlike in other reports,[11] we found no correlation between the percentage of salvage and the size of the risk zone. These variables are plotted for both groups in Figure 4. In Figure 5 the size of the infarct as a percentage of ventricular mass is plotted against the size of the region at risk as a percentage of the ventricular mass, as was done by Jugdutt et al.[13] Note that a linear relation results and that the lines project to the origin. Also, both drug and control points share the same line. The findings that both groups superimpose reinforce our view that there is no significant difference in infarct size between the 24-hour treatment and the 24-hour control group.

**Six hours of elapsed ischemia:** Although it appears that flurbiprofen cannot afford a sustained protection against ischemic injury, it may well delay injury, as indicated by the 6-hour study of Darsee et al.[10] The pre-

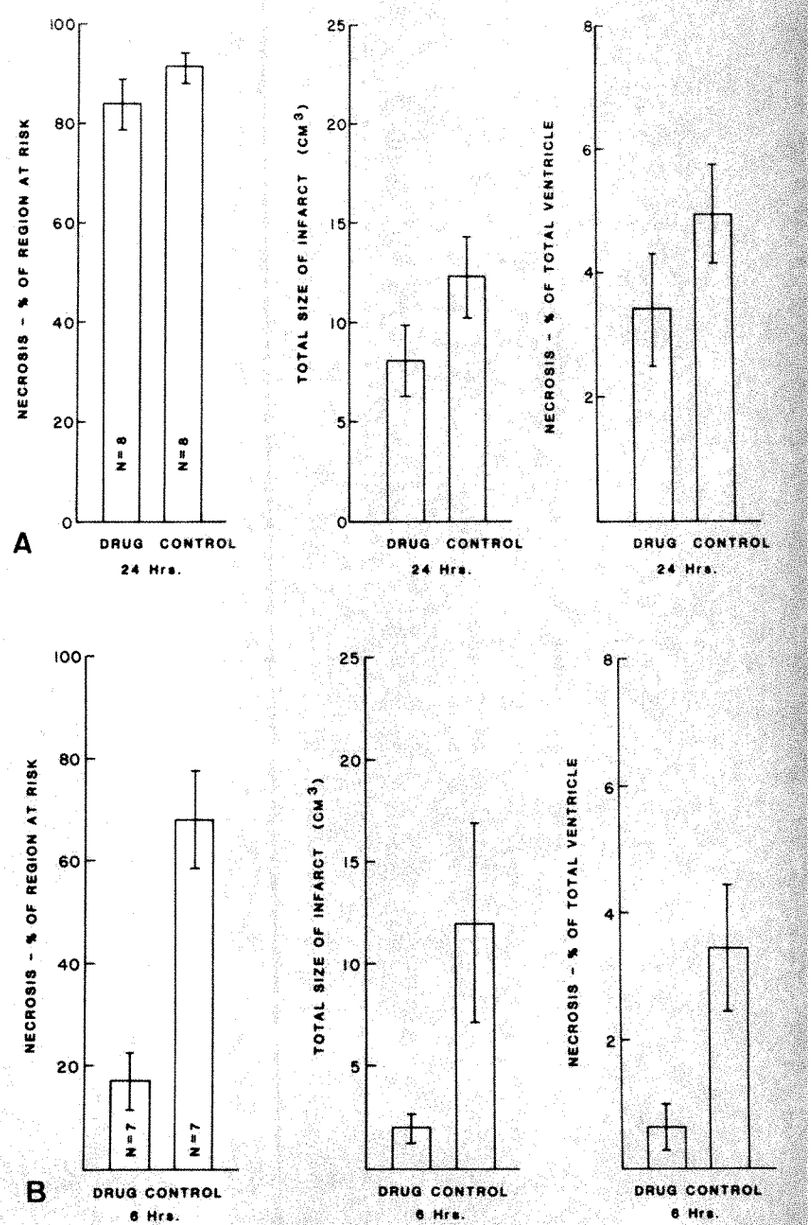

**FIGURE 3.** Three assessments of the effect of flurbiprofen on infarct size. **A: Left,** histogram showing the percentage of the region at risk, which deteriorates to necrosis after 24 hours of occlusion in control and drug-treated dogs. **Center,** histogram showing a comparison of absolute infarct size in these 2 groups. **Right,** histogram showing infarct size expressed as a percentage of the total ventricular weight for the 2 groups. **B:** Similar assessments carried out 6 hours after coronary artery occlusion. The number of dogs in each group is shown in the left-hand histograms and the standard error of the mean is indicated by the bars.

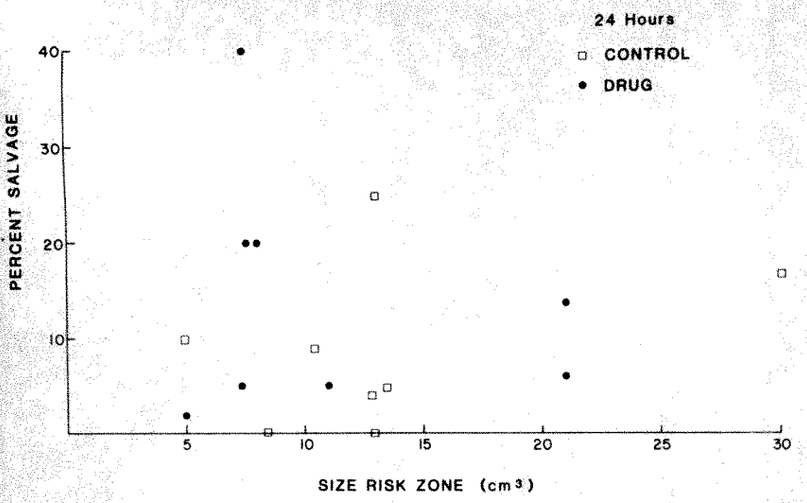

**FIGURE 4.** Tissue salvage and risk zone. The percentage of the risk zone which survived (percent salvage) after 24 hours of ischemia is plotted against the absolute size of the risk zone. No correlation was found, and the flurbiprofen-treated hearts (**closed circles**) do not segregate from the control hearts (**open squares**), suggesting that only 1 population exists.

ceding protocol was therefore repeated except that the duration of elapsed ischemia was reduced to 6 hours. The results (Table I and Fig. 3B) reveal that in the drug-treated groups the amount of necrotic tissue at 6 hours, as revealed by tetrazolium staining, was a much smaller fraction of the zone of risk than that seen at 24 hours (17.3 ± 5.7% versus 84.0 ± 5.0%). In the 6-hour control group this fraction (68.5 ± 9.2) was not significantly different from that in the 24-hour control group (91.8 ± 3.2%). The difference between the 6-hour drug-treated group and 6-hour control group, however, was highly significant when expressed as infarct mass ($p < 0.04$), percentage of ventricular mass ($p < 0.02$), or as a percentage of the risk region ($p < 0.002$). These results, which agree with those of Darsee et al,[10] indicate that flurbiprofen delays tissue injury as assessed by tetrazolium staining at 6 hours. By 24 hours, however, the drug-treated hearts had clearly sustained the same degree of injury as the control hearts.

When infarct size is expressed as a percentage of ventricular mass and plotted against risk-zone size, also expressed as a percentage of ventricular mass (Fig. 6), the drug treatment points and control points tend to segregate into 2 different populations. This contrasts with the 24-hour group (Fig. 5) and again supports the observation that at 6 hours infarct size was smaller in the drug-treated group.

**Blood flow studies:** In order to ascertain whether all of the 4 groups had experienced equivalent levels of ischemia, tissue samples were removed from the center of the ischemic zones and the microsphere content was determined. This allowed an accurate determination of

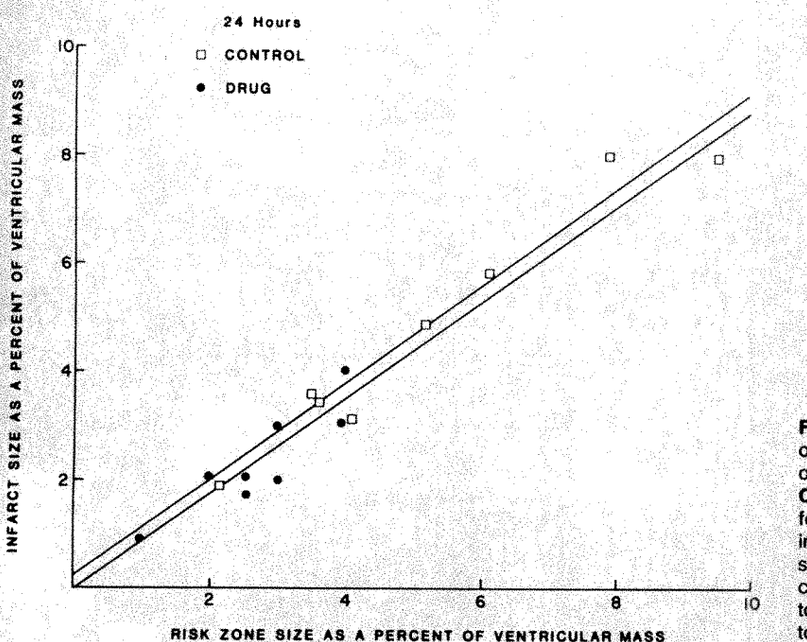

**FIGURE 5.** Relation between infarct size as a percentage of ventricular mass and risk-zone size as a percentage of ventricular mass after 24 hours of elapsed ischemia. **Open squares,** control hearts; **closed circles,** flurbiprofen-treated hearts. Note that the 2 groups superimpose, indicating that there was no significant change in infarct size between the 24-hour drug-treated and 24-hour control groups. The **lines** represent the least-squares fit to the data points in each group. The **upper line** belongs to the control group.

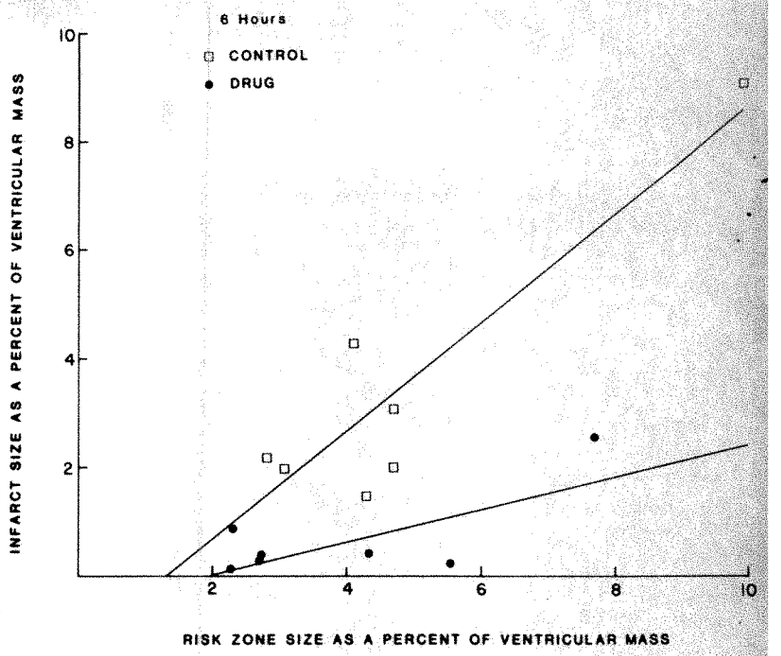

**FIGURE 6.** Relation between infarct size as a percentage of the ventricular mass and risk-zone size as a percentage of ventricular mass after 6 hours of elapsed ischemia. **Open squares,** control hearts; **closed circles,** flurbiprofen-treated hearts. Note that in comparison with Figure 5, the experimental groups segregate into 2 different populations, indicating that at 6 hours the infarct size was smaller as a result of drug treatment. Lines are fit by the least-squares method.

blood flow to these regions. The results showed a surprising degree of variability. All of the ischemic tissue experienced a reduction of flow by at least 75% and the residual flow tended to be higher in the subepicardium than the subendocardium, although these differences did not achieve statistical significance, probably due to the scatter in the data. No differences were seen between the 4 groups, indicating that they were indeed equivalent.

## Discussion

The results indicate that while flurbiprofen was able to limit the size of an infarct 6 hours after coronary artery occlusion in the dog, it was unable to sustain this protection. These results do not necessarily deny the ability of drugs to protect ischemic tissue. Our results suggest that the anti-inflammatory drug was capable of a remarkable delay in apparent tissue injury. If this delay can be equated with a delay in the onset of irreversible injury, then such a delay may be useful in providing additional time to permit secondary interventions such as thrombolysis or coronary artery surgery to be implemented. We must, however, distinguish whether the drug extends the duration of reversible injury or whether it simply alters the responsiveness of tissue to tetrazolium staining. This caution is particularly relevant to anti-inflammatory drugs such as flurbiprofen[19] which might influence permeability to intracellular proteins.[20]

Although our findings (not our conclusions) are in accord with those of Darsee et al,[10,12] our results appear to be at variance with those of Jugdutt et al,[13] who reported positive effects with ibuprofen as long as 48 hours after the onset of ischemia. To resolve this apparent conflict, a number of points of protocol should be considered. Jugdutt et al visualized the zone at risk at the *end* of the 48-hour occlusion period. Unfortunately, the distribution of flow in and around an infarct changes during the first 24 hours.[14,15,21] Thus, if the drug had any effect upon blood flow patterns around the ischemic zone, it might be incorrectly interpreted as a change in infarct size. In our study, the risk zone was marked with radioactive microspheres *immediately after* coronary occlusion and *before* the drug was administered. The only possible effect the drug could have had on the delineation of the risk zone would be to have induced some loss of microspheres from the myocardium over the 24-hour ischemic period. Although small (9 $\mu$m) microspheres can be lost during extended periods of ischemia and although this loss may be augmented by the process of necrosis,[22] we used 15 $\mu$m spheres for the present study and their loss, even from necrotic myocardium, appears limited.[23]

Other differences between our study and that of Jugdutt et al are related to the surgical procedures used. Jugdutt used an occluder which was placed on the circumflex artery several days before occlusion and in the process of implanting the occluder, sympathetic nerves to the region supplied by that vessel were likely to be disrupted. Jones et al[24] have reported that sympathectomy stimulates collateral growth; thus, it is conceivable that the hearts in the Jugdutt et al study may have developed a better collateral circulation than those used in our study. One difference in protocol from our model is that our study required the use of anesthesia, whereas Jugdutt et al were able to induce occlusion in the conscious animal. The possibility that the hypertension and the tachycardia associated with the anesthesia might have augmented the extent of necrosis cannot be ruled out.

One additional difference is related to the size of the ischemic bed under study. We induced ischemia by introducing a plastic bead into a coronary artery, thereby generating a relatively small area of ischemia compared

with those of others.[10,12,13] In our study only about 5% of the ventricular mass was rendered ischemic. Since Schaper et al[25] have suggested that collateral flow to the center of an ischemic region is inversely related to the mass of that region, it can be argued that our smaller risk zones should actually improve the chances of a beneficial drug action. Furthermore, if there is a salvageable zone of tissue of finite thickness at the periphery of an ischemic region, then the ratio of salvageable tissue at the periphery to condemned tissue at the core should be increased as the absolute mass of the ischemic zone gets smaller.[2]

The autoradiograms obtained in these studies revealed a sharp interface between well-perfused tissue and ischemic tissue. Some investigators believe[26,27] that progressive gradients of flow characterize the transition between normal and ischemic tissue. Other groups, including ourselves,[28–31] believe that the interface is sharp. The findings in the present study further reinforce this view.

In studies by others,[7,10–13] tissue salvage has been demonstrated at the lateral borders of the infarct. In the present study, we also observed a lateral region of tissue salvage at 6 hours. Although this zone had disappeared by 24 hours, it does support the view that certain areas within the infarct may be more amenable to protection. We observed that if any viable tissue remains within the risk zone after 24 hours, the tissue inevitably is subepicardial in location. This can probably be attributed to greater collateral flow to the subepicardium than to the subendocardium. In the present study, microsphere counting suggested a transmural gradient of collateral flow, which would agree with the previous reports.[15,32]

Since about 10% of the subepicardium survived in these hearts, any long-term beneficial drug effect would have been expected to have increased the size of that zone. In a previous study[33] from this laboratory, using a similar procedure for estimating changes in infarct size, propranolol increased the amount of epicardial salvage from 15 to nearly 40% of the risk zone after 24 hours of ischemia. Thus, some interventions do promote salvage in this model.

# Effects of Reduced Coronary Flow on Thallium-201 Accumulation and Release in an In Vitro Rat Heart Preparation

SAMUEL Z. GOLDHABER, MD, JOHN B. NEWELL, AB, JOANNE S. INGWALL, PhD, GERALD M. POHOST, MD, NATHANIEL M. ALPERT, PhD, and ERIC T. FOSSEL, PhD

**To study the relation between myocardial thallium-201 (Tl-201) uptake, Tl-201 release, and reduced coronary flow, isolated Langendorff rat hearts (n = 8) were perfused for 3 hours at constant flows ranging from physiologic (12 ml/min) to severely ischemic (1.5 ml/min); thallium activity was monitored with a scintillation probe. Each heart was perfused for 1 hour with thallium buffer, followed by 2 hours with thallium-free buffer at the same flow rate. Accumulation curves for all 4 flows were monoexponential. However, release curves during the 2 hours of washout with thallium-free buffer demonstrated a biexponential configuration. The early fast release component decreased with reductions in coronary flow, and the later slow release component did not vary significantly with flow. These data show that thallium clearance has at least 2 components: a rapid (possibly extracellular) component related to coronary flow and a slow (possibly intracellular) component independent of coronary flow. These findings should be useful in providing a better understanding of thallium redistribution observed clinically.**

Despite the widespread use of thallium-201 (Tl-201) myocardial imaging, confusion still exists about the kinetic features of Tl-201 release from normal and ischemic myocardium.[1] Yet, the determination of relative myocardial Tl-201 distribution and its change over time is being carried out clinically to evaluate patients with possible coronary artery disease.[2–5] Change in Tl-201 distribution over time after intravenous administration is related both to uptake and release in myocardial tissue. Up to 90% of Tl-201 is extracted during passage through the myocardium.[6] The initial distribution of Tl-201 is related to regional blood flow to viable myocardium.[2] Release of Tl-201 from nonischemic myocardium is directly related to the change in its concentration in the blood after an intravenous injection.[7] However, the impact of ischemia on the release of Tl-201 is not well-understood.

Gewirtz et al[8] demonstrated no change in the rate of Tl-201 release from ischemic versus nonischemic left ventricular myocardium, using myocardial biopsy evaluation of Tl-201 activity in the canine left anterior descending coronary artery occlusion model after intravenous administration of Tl-201. In a later study, Gewirtz et al[9] substantiated this finding in the same model by evaluating arteriovenous Tl-201 differences in ischemic and nonischemic regions. Recently, Grunwald et al[1] studied the impact of ischemia on myocardial Tl-201 release after administration of an intracoronary dose in order to evaluate its release without the complicating effects of Tl-201 in the systemic arterial blood, as would be the case clinically. These investigators found a slowing of Tl-201 release as blood flow was reduced, which seemed paradoxical, considering the similar behavior of thallium and potassium ions in biological systems[10–14] and the known release of potassium which occurs during myocardial ischemic insult.[15–17]

The present study uses isolated retrograde perfused rat hearts to clarify further the impact of ischemia on myocardial Tl-201 uptake and release. Hearts are perfused at constant flow rates for the 3-hour duration of each experiment. The flow rates vary from 12 ml/min (control) to hypoperfusion rates of 6, 3, or 1.5 ml/min. During the first hour of perfusion, a thallium-labelled buffer was used. In this model, Tl-201 accumulation and retention in the myocardium may be studied without

the complications due to the uptake and release of Tl-201 by other organs or by neurohumoral factors exogenous to the heart. Thus, by monitoring the global retention of Tl-201 by the myocardium during the 2-hour release period, the influence of reduced coronary flow could be investigated. Observations of Tl-201 accumulation and release patterns in this model should be useful in understanding Tl-201 release patterns as they might be measured in patients using new quantitative approaches.[18,19]

## Methods

Male Sprague-Dawley rats (Charles River Breeding Laboratories, Wilmington, Massachusetts) weighing 320 to 370 g were anesthetized with Nembutal® (10 mg/100 g) administered intraperitoneally. Hearts were isolated and the coronary arteries were perfused retrogradely from the aorta using a modified Langendorff technique (Fig. 1). After transverse incision of the abdominal cavity, the diaphragm was transected and the anterior chest wall was reflected to expose the heart. The heart and proximal aorta were isolated from the distal aorta, pulmonary artery, pulmonary veins, and venae cavae. The heart was then placed in a shallow dish of iced normal saline solution. After exposure of the lumen of the proximal aorta with fine, blunt tweezers, the heart and proximal aorta were lifted and the proximal aorta was placed approximately 3 mm onto an aortic cannula. The proximal aorta was secured around the cannula temporarily with a serrated clip. Retrograde coronary perfusion through the aorta at a nonischemic flow rate of 12 ml/min[20] was then begun immediately with Krebs-Henseleit bicarbonate buffer (pH 7.4) through previously primed tubing. The time required from the initial abdominal incision until retrograde perfusion was no more than 3 minutes. Any pulmonary or thymic tissue adherent to the heart was then removed. The proximal aorta was secured to the cannula with a 3-0 silk suture. An 18 gauge needle was inserted into the left ventricle between the left anterior descending and left circumflex coronary arteries to monitor heart rate and left ventricular pressure.[21] As outlined in Figure 1, the left ventricular cannula was connected to a Statham model P23Db pressure transducer with a 10 cm segment of flexible thick-walled tubing. The pressure transducer's calibration outlet was placed level with the right atrium and the transducer was connected to a B-D Electrodyne CB-124B 4-channel monitor to display a continuous pressure waveform. A B-D Electrodyne WR-4D paper recorder was used. During each experiment, the heart rate and left ventricular peak systolic pressure were recorded at baseline, after 1 hour (at the end of the Tl-201 perfusion period), and after 3 hours (at the end of the period of perfusion with Tl-201–free buffer).

The perfusate, a modified Krebs-Henseleit buffer, consisted of NaCl 118.0 m*M*, KCl 4.7 m*M*; EDTA (2Na+) 0.5 m*M*, $KH_2PO_4$, 1.2 m*M*, $MgSO_4$ 1.2 m*M*, $CaCl_2$ 1.75 m*M*, $NaHCO_3$ 25.0 m*M*, and glucose 11.0 m*M*, with a pH of 7.4. The buffer was warmed to 37°C in a water bath and bubbled with 95% oxygen and 5% carbon dioxide for at least 10 minutes before use and for the duration of each experiment. The perfusate was delivered with a Masterflex roller head 7016 pump and was recirculated during the 1-hour uptake period but was not recirculated during the 2-hour release period.

A gamma scintillation probe (Ludlum model 2200) was positioned 5 cm from the long axis of the heart and was fitted with an 8 mm thick lead collimator that was 3.5 cm in length. The body of the probe was also wrapped in a 2 mm thick sheet of lead. The gamma probe window was set at 60 to 90 keV.

Two perfusates were prepared: 1 with 1 ml of Tl-201 (0.25 to 1.0 mCi/ml) added to 500 ml of buffer and the other without any radionuclide. Experiments were performed with flow held constant at either 12, 6, 3 , or 1.5 ml/min for each 3-hour experiment. During the first hour of each study, the isolated rat heart was perfused with thallium-containing buffer. The Tl-201 buffer was then discontinued and followed with 2 hours of perfusion with buffer free of Tl-201. During the period of perfusion with Tl-201–containing buffer, probe-determined activity was noted at 0.25, 0.5, 1, 1.5, 2, 2.5, 5, 10, 20, 30, 40, 50, and 60 minutes. After 1 hour, perfusion was begun with buffer free of Tl-201 and probe-monitored myocardial activity was expressed as a percentage of the maximal counts per minute achieved during the accumulation phase. Activity was monitored 0.25, 0.5, 1, 1.5, 2, 2.5, 5, 10, 20, 30, 40, 50, 60, 70, 80, 90, 100, 110, and 120 minutes after initiation of perfusion with Tl-201 free buffer.

The model $u(t) = a_1 + a_0 (1 - e^{-\lambda_u t})$ was fit to the uptake data using the BMDP nonlinear regression program BMDP3R,[22] a commercially available statistics package. Parameters $\lambda_u$, $a_0$, and $a_1$ were estimated, in addition to their standard errors. A separate run of the program was performed for each experimental flow level. BMDP3R was also used to perform tests for a multiexponential uptake-model. Uptake was found to be monoexponential at each of the levels of flow, except for a very fast initial component which could not be resolved at the sampling rate we employed. Therefore, this

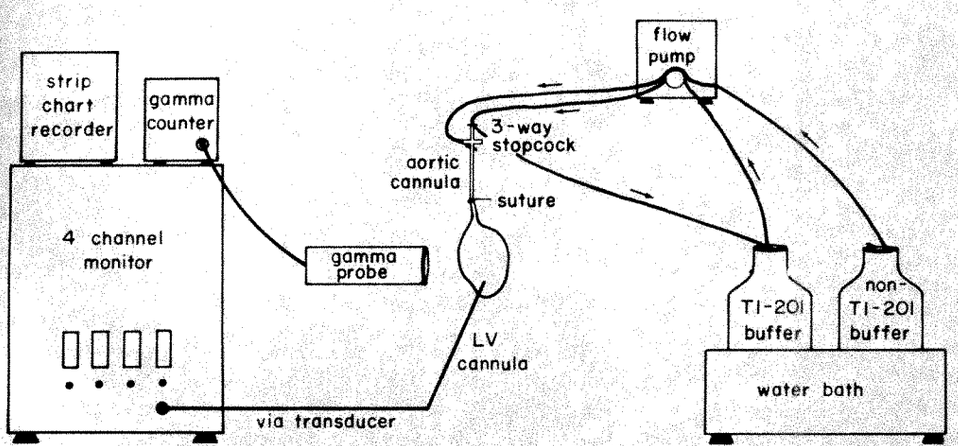

**FIGURE 1.** Schematic diagram of the experimental protocol. LV = left ventricular.

**TABLE I Hemodynamic Variables at Varying Flow Rates and Times (Mean ± Standard Deviation)**

| Flow (ml/min) | Baseline | | 1 Hour | | 3 Hours | |
|---|---|---|---|---|---|---|
| | HR | LVPSP | HR | LVPSP | HR | LVPSP |
| 12 | 260 ± 0 | 64 ± 4 | 235 ± 21 | 66 ± 7 | 250 ± 14 | 84 ± 8 |
| 6 | 220 ± 28 | 28 ± 24 | 240 ± 14 | 28 ± 5 | 220 ± 28 | 31 ± 1 |

HR = heart rate (beats/minute); LVPSP = left ventricular peak systolic pressure (mm Hg).

fast, small component was modeled as a constant at time zero (the parameter $a_1$).

For the release data, a multiexponential function was fit to the measured values of percent maximal counts per minute during washout, a(t), where $a(t) = A_1e^{-\lambda_1 t} + A_2e^{-\lambda_2 t}$, where $A_k$ (k = 1 or 2) are the amplitudes of the exponentials $e^{-\lambda_k t}$ and $\lambda_k$ are the respective washout constants. Time, t, is expressed relative to the beginning of the 2-hour washout period. The estimation of parameters $A_1$, $\lambda_1$, $A_2$, $\lambda_2$ and their standard errors was carried out using the computer program BMDP3R in the BMDP package from the University of California at Los Angeles. A separate run of the program was performed for each experimental flow level. The half-life of the washout constants was calculated as follows: $(\text{half-life})_k = \ln 2/\lambda_k$. Linear regressions were used to investigate the relations between flow and the exponential variables of both the uptake and release periods.

## Results

Baseline heart rate and left ventricular peak systolic pressure were significantly lower at 1.5, 3, and 6 ml/min of coronary perfusion than at the control perfusion rate of 12 ml/min (Table I). During the course of each 3-hour experiment, there was no significant change in the hemodynamic parameters at 12 and 6 ml/min of coronary flow (Table I). At 3 and 1.5 ml/min of coronary flow, the heart rate decreased during the first hour of the experimental protocol, but left ventricular peak systolic pressure did not change significantly during the 3-hour duration of each experiment. Reduction in coronary flow rates was correlated with both lower heart rate (r = 0.94) and lower left ventricular peak systolic pressure (r = 0.97).

During the 1-hour period of perfusion with the Tl-201–containing buffer, there was a monoexponential increase in Tl-201 activity (Fig. 2). For uptake, we found that $\lambda_u(\text{flow}) = (0.00766 \pm 0.00075) \times \text{flow} + 0.023 \pm 0.005$ (r = 0.99, p = 0.01), where $\lambda_u$ is the single exponential parameter for uptake. As flow decreased, the uptake constant decreased from $0.117 \pm 0.004$ $\text{min}^{-1}$ at 12 ml/min to $0.034 \pm 0.0004$ $\text{min}^{-1}$ at 1.5 ml/min. Accordingly, the half-life for the uptake constant increased from 6 to 23 minutes as coronary flow was reduced from 12 to 1.5 ml/min (Table II).

During perfusion with Tl-201–free buffer, release of Tl-201 demonstrated a biexponential pattern (Fig. 3). There was a fast release component initially; this was followed by a slow release component at each of the 4 flow rates (Fig. 4). As coronary flow was reduced, the initial fast release rate decreased significantly as assessed by linear regression analysis (r = 0.97, p = 0.03).

**TABLE II Uptake Constants $\lambda_u$ and Half-Life at Varying Flows**

| Flow (ml/min) | Uptake Constant $\lambda_u \pm$ SD ($\text{min}^{-1}$) | Half-Life (min) |
|---|---|---|
| 12 | 0.117 ± 0.004 | 6 |
| 6.0 | 0.067 ± 0.0005 | 10 |
| 3.0 | 0.053 ± 0.001 | 13 |
| 1.5 | 0.03 ± 0.0004 | 23 |

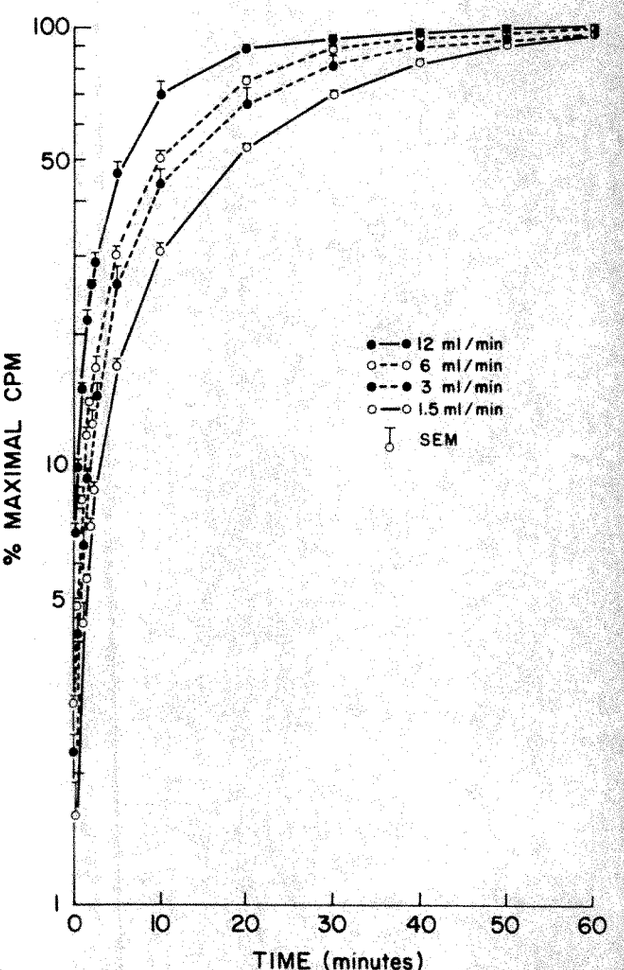

**FIGURE 2.** Net thallium-201 uptake during the 1 hour of Tl-201 loading. Note that even at the lowest coronary flow rate, 1.5 ml/min, 50% of the maximal counts per minute (CPM) have occurred by 20 minutes. SEM = standard error of the mean.

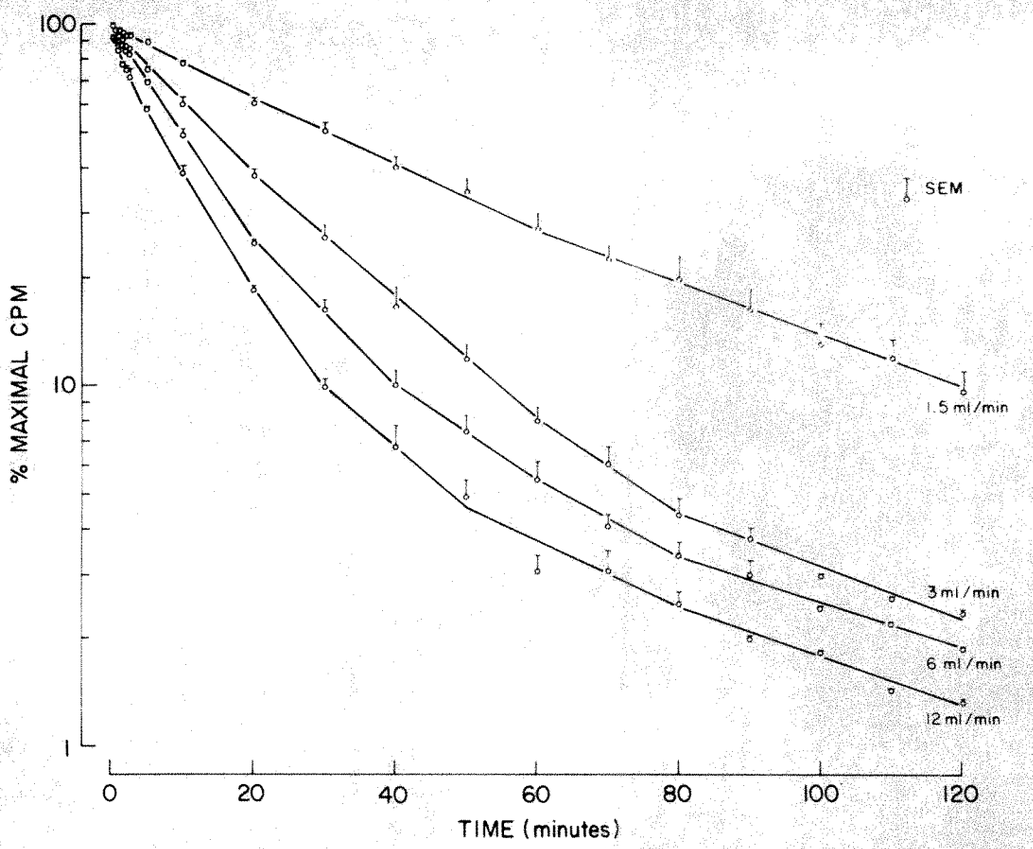

**FIGURE 3.** Thallium-201 release curves are shown at varying coronary flows. A biexponential model fits these release curves. CPM = counts per minute; SEM = standard error of the mean.

Because of the nonlinearity of this relation (Fig. 4), the data were reanalyzed using a linearizing transformation [ln $(0.125 - \lambda_1)$] of the release constants, and the significant monotonic relation between the fast release constant ($\lambda_1$) and flow was confirmed. The value of the fast initial exponential release constant decreased from $0.107 \pm 0.009$ min$^{-1}$ at 12 ml/min to $0.036 \pm 0.015$ min$^{-1}$ at 1.5 ml/min (Fig. 4). Accordingly, the half-time for the fast component of thallium released increased from 6.5 to 19 minutes as flow decreased from 12 to 1.5 ml/min (Table III). Although the value of the slow later exponential release constant decreased from $0.022 \pm 0.006$ min$^{-1}$ at 12 ml/min to $0.015 \pm 0.004$ min$^{-1}$ at 1.5 ml/min (Fig. 4), this change was not significant. The half-time for the slow component of thallium release increased from 32 minutes at 12 ml/min to 46 minutes at 1.5 ml/min, but this increase was not significant (Table III).

## Discussion

The results of this study show that if Tl-201 is delivered continuously using perfusate with a constant concentration, the myocardial uptake rate is monoexponential and decreases as the perfusion rate decreases. After the heart contains Tl-201, during perfusion with thallium-free buffer, 2 distinct exponential release phases are noted: a more rapid early phase and a slower late phase. The earlier more rapid phase showed a distinct and significant slowing as flow decreased, whereas the later and slower phase demonstrated a more subtle and insignificant decrease with decreasing perfusion. The fast release component may be related to myocardial clearance of Tl-201 from an extracellular space, whereas the slow release component may reflect a cellular compartment.

**Kinetic features of thallium-201 uptake:** There is a monoexponential increase in Tl-201 uptake when it is delivered at a constant rate over a 1-hour interval. Studies by our group have demonstrated that even during extreme ischemic-like insult in the fetal mouse heart culture model, thallium accumulates in myocardium during a 4-hour interval, after which net Tl-201 efflux from insulted myocardium occurs.[23] The rate constant of Tl-201 accumulation ($\lambda_u$) in the present model decreased with reduction in perfusion, mainly due to reduced delivery.

**Kinetic features of thallium-201 release:** It is known that ionic potassium is released from ischemic myocardium during ischemic insult.[15–17] Because thallium has been found to behave like potassium in biologic systems,[10–14] it was surprising when Gewirtz et al[8] demonstrated a comparable rate of release of Tl-201 from a region of myocardium made ischemic by ligation of the left anterior descending coronary artery and from a normally perfused region. This study was done using analysis of myocardial biopsy in a canine model, in

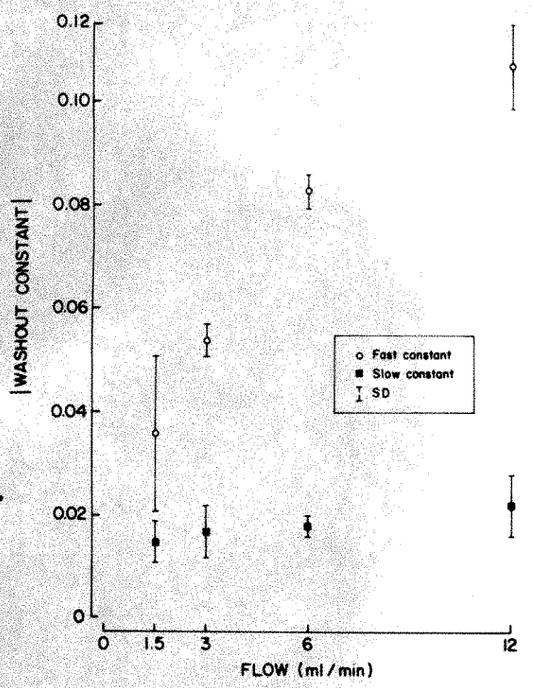

**FIGURE 4.** The absolute values of the slow and fast release constants are shown with varying coronary flow rates. The slow release constant does not change significantly with changes in coronary flow. In contrast, the fast release constant decreases with reduction in coronary flow. SD = standard deviation.

which Tl-201 was given intravenously followed by ligation of the left anterior descending coronary artery. Further studies by Gewirtz et al[9] using measurements of change in coronary arterial-coronary venous Tl-201 difference substantiated the previous observations.

Okada et al[24] examined the clearance of Tl-201 in a canine model with normal myocardial perfusion using implanted myocardial radiation detection probes. After an intravenous dose of thallium, 3 exponential phases of clearance from blood occurred: (1) a very early and relatively rapid component (half-life 2.4 minutes) which was most likely vascular; (2) a second less rapid component (half-life 14.1 minutes) which was probably interstitial; and (3) a third slow component (half-life 446 minutes) which was most likely intracellular. Myocardial activity reached 80% of peak within 1 minute. Afterward, a slow monoexponential myocardial release rate occurred (half-life 437 minutes) which ran parallel to the slowest exponential component of release from the blood. Further studies demonstrated that in zones of myocardium that were supplied by vessels with subnormal blood flow, Tl-201 activity increased more slowly, but that after a peak was achieved myocardial clearance again closely paralleled blood clearance.[7]

In an effort to investigate myocardial release more directly, Krivokapich and Shine[25] studied efflux of Tl-201 under nonischemic conditions with isolated perfused rabbit interventricular septa. Their experiments included a set of conditions similar to our protocol at 12 ml/min flow. Four septa labeled with Tl-201 for at least 40 minutes had washout conducted for ≥90 minutes with a buffer containing 5 m*M* of potassium chloride. The tissue clearance after 40 minutes of washout was 0.013 ± 0.003 $min^{-1}$, not significantly different from our slow release constant at 12 ml/min, 0.015 ± 0.004 $min^{-1}$. These investigators proposed 4 phases of thallium release: vascular, interstitial, rapid cellular, and slow cellular.

Finally, Grunwald et al[1] evaluated the relation between myocardial release and blood flow in the normal and subnormal range after intracoronary Tl-201 administration in a canine model. Tl-201 activity was monitored with an external scintillation detector. These investigators studied Tl-201 release for an interval of 50 minutes and demonstrated a monoexponential release component with a half-life of approximately 70 minutes. When measurements were made using coronary sinus Tl-201 output, 3 exponential components were demonstrated: (1) an early rapid component with a half-life of 2.25 minutes, (2) a slower intermediate component which the investigators did not comment upon (half-life approximately 13 minutes), and (3) a slow component with a half-life of 67 minutes. There is remarkable similarity in the data generated using the dog model of Grunwald and our isolated rat heart model. First, the slow washout phase is of the same order of magnitude (half-life = 67 minutes [dog] versus 32 minutes [isolated rat heart]). Species differences in the normal coronary blood flow/g in dog (1 ml/min/g)[26] versus isolated rat heart (15 ml/min/g)[20] are likely to account in part for this difference. In addition, there may be species differences in the way Tl-201 is handled. Furthermore, we, too, have clearly demonstrated that as coronary blood flow is reduced, the myocardial release rate also decreases.

**Clinical implications:** This report provides further clinically relevant understanding of the relation between the kinetic effects and myocardial perfusion of thallium. Recognizing that several distribution spaces are confounded in a purely exponential model and that specific variables for the mechanisms of transport cannot be estimated in this way,[27] one might view the

**TABLE III Half-Life (in Minutes) of the Fast ($\lambda_1$) and Slow ($\lambda_2$) Release Constants at Varying Flows**

| Flow (ml/min) | Fast Release | | Slow Release | |
|---|---|---|---|---|
| | $\lambda_1$ ± SD ($min^{-1}$) | Half-Life (min) | $\lambda_2$ ± SD ($min^{-1}$) | Half-Life (min) |
| 1.5 | 0.036 ± 0.015 | 19.0 | 0.015 ± 0.004 | 46 |
| 3 | 0.054 ± 0.003 | 13.0 | 0.017 ± 0.005 | 41 |
| 6 | 0.083 ± 0.003 | 8.4 | 0.018 ± 0.002 | 39 |
| 12 | 0.107 ± 0.009 | 6.5 | 0.022 ± 0.006 | 32 |

fast component as being primarily identified with the extracellular distribution space and the slow component as being primarily identified with the intracellular distribution space. Thus, changes in the early exponential component of thallium release after peak uptake are related to changes in blood flow, while later release is not significantly related to blood flow.

Our data should be helpful in interpreting myocardial clearance rates for thallium and in differentiating initial thallium distribution in normally perfused myocardium from tissue undergoing ischemic insult.[18,19] Some patients with initial defects due to chest wall or diaphragmatic attenuation or apical thinning have normal coronary arteries. Clearance rate measurements might allow more accurate definition of those patients with normal myocardial perfusion. From our data, it appears that the clearance rates which predominate during early thallium release provide insight into coronary blood flow. However, the clearance rates which predominate during later thallium release did not provide insight into the severity of myocardial ischemia.

Our previous work in the fetal mouse heart suggests that during ischemic-like injury, thallium efflux exceeds thallium influx only after 4 hours of insult.[23] Therefore, evaluation of very late clearance rates might provide further information on myocardial cellular necrosis. In the present study, observations made on thallium clearance rates during the first 20 minutes are predominantly related to coronary flow and might confound any estimate of cell viability. Our data suggest that observations on thallium release should be extended to identify more precisely the cellular component of thallium release.

**Acknowledgment:** We thank Kumpei Kobayashi, PhD for helpful suggestions and Linda Bosomworth, Lisa Bergantino, and Christine Coleman for preparation of the manuscript.

# BASIC THERAPY FOR THE PREVENTION OF ANGINA PECTORIS*

Report from "Step-Care Therapy for Ischemic Heart Disease"
—a special symposium preceding the annual meeting
of the American College of Cardiology, April 24, 1982.

## Synopsis of the Symposium

### Step 1: Nitrates

Since nitrates both reduce myocardial oxygen demand and increase myocardial oxygen supply, their use is warranted as initial therapy for the control of angina pectoris. Dosage needs often vary significantly from patient to patient, and attention should be given to ensure that an adequate dosage level has been established.

### Step 2: Nitrates and beta blockers

For angina refractory to maximum-dose nitrate therapy, the complementary actions of beta blockers and nitrates provide a rational therapeutic modality. At this point a beta blocker should be added to the nitrate regimen.

### Step 3: Nitrates and calcium antagonists

Calcium antagonists have special usefulness in controlling cases where the myocardial oxygen supply is diminished by coronary vasospasm; their use in combination with nitrates is recommended if Step 2 therapy is unsatisfactory (or if the patient has variant or vasospastic angina).

Consensus of the Symposium

**Nitrates are basic in step-care therapy for ischemic heart disease**

**Step 1**
Stable or unstable angina: Nitrates

**Step 2**
If not controlled: Nitrates + beta blockers

**Step 3**
If still not controlled (or in variant angina): Nitrates + calcium antagonists

**The basic antianginal agent in these basic dosage forms**

*In angina pectoris...*

# ISORDIL® (ISOSORBIDE DINITRATE)

*is basic*

*ISORDIL has been evaluated as probably effective when taken by the sublingual or chewable route and possibly effective when taken orally for this indication. See Brief Summary on following page.

Ives®

1982 Ives Laboratories Inc.

# ISORDIL®
# (ISOSORBIDE DINITRATE) IS BASIC

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: When taken by the sublingual or chewable route, Isordil Sublingual and Chewable Tablets are indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.

"Possibly" effective: When taken by the oral route, Isordil is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded as useful in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indications requires further investigation.

**Contraindication:** Idiosyncrasy to this drug.
**Warnings:** Data supporting the use of nitrites and nitrates during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.
**Precautions:** Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.
**Adverse Reactions:** Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

# MYOCARDIAL REVASCULARIZATION
## MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

## The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

## Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

## Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982

**The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.**

**To order your copy of this important new book use the order form below.**

**edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD**
**ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00**

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

## Who are the editors?

**Lawrence H. Cohn, MD,** is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982*.

**Vincenzo Gallucci, MD,** is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

## Table of Contents

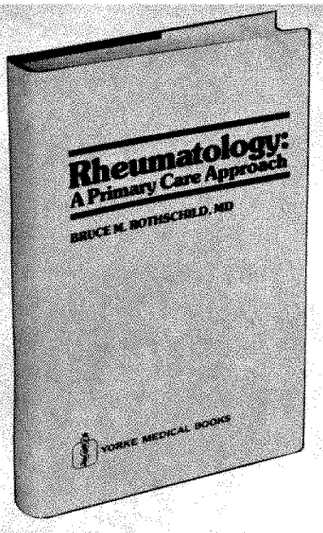
# Dialog of the Hearts –by Shakespeare:

**JULIET**

"Wilt thou be gone? It is not yet near day.
It was the nightingale, and not the lark,
That pierced the fearful hollow of thine ear.
Nightly she sings on yond pomegranate tree.
Believe me, love, it was the nightingale.

**ROMEO**



It was the lark, the herald of the morn;
No nightingale. Look, love, what envious streaks
Do lace the severing clouds in yonder East.
Night's candles are burnt out, and jocund day
Stands tiptoe on the misty mountain tops.
I must be gone and live, or stay and die.

**JULIET**

Yond light is not daylight; I know it, I.
It is some meteor that the sun exhales
To be to thee this night a torchbearer
And light thee on thy way to Mantua.
Therefore stay yet; thou need'st not to be gone."

The Dialogue of Romeo and Juliet, Act III, scene V.

**Another Dialog soon to appear—by Siemens.**

# The Diagnosis and Treatment Oriented Approach to Rheumatology with the Primary Care Physician in Mind

# Rheumatology

## A Primary Care Approach

Written by:

**Bruce M. Rothschild, MD**

Director, Division of Rheumatology, University Health Sciences, The Chicago Medical School Chief, Section of Rheumatology, V. A. Medical Center North Chicago, Illinois

**ISBN 0-914316-33-8 430 pp., illus., November 1982, $39.50**

## What is Rheumatology: A Primary Care Approach?

- a succinct (approx. 450 pp.) yet comprehensive presentation of the latest techniques in diagnosis and therapeutic interventions of most use to the primary care physician
- a practical "how-to" desk reference to a difficult but common disease affecting over 35 million patients in the U.S. alone
- a book meant to be used regularly, not read once and stored away on a library shelf
- the primary care physicians' answer to the huge, weighty tomes on Rheumatology which offer too little on diagnosis and treatment and too much on etiology and mechanisms of disease

## Rheumatology: A Primary Care Approach is Not

- a research monograph filled with esoteric information of little use to the practicing primary care physician
- a difficult to follow, badly organized reference tool requiring a thorough knowledge of the subject matter before it can be used effectively
- a massive and verbose dissertation more useful as a door stop than a clinical reference

We know of no other book on rheumatic disease which covers the subject as exhaustively in terms of diagnosis and treatment while avoiding wasting the busy practitioner's time by including information of little interest to the primary care physician. This book emphasizes that information necessary to recognize basic disease processes and their natural history. It provides the reader with the information necessary for making a diagnosis and initiating a plan of treatment. Information on differential diagnosis from the point of view of characteristics which would not fit with a given diagnosis is also provided. It is especially strong on the interpretation of rheumatologic radiology and in its approach to joint examination and assessment of lab results. Rheumatic disease cannot be cured but proper intervention can reduce and sometimes eliminate the attendant disability. This book provides you with the means to diagnose, assess and decide for yourself the necessary intervention.

## From the Preface:

*"More than 15 million individuals in the United States suffer from arthritis, and there are only 3,000 physicians practicing rheumatology. It is evident that the majority of patients receive continuing care from the nonrheumatologist, i.e., the internist, family practitioner, pediatrician and other disciplines in medicine. Therefore, we require concise and authoritative clinical guidelines for the primary care physician. With this as motivation Dr. Bruce Rothschild has skillfully structured a text geared to the particular and immediate needs of the practitioner. . . This text. . . is an important contribution to continuing medical education of the clinician. It will be of immediate interest and value to clinicians in a wide variety of specialties and should be of great assistance to the faculties and student bodies of our medical schools. We have long needed this type of approach to primary care of patients with musculoskeletal diseases and we are indebted to the author for his accomplishments."*

**Alfred Soffer, MD**
Chief Editor Archives of Internal Medicine

## Table of contents

**Section 1 - Investigative Techniques** • Chapter 1 - The Rheumatologic History and Physical Examination • Chapter 2 - Arthrocentesis and Joint Fluid Evaluation • Chapter 3 - Laboratory Studies • Chapter 4 - Radiology of Joint Disease • **Section 2 - Patterns of Disease** • Chapter 5 - Infectious Agent Arthritis • Chapter 6 - Arthritis of Mechanical Derivation • Chapter 7 - Crystalline Arthritis • Chapter 8 - Rheumatoid Arthritis • Chapter 9 - Juvenile Rheumatoid Arthritis • Chapter 10 - Ankylosing Spondylitis • Chapter 11 - Reiter's Syndrome and Psoriatic Arthritis • Chapter 12 - Arthritis Associated with Gastrointestinal Disease • Chapter 13 - Endocrine, Metabolic, and Deposition Disease • Chapter 14 - Arthritis Associated with Hematologic Disease • Chapter 15 - Miscellaneous Causes of Arthritis • Chapter 16 - Nonarticular Rheumatism • Chapter 17 - Systemic Lupus Erythematosus, Polymyositis, and Sjogren's Syndrome • Chapter 18 - Scleroderma • Chapter 19 - Vasculitis/ Vasculopathy • **Section 3 - Management** • Chapter 20 - Approach to Diagnosis • Chapter 21 - Compliance and Quackery • Chapter 22 - Salicylate Pharmacodynamics • Chapter 23 -Medication Therapy • Chapter 24 - Rehabilitation Therapy • Chapter 25 - Surgical Intervention

NOW...FOR OPTIMAL HEMODYNAMIC RESPONSE
(nitroglycerin) TRIDIL®
THE IV NITRO
Tridil™
Tridil™
Tridil™
10 ml
Tridil is a concentrated drug which must be diluted prior to use.
© 1982 American Critical Care
Division of American Hospital Supply Corporation

## IN CHF ASSOCIATED WITH ACUTE MI

# SYSTEM THAT DELIVERS

## Efficacy:

- Quickly relieves pulmonary congestion with little effect on cardiac output[1]
- Helps redistribute blood flow to the infarcted myocardium[2,3]

## Predictability:

- Produces dose-responsive venous and arterial dilation to help control both preload and afterload
- Tridilset,™ a special non-absorbing IV administration set, delivers Tridil with the greatest possible accuracy[4,5]

## Safety:

- Metabolites have only minor activity and are rapidly excreted
- Highly concentrated Tridil (5 mg/ml) helps avoid the risk of fluid overload (especially helpful in the presence of oliguria)

***TRIDIL SYSTEM*—the preferred IV nitroglycerin in CHF associated with acute MI**

- Highest concentration currently available—easy dilution, convenient administration, conserves fluid intake.
- Non-absorbing Tridilset IV set allows precise titration
- Comprehensive clinical/technical support

## *TRIDIL SYSTEM*

**delivers a new level of therapeutic precision to the treatment of CHF associated with acute MI**

Please see the following page for a brief summary of prescribing information.

TRIDIL® (nitroglycerin) SYSTEM

**American Critical Care**

# TRIDIL® (nitroglycerin)

**Brief Summary of Full Prescribing Information**

NOT FOR DIRECT INTRAVENOUS INJECTION. TRIDIL® MUST BE DILUTED IN DEXTROSE (5%) INJECTION, USP OR SODIUM CHLORIDE (0.9%) INJECTION, USP PRIOR TO ITS INFUSION (SEE DOSAGE AND ADMINISTRATION SECTION OF FULL PRESCRIBING INFORMATION). THE ADMINISTRATION SET USED FOR INFUSION WILL AFFECT THE AMOUNT OF TRIDIL DELIVERED TO THE PATIENT. (SEE WARNINGS, AND DOSAGE AND ADMINISTRATION SECTIONS.)

**CAUTION**

SEVERAL PREPARATIONS OF NITROGLYCERIN FOR INJECTION ARE AVAILABLE. THEY DIFFER IN CONCENTRATION AND/OR VOLUME PER VIAL. WHEN SWITCHING FROM ONE PRODUCT TO ANOTHER ATTENTION MUST BE PAID TO THE DILUTION AND DOSAGE AND ADMINISTRATION INSTRUCTIONS.

**CONTRAINDICATIONS**

TRIDIL should not be administered to individuals with:

1. A known hypersensitivity to nitroglycerin or a known idiosyncratic reaction to organic nitrates.
2. Hypotension or uncorrected hypovolemia, as the use of TRIDIL in such states could produce severe hypotension or shock.
3. Increased intracranial pressure (e.g., head trauma or cerebral hemorrhage).
4. Constrictive pericarditis and pericardial tamponade.

**WARNINGS**

1. Nitroglycerin readily migrates into many plastics. To avoid absorption of nitroglycerin into plastic parenteral solution containers, the dilution and storage of TRIDIL for intravenous infusion should be made only in *glass* parenteral solution bottles.
2. Some filters absorb nitroglycerin; they should be avoided.
3. Forty to 80% of the total amount of nitroglycerin in the final diluted solution for infusion is absorbed by the polyvinylchloride (PVC) tubing of the intravenous administration sets currently in general use. The higher rates of absorption occur when flow rates are low, nitroglycerin concentrations are high, and the administration set is long. Although the rate of loss is highest during the early phase of infusion (when flow rates are lowest) the loss is neither constant nor self-limiting; consequently no simple calculation or correction can be performed to convert the theoretical infusion rate (based on the concentration of the infusion solution) to the actual delivery rate.

Because of this problem, American Critical Care has developed TRIDILSET,™ an administration set in which loss of TRIDIL is minimal (less than 1%). TRIDILSET (or a similar administration set) is recommended for infusions of TRIDIL.

DOSING INSTRUCTIONS MUST BE FOLLOWED WITH CARE. IT SHOULD BE NOTED THAT WHEN TRIDILSET IS USED, THE CALCULATED DOSE WILL BE DELIVERED TO THE PATIENT BECAUSE THE LOSS OF TRIDIL DUE TO ABSORPTION IN STANDARD PVC TUBING WILL BE KEPT TO A MINIMUM. NOTE THAT THE DOSAGES COMMONLY USED IN PUBLISHED STUDIES UTILIZED GENERAL-USE PVC ADMINISTRATION SETS AND RECOMMENDED DOSES BASED ON THIS EXPERIENCE ARE TOO HIGH WHEN TRIDILSET IS USED.

**PRECAUTIONS**

TRIDIL (nitroglycerin) should be used with caution in patients with severe liver or renal disease.

Excessive hypotension, especially for prolonged periods of time, must be avoided because of possible deleterious effects on the brain, heart, liver, and kidney from poor perfusion and the attendant risk of ischemia, thrombosis, and altered function of these organs. Paradoxical bradycardia and increased angina pectoris may accompany nitroglycerin-induced hypotension. Patients with normal or low pulmonary capillary wedge pressure are especially sensitive to the hypotensive effects of TRIDIL. If pulmonary capillary wedge pressure is being monitored, it will be noted that a fall in wedge pressure precedes the onset of arterial hypotension, and the pulmonary capillary wedge pressure is thus a useful guide to safe titration of the drug.

**Carcinogenesis, mutagenesis, impairment of fertility**

No long-term studies in animals were performed to evaluate carcinogenic potential of TRIDIL.

**Pregnancy**

Category C. Animal reproduction studies have not been conducted with TRIDIL. It is also not known whether TRIDIL can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. TRIDIL should be given to a pregnant woman only if clearly needed.

**Nursing Mothers**

It is not known whether nitroglycerin is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when TRIDIL is administered to a nursing woman.

**Pediatric Use**

The safety and effectiveness of TRIDIL in children have not been established.

**ADVERSE REACTIONS**

The most frequent adverse reaction in patients treated with TRIDIL is headache, which occurs in approximately 2% of patients. Other adverse reactions occurring in less than 1% of patients are the following: tachycardia, nausea, vomiting, apprehension, restlessness, muscle twitching, retrosternal discomfort, palpitations, dizziness and abdominal pain.

The following additional adverse reactions have been reported with the oral and/or topical use of nitroglycerin: cutaneous flushing, weakness, and occasionally drug rash or exfoliative dermatitis.

**OVERDOSAGE**

Accidental overdosage of TRIDIL may result in severe hypotension and reflex tachycardia which can be treated by elevating the legs and decreasing or temporarily terminating the infusion until the patient's condition stabilizes. Since the duration of the hemodynamic effects following TRIDIL administration is quite short, additional corrective measures are usually not required. However, if further therapy is indicated, administration of an intravenous alpha adrenergic agonist (e.g., methoxamine or phenylephrine) should be considered.

**DOSAGE AND ADMINISTRATION**

(For complete information, please see Full Prescribing Information)

**NOT FOR DIRECT INTRAVENOUS INJECTION**

TRIDIL IS A CONCENTRATED, POTENT DRUG WHICH MUST BE DILUTED IN DEXTROSE (5%) INJECTION, USP OR SODIUM CHLORIDE (0.9%) INJECTION, USP PRIOR TO ITS INFUSION. TRIDIL SHOULD NOT BE ADMIXED WITH OTHER DRUGS.

Some patients with normal or low left ventricular filling pressures or pulmonary capillary wedge pressure (e.g., angina patients without other complications) may be hypersensitive to the effects of TRIDIL and may respond fully to doses as small as 5 mcg/min. These patients require especially careful titration and monitoring.

There is no fixed optimum dose of TRIDIL. Due to variations in the responsiveness of individual patients to the drug, each patient must be titrated to the desired level of hemodynamic function. Therefore, continuous monitoring of physiologic parameters (e.g., blood pressure and heart rate in all patients, other measurements such as pulmonary capillary wedge pressure, as appropriate), MUST BE PERFORMED to achieve the correct dose. Adequate systemic blood pressure and coronary perfusion pressure must be maintained.

**HOW SUPPLIED**

NDC 0094-0090-10, 50 mg-10 ml ampul. Each ml contains 5 mg nitroglycerin. Protect from freezing.

*Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...*

# THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

**Libi Sherf, MD, FACC**

Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

**Henry N. Neufeld, MD, FACC**

Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon—indeed, *every physician*—should have a good basic knowledge of the Pre-excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

*"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."*

*Thomas N. James, MD*
*The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals.*

**YORKE MEDICAL BOOKS, Box C-757, Brooklyn, NY 11205**

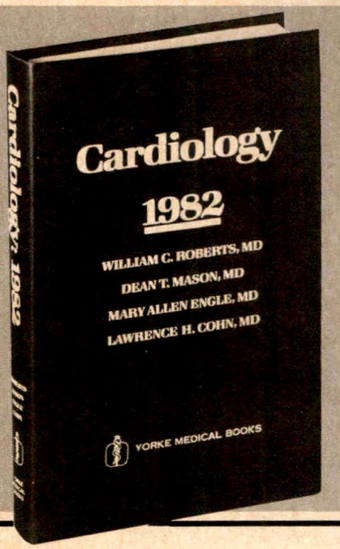
# CARDIOLOGY: 1982



## The Second Issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

*written by:*

- **William C. Roberts, M.D.**
  *Chief, Pathology Branch/National Heart, Lung & Blood Institute/National Institutes of Health/and Clinical Professor of Pathology & Medicine (Cardiology)/Georgetown University School of Medicine, Washington, D.C.*
- **Dean T. Mason, M.D.**
  *Professor of Medicine and Physiology, and Chief of Cardiovascular Medicine, University of California, Davis School of Medicine and University Medical Center, Davis and Sacramento, California*
- **Mary Allen Engle, M.D.**
  *Stavros S. Niarchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York*
- **Lawrence H. Cohn, M.D.**
  *Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston*

**ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066**

## What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

## CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

**CARDIOLOGY: 1982** provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well-established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and original tables condenses valuable information into instantly understandable knowledge.

### *Reviews of the first edition*

***"...recommend...to any reader interested in the literature of cardiology."***
Irwin R. Callen, M.D.
JAMA, November, 1981

***"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended."***
Philip Reichert, M.D.
New York State Journal of Medicine, September, 1981

***"This is an excellent book, very well organized and written...should be on the shelf of the library, cardiologist, and internist."***
COL. Robert B. Franklin, MC, USA
Military Medicine, November, 1981

The Secure Diabetic
When diet alone has failed in NIDDM, successful management with diet and Diabinese® (chlorpropamide) is a source of great security to both patient and physician.
By safely lowering blood sugar, once-a-day Diabinese provides uncomplicated control every day for nearly a million secure diabetics.*
Diabinese is the most widely prescribed oral anti-diabetic agent. Its extensive record of efficacy and safety gives physicians confidence that their patients will be well controlled...while the once-daily regimen, regardless of dosage, helps assure compliance. And, Diabinese is economical.
*As with all sulfonylureas, hypoglycemia may occur with Diabinese, especially when dosage is not properly adjusted to the patient's requirements.

Diet &
Diabinese®
(chlorpropamide)
Tablets
100 mg and
250 mg
A proven regimen...
continue it with confidence.

© 1982 PFIZER INC

# Diet & Diabinese (chlorpropamide)

Tablets 100 mg and 250 mg

## A proven regimen... continue it with confidence.

**BRIEF SUMMARY**
**DIABINESE® (chlorpropamide) Tablets**

**Contraindications:** Diabinese is not indicated in patients having juvenile or growth-onset diabetes mellitus, severe or unstable "brittle" diabetes, and diabetes complicated by ketosis and acidosis, diabetic coma, major surgery, severe infection, or severe trauma. Diabinese is contraindicated during pregnancy. Serious consideration should be given to the potential hazard of its use in women of childbearing age who may become pregnant.
Diabinese is contraindicated in patients with serious impairment of hepatic, renal, or thyroid function.
**Precautions:** Use chlorpropamide with caution with barbiturates, in patients with Addison's disease or in those ingesting: alcohol, antibacterial sulfonamides, thiazides, phenylbutazone, salicylates, probenecid, dicoumarol or MAO inhibitors. Adequate dietary intake should be assured in all patients using Diabinese.
**Warnings:** DIABINESE (CHLORPROPAMIDE) SHOULD NOT BE USED IN JUVENILE DIABETES OR IN DIABETES COMPLICATED BY ACIDOSIS, COMA, SEVERE INFECTION, MAJOR SURGICAL PROCEDURES, SEVERE TRAUMA, SEVERE DIARRHEA, NAUSEA AND VOMITING, ETC. HERE, INSULIN IS INDISPENSABLE.
HYPOGLYCEMIA, IF IT OCCURS, MAY BE PROLONGED. (SEE ADVERSE REACTIONS.) IN INSTANCES OF CONCOMITANT USE WITH INSULIN, PATIENTS SHOULD BE CAREFULLY MONITORED.
**Adverse Reactions:** Usually dose-related and generally respond to reduction or withdrawal of therapy. Generally transient and not of a serious nature and include anorexia, nausea, vomiting and gastrointestinal intolerance; weakness and paresthesias.
Certain untoward reactions associated with idiosyncrasy or hypersensitivity have occasionally occurred, including jaundice, skin eruptions rarely progressing to erythema multiforme and exfoliative dermatitis, and probably depression of formed elements of the blood. They occur characteristically during the first six weeks of therapy. With a few exceptions, these manifestations have been mild and readily reversible on the withdrawal of the drug. The more severe manifestations may require other therapeutic measures, including corticosteroid therapy. Diabinese should be discontinued promptly when the development of sensitivity is suspected.
Jaundice has been reported, and is usually promptly reversible on discontinuance of therapy. THE OCCURRENCE OF PROGRESSIVE ALKALINE PHOSPHATASE ELEVATION SHOULD SUGGEST THE POSSIBILITY OF INCIPIENT JAUNDICE AND CONSTITUTES AN INDICATION FOR WITHDRAWAL OF THE DRUG.
Leukopenia, thrombocytopenia and mild anemia, which occur occasionally, are generally benign and revert to normal, following cessation of the drug.
Cases of aplastic anemia and agranulocytosis, generally similar to blood dyscrasias associated with other sulfonylureas, have been reported.
BECAUSE OF THE PROLONGED HYPOGLYCEMIC ACTION OF DIABINESE, PATIENTS WHO BECOME HYPOGLYCEMIC DURING THERAPY WITH THIS DRUG REQUIRE CLOSE SUPERVISION FOR A MINIMUM PERIOD OF 3 TO 5 DAYS, during which time frequent feedings or glucose administration are essential. The anorectic patient or the profoundly hypoglycemic patient should be hospitalized.
Rare cases of phototoxic reactions have been reported.
Edema associated with hyponatremia has been infrequently reported. It is usually readily reversible when medication is discontinued.
**Dosage:** The total daily dosage is generally taken at a single time each morning with breakfast. Occasionally, cases of gastrointestinal intolerance may be relieved by dividing the daily dosage. A LOADING OR PRIMING DOSE IS NOT NECESSARY AND SHOULD NOT BE USED. The mild to moderately severe, middle-aged, stable diabetic should be started on 250 mg daily. Because the geriatric diabetic patient appears to be more sensitive to the hypoglycemic effect of sulfonylurea drugs, older patients should be started on smaller amounts of Diabinese, in the range of 100 to 125 mg daily.
After five to seven days following initiation of therapy, dosage may be adjusted upward or downward in increments of 50 to 125 mg at intervals of three to five days. PATIENTS WHO DO NOT RESPOND COMPLETELY TO 500 MG DAILY WILL USUALLY NOT RESPOND TO HIGHER DOSES. Maintenance doses above 750 mg daily should be avoided.
**Supply:** 100 mg and 250 mg, blue, 'D'-shaped, scored tablets.
*More detailed professional information available on request.*

# Supraventricular Nonreentrant Tachycardia Due to Simultaneous Conduction Through Dual Atrioventricular Nodal Pathways

FREDERICK J. SUTTON, MD and YU-CHEN LEE, MD

Simultaneous conduction of atrial paced beats through dual atrioventricular (AV) nodal pathways was first described by Wu et al[1] in 1975. Subsequently, Csapo[2] reported on a patient with paroxysmal nonreentrant tachycardia due to this mechanism. Recently, Gomes et al[3] performed electrophysiologic studies in 3 patients with supraventricular tachycardia and stated that procainamide altered conduction and refractoriness of the anterograde fast and slow pathways of the AV node so that simultaneous conduction could occur during atrial pacing. The present report describes 2 patients with sustained nonreentrant tachycardia due to simultaneous conduction through dual AV nodal pathways, and discusses various precipitating factors of this unusual arrhythmia.

From the Division of Cardiology, Department of Medicine, University of Maryland Hospital, Baltimore, Maryland. Manuscript received June 7, 1982; revised manuscript received November 25, 1982, accepted November 27, 1982.

*Patient 1: A 33-year-old man was hospitalized for palpitations. A 24-hour Holter tape had previously revealed irregular paroxysmal supraventricular tachycardia which was interpreted as atrial fibrillation (Fig. 1). He received propranolol, 20 mg orally 4 times daily, which aggravated the palpitations. Administration of 50 mg of bethanecol chloride, orally, prolonged the episodes of supraventricular tachycardia, which were terminated by 0.5 mg of atropine sulfate administered intravenously. During tachycardia an intraatrial electrogram showed that most of the P waves were followed by 2 QRS complexes (Fig. 2). When the P wave was followed by a single QRS complex, the P-R interval was markedly prolonged. Administration of procainamide and disopyramide also aggravated the arrhythmia.*

*Pacing techniques included incremental atrial pacing until the development of second degree AV nodal block, programmed atrial extrastimuli scanning diastole during atrial pacing at a cycle length of 700 ms, and programmed single ventricular extrastimulus scanning diastole during sinus rhythm. No discontinuity of $A_1$-$A_2$, $A_2$-$H_2$ could be demonstrated, and no arrhythmia was induced by atrial pacing. During sinus rhythm an interpolated ventricular extrastimulus produced 2 distinct patterns (Fig. 3). When the coupling interval was ≤330 ms, no tachycardia was induced, and there was minimal prolongation of the A-H interval of the first sinus beat which followed the ventricular extrastimuli (Fig. 3 and 4). At longer coupling intervals, most extrastimulus beats had a prolonged A-H interval ranging from 400 to 550 ms (Fig. 3) and were followed by short runs of nonreentrant tachycardia (Fig. 5). The induced tachycardia was similar to the spontaneous tachycardia. A His potential was recorded preceding each QRS complex with the H-V interval constant at 45 ms. No ventriculoatrial conduction was present during ventricular pacing.*

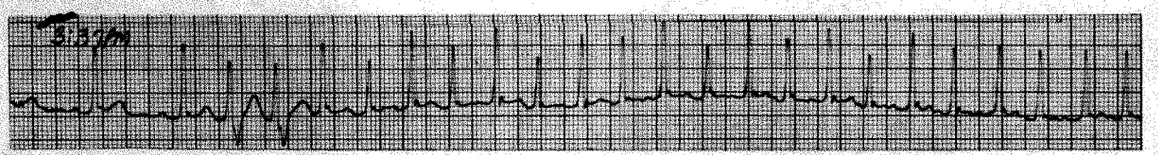

**FIGURE 1.** Patient 1. Holter tracing. After 2 sinus beats a rapid irregular rhythm is seen which was initially interpreted as atrial fibrillation.

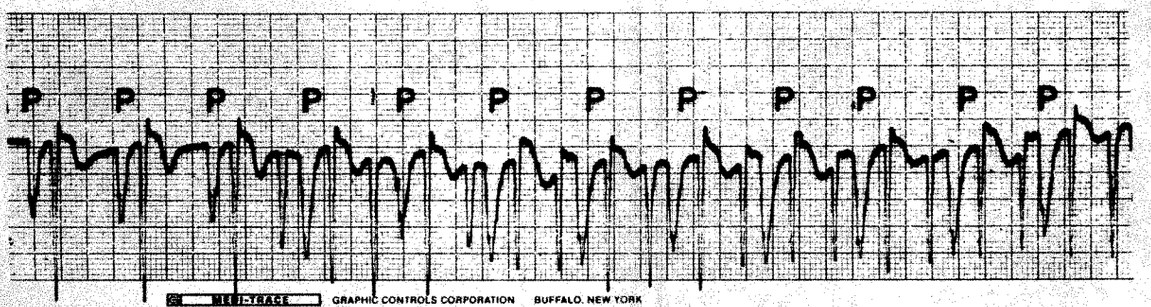

**FIGURE 2.** Patient 1. Intraatrial electrogram after administration of bethanocal chloride. After 2 sinus beats a supraventricular tachycardia is seen. P waves are regular, and each P wave is followed by 2 QRS complexes.

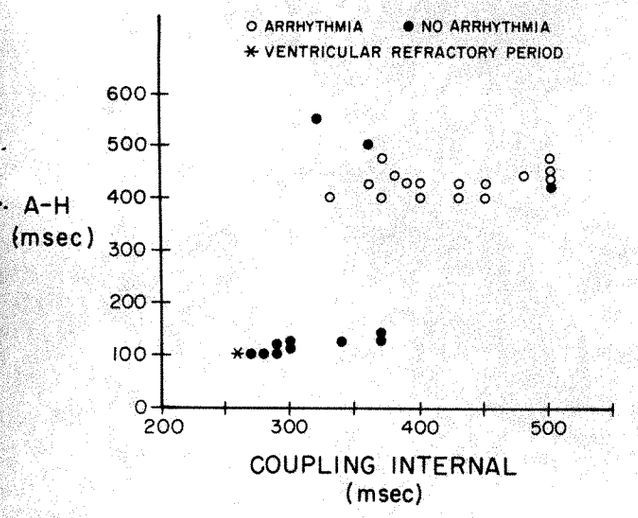

**FIGURE 3.** Patient 1. The relation of the coupling interval of the programmed ventricular extrasystole and the A-H interval of the first sinus beat after the extrasystole. Prolonged A-H interval of the first sinus beat was seen only when the coupling interval was more than 330 ms. The supraventricular tachycardia was induced only when the A-H interval was prolonged.

*Patient 2: A 68-year-old man was referred for evaluation of supraventricular tachycardia, which developed after quinidine treatment for ventricular premature contractions. Procainamide and disopyramide also induced similar supraventricular tachycardia characterized by 1 P wave followed by 2 QRS complexes (Fig. 6).*

The supraventricular tachycardia in these 2 patients is extremely unusual in that the arrhythmia was aggravated by increased vagal tone, propranolol, and type 1 antiarrhythmic drugs. This tachyarrhythmia is most likely due to simultaneous conduction through dual AV nodal pathways. In the first patient, the spontaneous paroxysmal nonreentrant supraventricular tachycardia was repeatedly reproduced by appropriately timed ventricular stimuli during sinus rhythm. The interpolated ventricular beats partly penetrated the distal AV node, which remained refractory for the oncoming sinus impulse traveling through the fast pathway. However, the same sinus impulse traveling down the slow pathway was sufficiently delayed to allow recovery of the distal AV nodal tissue, making ventricular capture possible. The subsequent sinus impulse was conducted simultaneously through both fast and slow AV nodal tracts, resulting in 2 QRS complexes after each P wave (Fig. 7

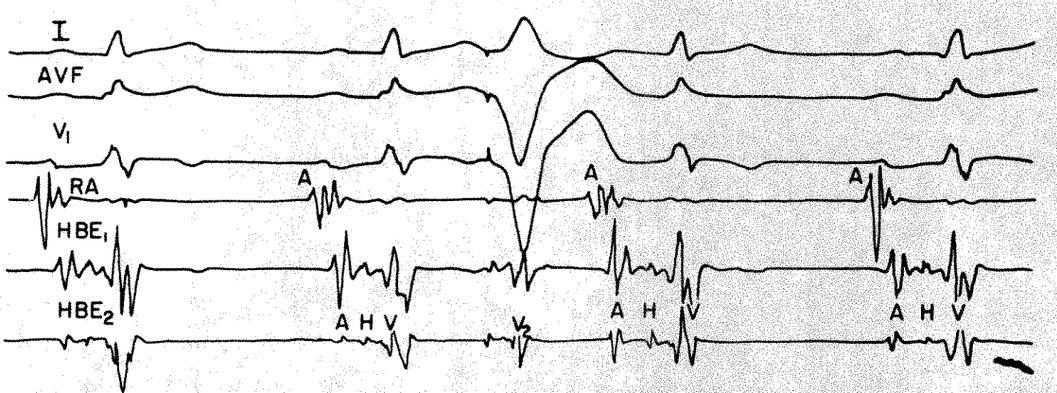

**FIGURE 4.** Patient 1. During sinus rhythm an interpolated ventricular extrastimulus (coupling interval of 320 ms) failed to induce a supraventricular tachycardia and the A-H interval of the following sinus beat prolonged minimally. I, aVF, V = surface electrocardiographic leads; RA = right atrial electrocardiogram; $HBE_1$ and $HBE_2$ = proximal and distal His bundle electrograms, respectively; $V_2$ = programmed ventricular extrasystole.

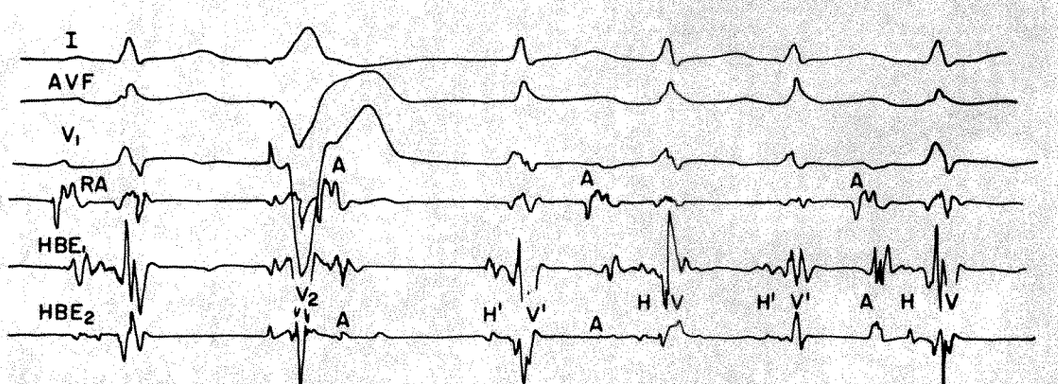

**FIGURE 5.** Patient 1. During sinus rhythm an interpolated ventricular extrastimulus (coupling interval of 460 ms) induced a nonreentrant supraventricular tachycardia. A-H interval of the first sinus beat after the ventricular extrastimulus was markedly prolonged (440 ms).

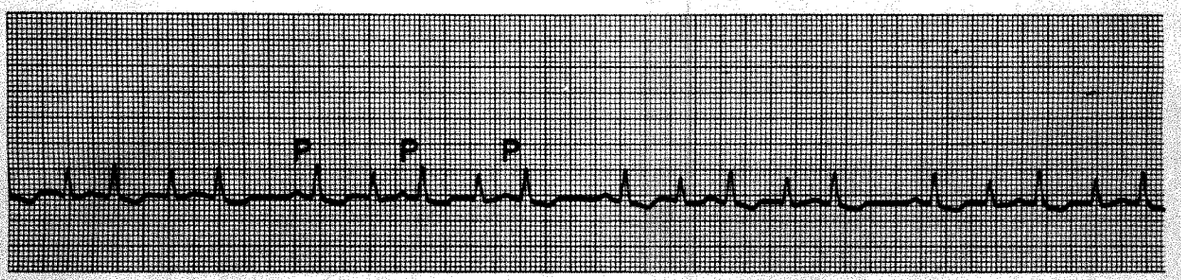

**FIGURE 6.** Patient 2. Lead II surface electrocardiogram. The QRS complexes occur in groups of 5. The first 2 P waves in each group are followed by 2 QRS complexes and the third P wave is followed by a single QRS complex.

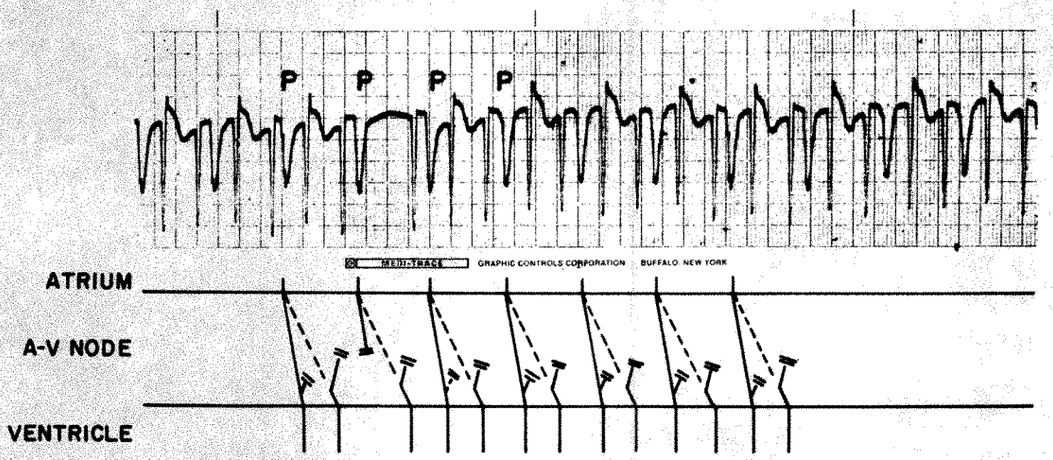

**FIGURE 7.** Patient 1. Laddergram of the proposed mechanism of tachycardia. Presence of retrograde conduction block of both pathways enabled simultaneous anterograde conduction of the sinus P waves. The fourth P wave is conducted through only the slow pathway (**dotted line**) due to deeper retrograde penetration of the fast pathway (**solid line**) which prevented anterograde conduction.

and 8). This rhythm was maintained because the refractory period of the distal common pathway was shorter than the shortest cardiac cycle, and the distal AV nodal pathway of either side was refractory to the retrograde stimuli from the opposite tract (Fig. 8). Shortening of the coupling interval of the ventricular extrastimulus to ≤330 ms allowed sufficient recovery time for the following sinus beat to conduct normally through the fast pathway, and this impulse could then penetrate the slow pathway retrogradely and abort the tachycardia. The presence of 2 distinct patterns of A-H conduction in Figure 3 suggests dual nodal tracts which are not excluded by the failure to document a discontinuous $A_1$-$A_2$, $A_2$-$H_2$ curve in an anterograde fashion.[4]

The supraventricular tachycardia of the first patient was aggravated by increased vagal tone and improved by atropine sulfate. Such paradoxical response has not been reported previously. One possible explanation is that increased vagal tone potentiated the unidirectional

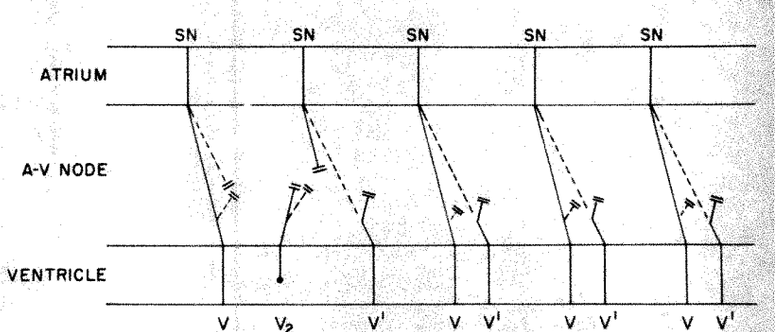

**FIGURE 8.** Mechanism of the programmed ventricular extrastimulus inducing supraventricular tachycardia. The ventricular extrasystole penetrated both pathways retrogradely, and was deep enough to prevent anterograde conduction of the first pathway. However, the slow pathway recovered soon enough to allow anterograde conduction. Presence of retrograde conduction block of both pathways enabled subsequent simultaneous anterograde conduction of the sinus P waves. SN = sinus node; V = QRS conducted through fast pathway; $V^1$ = QRS conducted through slow pathway.

retrograde block that is present in the AV nodal pathway in the basal state. The increased vagal tone insulates both AV nodal pathways and makes anterograde conduction through both AV nodal pathways possible. The supraventricular tachycardia in the second patient probably had the same mechanism as that in the first patient, although electrophysiologic study could not be performed. The episodes manifested by QRS complexes in groups of 5 are explained by the presence of 3 to 2 anterograde AV block through the slow pathway.

Procainamide has been reported to facilitate simultaneous conduction through dual AV nodal pathways by altering conduction and refractoriness of the anterograde fast and slow pathways of the AV node during atrial pacing.[3] However, we believe that the type 1 antiarrhythmic drug in our patients potentiated simultaneous conduction through dual AV nodal pathways by blocking retrograde conduction. Impairment of retrograde conduction of the AV node by these drugs has been reported previously.[5–7]

**Acknowledgment:** We thank Leonard Scherlis, MD, for review of the manuscript, Debbie Trust for secretarial assistance, and Frank Morris, MD, for referring the second case.

# Survival After Sudden Obstruction of The Left Main Coronary Artery

MOSHE Y. FLUGELMAN, MD, MEIR SHALIT, MD, ARIE SHEFER, MD, YONATHAN HASIN, MD, and MERVYN S. GOTSMAN, MD, FRCP

Left main coronary artery (LMCA) stenosis occurs in 10% of patients undergoing coronary arteriography, but total occlusion is rare.[1] Goldberg et al[2] reported 6 cases of complete obstruction of the LMCA among 2,200 patients studied arteriographically. Sudden obstruction of the LMCA should be lethal,[3] and we found no report describing survival with sudden obstruction of the LMCA. The present report describes such a patient.

*A 55-year-old man, a heavy smoker with no history of ischemic heart disease, had ventricular fibrillation 30 minutes after the onset of severe retrosternal chest pain. Sinus rhythm was restored after 6 direct-current cardioversions combined with lidocaine infusion. After resuscitation, pulmonary edema developed; the patient had a systolic blood pressure of 60 mm Hg, a pulse rate of 120 beats/min and frequent premature ventricular contractions. Electrocardiograms showed sinus tachycardia with frequent ventricular premature contractions and an acute extensive anterior myocardial infarction. The cardiac index, measured with a thermodilution Swan-Ganz catheter, was 1 liter/min/m$^2$. An intraaortic counterpulsation balloon was inserted through the right femoral artery during resuscitation; the blood pressure increased to 110/70 mm Hg and the cardiac index to 1.9 liters/min/m$^2$. Mechanical assistance was combined with intravenous treatment of glucose-potassium-insulin solutions and oral isorbide-dinitrate, digoxin, and diuretic agents. Cardiac catheterization and angiography, performed 15 days later, revealed a left ventricular end-diastolic pressure of 35 mm Hg, a large aneurysm of the anterior and apical regions, and normal contraction of the inferior wall. Coronary arteriography demonstrated complete obstruction of the LMCA (Fig. 1) while the right coronary artery was normal; there was no collateral filling of the left coronary system. The left ventricular ejection fraction was 16% with mechanical assistance and 5% without assistance.*

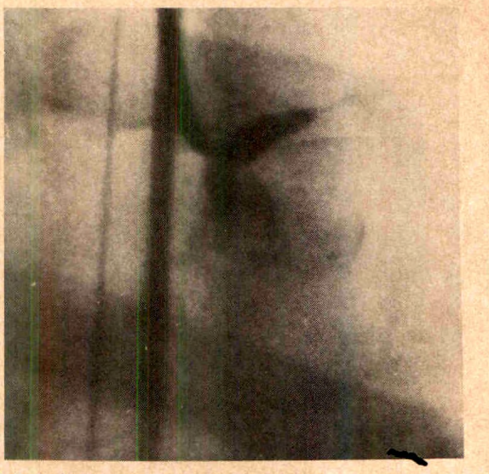

**FIGURE 1.** Left coronary arteriogram (right anterior oblique view) showing complete obstruction of the left main coronary artery.

*After 26 days, the patient developed a shaking chill and the intraaortic counterpulsation balloon was removed. The patient was discharged after 40 days. By this time he had signs of moderate congestive heart failure but no angina pectoris and was in New York Heart Association functional class III. On discharge, the cardiac index was 1.8 liters/*

From the Department of Cardiology, Hadassah University Hospital, Jerusalem, Israel. Manuscript received June 8, 1982; revised manuscript received September 10, 1982, accepted September 17, 1982.

*min/m². Radionuclide angiography showed a left ventricular ejection fraction of 10%. A year later he was in functional class III.*

The fulminant course with no previous angina pectoris led us to the conclusion that the obstruction of the LMCA was sudden. The prognosis of severe LMCA narrowing is grave, but early intervention with mechanical support and afterload reduction permitted compensatory mechanisms during the 6 weeks after the infarct and allowed the patient to maintain a cardiac output compatible with life. Ventricular damage was severe, the patient has little cardiac reserve, and he remains severely disabled but alive 12 months later.

**Acknowledgment:** We thank D. R. Rosing, MD for reviewing the article and for his useful remarks.

# Hyperkalemia and Cardiac Arrest From Fluoride Exposure During Hemodialysis

MICHAEL McIVOR, MD, ROMULO F. BALTAZAR, MD, JUAN BELTRAN, MD, MORTON M. MOWER, MD, ROBERT WENK, MD, JACK LUSTGARTEN, PhD, and JOSEPH SALOMON, MD

Hyperkalemia as a cause of death after fluoride intoxication has not been appreciated previously. The following report is the first documentation of fluoride-induced hyperkalemia in humans.

*Approximately 1,000 gallons of 22% hydrofluosilicic acid accidentally leaked into a small community's public water supply, raising fluoride levels in tap water samples to 30 ppm. The concentration did not return to acceptable levels (1.6 ppm) for 7 days.[1] Two days after the spill, 8 patients undergoing hemodialysis in an outpatient hemodialysis center developed gastrointestinal symptoms.[2] One patient was found dead at home soon afterward and another patient, the subject of this report, had cardiopulmonary arrest and was found to have marked hyperkalemia after resuscitation.*

*The patient is a 36-year-old white man with chronic renal failure and uremic pericarditis who developed diffuse pruritis 2 hours after the start of hemodialysis. Dialysis was discontinued 30 minutes later because of the development of pressure-like chest pain radiating to the neck, associated with dyspnea, nausea, vomiting, diaphoresis, diarrhea, and numbness in the right arm. After the symptoms abated he went home, but 14 hours later, the dyspnea recurred, and while en route to the hospital via ambulance, he had a cardiopulmonary arrest and was resuscitated.*

*Shortly thereafter he was alert but intubated. The blood pressure was 130/80 mmHg, the pulse 100 beats/min, the respiratory rate 24 breaths/min, and the temperature 96.2°F. Diffuse wheezing and bibasilar rales were present in the lungs, the heart was enlarged, and a grade 2/6 apical systolic crescendo-decrescendo murmur was present. The liver was enlarged and the abdominal cavity contained excessive fluid. The ankles and feet were edematous. The blood hematocrit was 23% and the leukocyte count 11,000/mm³. The serum sodium level was 138, chloride 98, bicarbonate 22, and potassium 10.5 mEq/liter. The blood urea nitrogen and glucose levels were 64 and 141 mg/100 ml. Free fluoride concentration was 0.4 mg/liter (normal 0.01 to 0.20). Arterial blood gas analysis while the patient was breathing 100% oxygen revealed a pH of 7.19, partial pressure of carbon dioxide 51 mm Hg, and partial pressure of oxygen 153 mm Hg. Electrocardiograms recorded sinus arrhythmia with an average rate of 70 beats/min, probable biatrial overload and left ventricular hypertrophy.*

*Cation exchange resin therapy and peritoneal dialysis were instituted, and 4 days later the arterial blood gases and serum electrolyte levels were normal.*

The connection between potassium alterations and death from fluoride poisoning has gone unnoticed in the literature. We previously observed a patient with fatal fluoride ingestion who developed markedly peaked T waves on the electrocardiogram before refractory ventricular fibrillation, were able to reproduce these electrocardiographic changes with fluoride administration in the experimental animal, and showed that they were indeed accompanied by elevated potassium levels.[3]

Fluoride, being the most electronegative element, is well known to lower the levels of cations such as calcium and magnesium because of the tight binding of the fluoride with these cations.[4] The exact mechanism of the hyperkalemia is not known but might be related to the toxic effects of fluoride on the cell membranes,[5] allowing potassium to leak into the blood.

The mode of exposure to the fluoride ion in this case is unusual and has not been previously described as a route of fluoride intoxication. If over 100 gallons of tap water with normal fluoride levels of 1 ppm is used by a patient during dialysis, up to 36 mg of fluoride can be absorbed in a single run. After the contamination of the public water supply, the dialysis patients were subjected to a very high fluoride load and since the elimination of fluoride is almost exclusively renal,[6] a patient with renal failure (undergoing repeated hemodialysis) will have no mechanism for excreting the very high fluoride load.

# Coronary Arterial Rupture During Coronary Angioplasty

JEFFREY E. SAFFITZ, MD, PhD,*
THOMAS E. ROSE, MD, JOHN B. OAKS, MD,
and WILLIAM C. ROBERTS, MD

Although percutaneous transluminal coronary angioplasty (PTCA) appears to be a relatively safe and effective procedure, reported complications include coronary occlusion and dissection with or without acute myocardial infarction.[1,2] Herein, a hitherto unreported complication of PTCA is described.

From the Pathology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland. Manuscript received November 4, 1982, accepted December 6, 1982.

* On leave of absence from the Department of Pathology, Washington University, St. Louis, Missouri.

*A 77-year-old man with unstable angina pectoris by coronary angiography had focal severe stenosis of a dominant right coronary artery (Fig. 1a), a normal left coronary system, and normal left ventricular function. PTCA of the right coronary artery was performed. The tight stenosis prevented appropriate placement of a 2-mm Gruntzig catheter; therefore, the narrowing was dilated initially by multiple inflations of a Simpson catheter advanced across a guide wire, and subsequently by a 3-mm Gruntzig catheter at 4 atm (Fig. 1b). Post-PTCA angiograms demonstrated mild residual stenosis (Fig. 1c). Coronary angiography 3 months later disclosed significant stenosis again at the site of the previous dilatation procedure (Fig. 1d). Repeat PTCA was performed. Multiple inflations of a 3-mm Gruntzig catheter at a maximal pressure of 9 atm reduced the stenosis to about 60% diameter reduction. A 3.7-mm Gruntzig catheter was then positioned and inflated 5 times at a maximal pressure of 10*

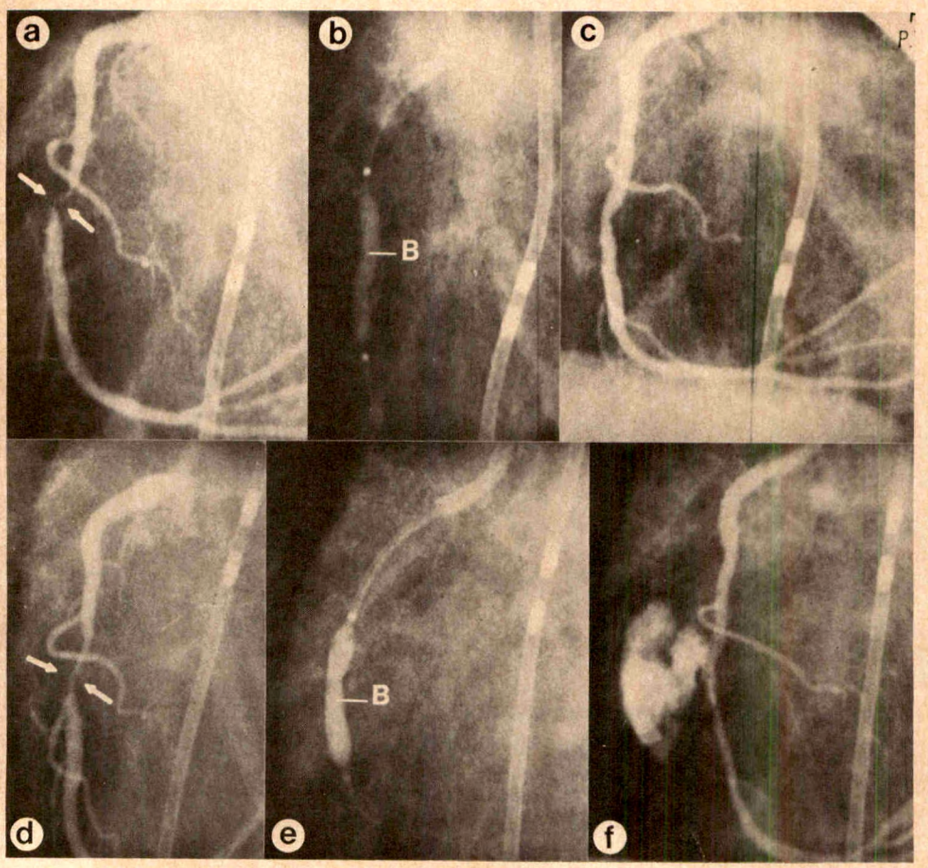

**FIGURE 1.** Right coronary arteriograms before (**a** and **d**), during (**b** and **e**), and after (**c** and **f**) percutaneous transluminal coronary angioplasty (PTCA). **a,** a discrete severe narrowing is present (**arrows**). **b,** the stenosis was dilated by a 3-mm Gruntzig balloon (B) catheter. **c,** mild residual narrowing remained after the first PTCA procedure. **d,** the previously dilated area was again severely narrowed (**arrows**) 3 months after the first PTCA procedure. **e,** the narrowing was dilated by a 3.7-mm Gruntzig balloon (B) catheter. **f,** arteriography after PTCA showed leakage of contrast material into the epicardial tissues. The luminal diameter immediately proximal and distal to the narrowing is approximately equal to that of the pacing catheter (**d**). The diameter of the inflated balloon (**e**) is larger than that of the pacing catheter and thus exceeds the diameter of the nonstenotic arterial lumen.

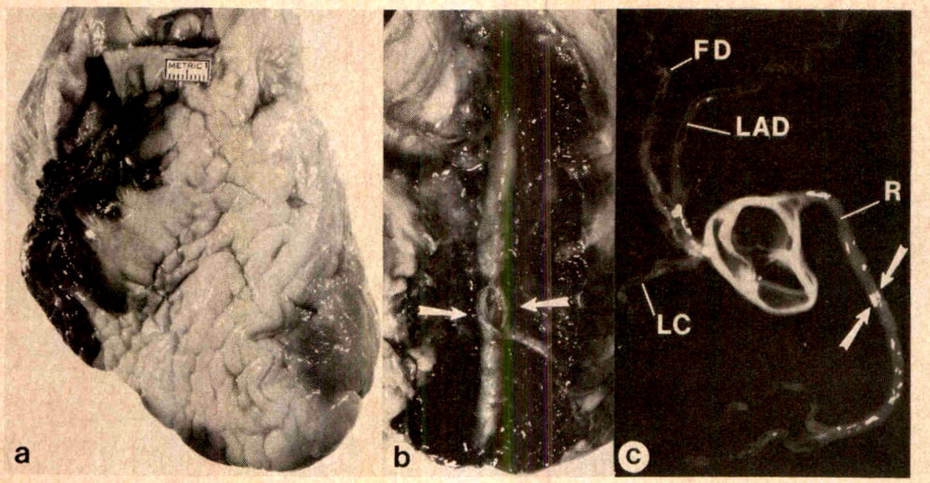

**FIGURE 2. a,** Photograph of heart showing hemorrhage in the right atrioventricular sulcus which contains the right coronary artery. **b,** a rupture site (**arrows**) in the right coronary artery 3.5 cm from the aortic ostium. **c,** radiograph of the major epicardial coronary arteries demonstrating focal calcific deposits. **Arrows** designate the site of rupture of the right (R) coronary artery. FD = first diagonal; LAD = left anterior descending; LC = left circumflex. (Photographs by M. M. M. Moore.)

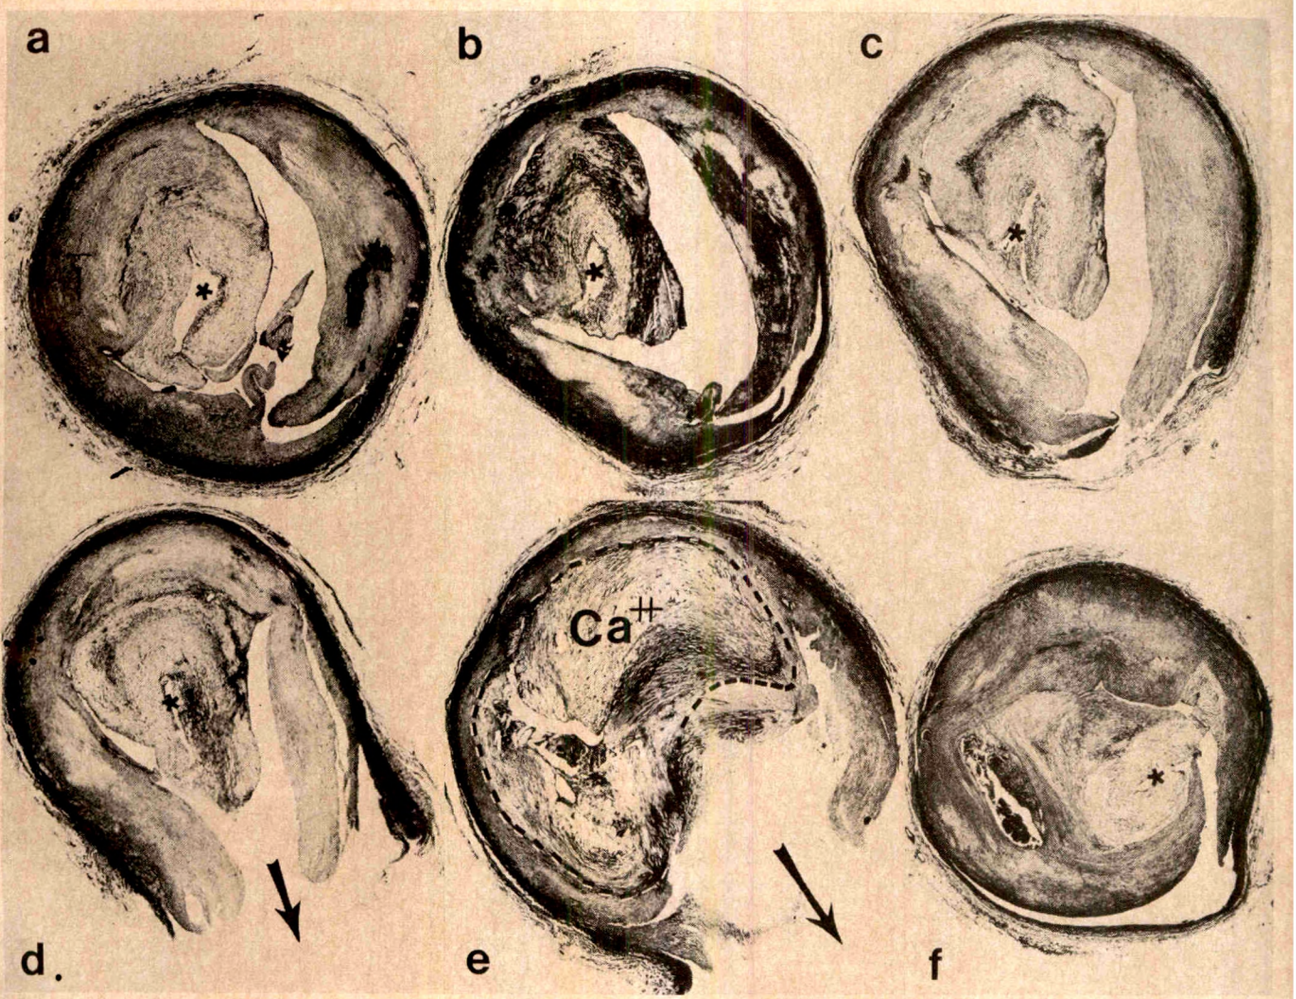

**FIGURE 3.** Photomicrographs of cross-sections of the right coronary artery in the vicinity of the rupture site. Proximal to the rupture site (**a**) the atherosclerotic plaque is split. This split communicates with the original lumen, indicated by the **asterisks.** The split extends through the media (**b**) and adventitia (**c**) until through-and-through rupture (**arrows**) occurs (**d,e**). Rupture occurred opposite a large calcified ($Ca^{++}$) plaque (outlined by **dashed line**). Distal to the rupture site (**f**), additional splitting of the intimal plaque is seen communicating with the original lumen.

**TABLE I Number of 5-mm Segments of the 4 Major Epicardial Coronary Arteries Showing the 4 Grades of Cross-Sectional Area Narrowing**

| Coronary Artery | Length (cm) | 5-mm Segments (n) | 5-mm Segments (n) Narrowed to Each of 4 Categories of Cross-Sectional Area Narrowing | | | |
|---|---|---|---|---|---|---|
| | | | 0–25% | 26–50% | 51–75% | 76–100% |
| R | 8.5 | 17 | 1 | ... | 9 | 7 |
| LM | 0.5 | 1 | ... | 1 | ... | ... |
| LAD | 9.0 | 18 | 2 | 11 | 5 | ... |
| LC | 4.5 | 9 | 3 | 6 | ... | ... |
| Totals | 22.5 | 45 | 6 (13%) | 18 (40%) | 14 (31%) | 7 (16%) |

LAD = left anterior descending, LC = left circumflex, LM = left main, and R = right coronary artery.

*atm (Fig. 1e). On the fifth inflation, the proximal end of the balloon ruptured. Angiography then demonstrated extravasation of contrast material into the epicardial tissue plus run-off into the distal right coronary artery (Fig. 1f). The heart rate and arterial blood pressure quickly decreased; blood was drained from the pericardial sac, but fatal cardiac arrest ensued.*

*At necropsy, the heart weighed 265 g. The epicardial adipose tissue surrounding the right coronary artery was hemorrhagic (Fig. 2a) and an elliptical rupture site measuring 0.6 cm in the long axis was present in the right coronary artery 3.5 cm from the ostium (Fig. 2b). Radiographs of the major epicardial coronary arteries (Fig. 2c) disclosed focal calcific deposits. The results of histologic examination of 5-mm segments of the major epicardial coronary arteries are shown in Table I. A 1.7-cm segment of right coronary artery containing the rupture site was subserially sectioned and photomicrographs of several sections are illustrated in Figure 3.*

It is clear that the right coronary artery in the patient just described ruptured during the PTCA procedure. At the site of the arterial rupture, the lumen of the artery was extremely small and a large amount of calcium was present in the atherosclerotic plaque. In addition, the artery itself was quite small. (The patient weighed only 105 pounds and the heart weighed only 265 g.) The presence of a *small, rigid (calcified) artery* and the use of a *balloon larger than the artery* itself caused the arterial rupture in this patient. Balloon dilatation was successful in enlarging the lumen by splitting the plaque. However, the splitting was not limited to plaque but extended into the media and adventitia, resulting in fatal rupture.

To our knowledge, rupture of a coronary artery during PTCA has not been reported previously. The lesson of this case is that angioplasty balloons larger than the artery to be dilated should not be employed.

# Q-T Prolongation and Torsades de Pointes Ventricular Tachycardia Produced by the Tetracyclic Antidepressant Agent Maprotiline

HOWARD C. HERRMANN, MD, LEE M. KAPLAN, MD, PhD, and BARBARA E. BIERER, MD

Tricyclic antidepressant drugs such as imipramine and desipramine have long been known to produce cardiovascular side effects including sinus tachycardia, prolongation of the P-R, QRS, and Q-T intervals, and decreased T-wave amplitude.[1,2] Life-threatening ventricular ectopic activity has occurred after tricyclic drug overdose.[3] Recently, maprotiline (Ludiomil®), a tetracyclic anthracene-derivative antidepressant, has become available for the treatment of affective disorders. It appears as effective as the tricyclic drugs in relieving unipolar depression.[4–6] Although several studies have reported a low incidence of cardiovascular side effects,[4,6] others show little difference between the tetracyclic and tricyclic drugs.[2,4,5] This report describes a patient in whom maprotiline treatment caused Q-T prolongation and life-threatening torsades de pointes ventricular tachycardia (VT).

From the Medical Services, Massachusetts General Hospital, Boston, Massachusetts. Manuscript received October 18, 1982; revised manuscript received December 3, 1982, accepted December 6, 1982.

*An 81-year-old woman was hospitalized after falling from a chair. She had previously been treated for recurrent depression with imipramine, desipramine, doxepin, and methylphenidate, which were discontinued because of anticholinergic side effects or poor compliance. Treatment with maprotiline (25 mg daily) was begun 10 months before admission. The dosage was increased to 50 mg daily 1 month before admission and then to 62.5 mg 8 days before her fall. The patient was also taking levothyroxine (0.125 mg), tol-*

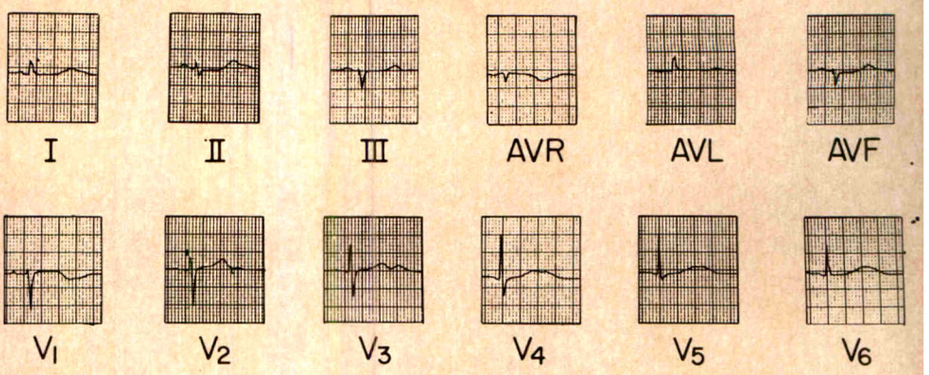

**FIGURE 1.** Admission electrocardiogram.

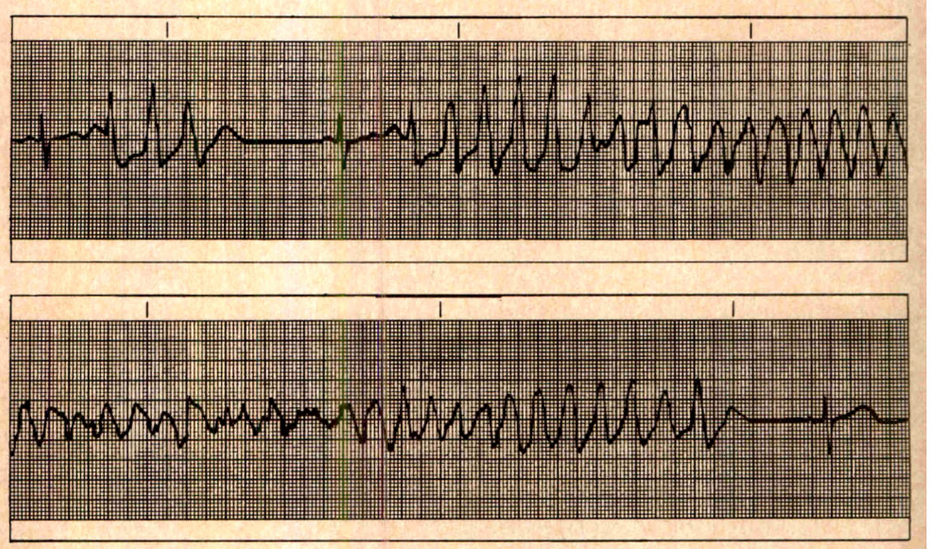

**FIGURE 2.** Ventricular ectopy with torsades de pointes.

*butamide (500 mg), hydrochlorothiazide (25 mg), and spironolactone (25 mg).*

*On arrival at the hospital, the patient had a regular pulse and was normotensive. She had no precordial murmurs and no neurologic abnormalities. Electrolyte and thyroid function tests gave normal results; the electrocardiogram revealed a prolonged Q-T interval of 0.64 second at a rate of 75 beats/min (Fig. 1). In the emergency room, ventricular bigeminy and runs of VT developed which were suppressed with intravenous lidocaine. All medications were discontinued and she received 1 dose of oral propranolol which was then stopped because of sinus bradycardia. Because of recurring VT, her antiarrhythmic regimen was changed to intravenous bretylium (300 mg bolus and infusion at 2 mg/min). A prolonged episode of torsades de pointes configuration VT causing hypotension and loss of consciousness occurred 30 hours after admission (Fig. 2). At that time, she was still receiving bretylium and had a serum potassium level of 4.1 mEq/liter (normal range 3.5 to 5.0). Dilantin was begun and over the ensuing 4 days, no further ectopy occurred and all antiarrhythmic drugs were gradually withdrawn and discontinued. The Q-T interval gradually shortened in association with a measured decrease in serum maprotiline level (Table I). A 24-hour ambulatory electrocardiogram, recorded just before discharge while the patient was taking her original medications (except maprotiline) and no antiarrhythmic drugs, disclosed a Q-T interval of 0.42 second ($Q\text{-}T_c$ = 0.43). No ventricular ectopic activity was recorded.*

We report the occurrence of a prolonged Q-T interval resulting in VT and torsades de pointes in a patient taking the tetracyclic antidepressant, maprotiline. Prolongation of the Q-T interval predisposes to reentrant arrhythmias probably by increasing the disparity in ventricular repolarization. In our patient, Q-T prolongation and consequent torsades de pointes occurred coincident with a recent increase in maprotiline dosage and resolved after discontinuation of the drug and a decrease in the serum maprotiline level. The increased Q-T interval observed 24 to 36 hours after the last dose was taken may be due to a cardioactive metabolite of maprotiline or a drug interaction, as with levothyroxine. Thus, the tetracyclic antidepressant drug maprotiline may cause Q-T prolongation similar to that seen with the closely related tricyclic antidepressants, and this effect can occur at a therapeutic serum concentration. We recommend that physicians prescribing maprotiline maintain the same vigilance for cardiovascular side effects as that currently accorded tricyclic antidepressant drugs.

**TABLE I Serum Maprotiline Levels and Q-T Intervals With Time**

| Time After Last Dose (days) | Maprotiline Level (ng/ml)* | Q-T Interval (s) | Q-$T_c$† (s) |
|---|---|---|---|
| 1 (A.M.) | 169 | 0.68 | 0.683 |
| (P.M.) | 118 | ... | ... |
| 2 (A.M.)‡ | 82 | 0.84 | 0.808 |
| (P.M.) | ... | 0.77 | 0.794 |
| 3 | 69 | 0.76 | 0.700 |
| 4 | 54 | 0.60 | 0.588 |
| 5 | 31 | 0.55 | 0.545 |
| 6 | 55 | 0.48 | 0.500 |

* Therapeutic level = 100 to 300 ng/ml[4]; reported half-life = 43 to 48 hours.[6]

† Q-$T_c$ = Q-T interval (including U wave)/$\sqrt{\text{R-R interval}}$ (upper limit of normal for adult woman = 0.43 second).

‡ Occurrence of torsades VT.

# Angiographic Evidence of Hemorrhagic Myocardial Infarction After Intracoronary Thrombolysis With Streptokinase

WILLIAM C. LITTLE, MD and
EDWIN W. ROGERS, MD

The reperfusion of acutely ischemic myocardium by intracoronary streptokinase thrombolysis is an exciting new therapy for acute myocardial infarction (MI).[1] It appears that successful thrombolysis and reperfusion in the first few hours after acute coronary occlusion may salvage myocardium and possibly improve prognosis. A potential adverse effect of reperfusion is the production of hemorrhage in the area of myocardial necrosis.[2–4] We report on a patient with prompt, successful coronary thrombolysis by streptokinase infusion who showed angiographic evidence of a hemorrhagic MI.

*A previously well 72-year-old man was admitted with chest pain of 1 hour's duration. An electrocardiogram showed an acute inferior wall MI (Fig. 1). Immediate coronary angiography demonstrated no significant narrowing of the left coronary system but complete occlusion of the proximal portion of the right coronary artery (Fig. 2, left). The angiogram was unchanged after intracoronary administration of 200 μg of nitroglycerin. The intracoronary administration of a 10,000 unit bolus of streptokinase followed by an infusion of 2,500 units/min for 30 minutes produced no change. A 0.035 inch flexible tipped guidewire was passed through the occlusion in the right coronary artery, and streptokinase was infused for another 15 minutes. Repeat angiography (approximately 2.5 hours after the onset of chest pain) demonstrated that the right coronary artery was patent with a residual high-grade stenosis of the proximal and middle portions (Fig. 2, right). A nonopacified lucency probably represented thrombus was seen to move from the area of previous occlusion in the proximal right coronary and lodge in the midportion of the posterior descending artery. After injection of the right coronary artery, contrast material was seen in the wall of the left ventricle (Fig. 3, left). On the subsequent left ventriculogram, the intramyocardial contrast material was seen in the endocardium of the posterior basilar segment of the left ventricle, in an area of localized akinesia (Fig. 3, right). A resting thallium scan immediately after reperfusion showed a large area of markedly decreased thallium uptake in the inferior wall (Fig. 4). Twenty-four hours after reperfusion, the subendocardial contrast material was again visualized fluoroscopically and repeat angiography demonstrated that the right coronary artery remained patent. The filling defect in the mid-posterior descending coronary artery had resolved. A 2-dimensional echocardiogram demonstrated inferoposterior hypokinesia before reperfusion. After reperfusion, the inferoposterior wall had become akinetic and the apex was hypokinetic. Initially, the electrocardiograms (Fig. 1) demonstrated an evolving inferior*

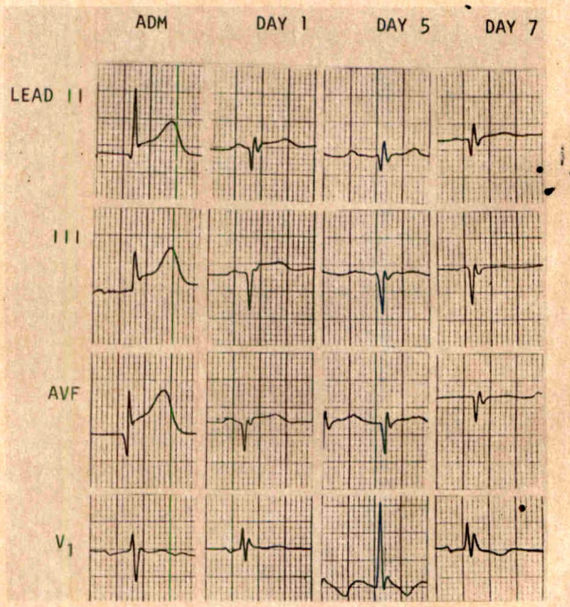

**FIGURE 1.** Serial electrocardiograms.

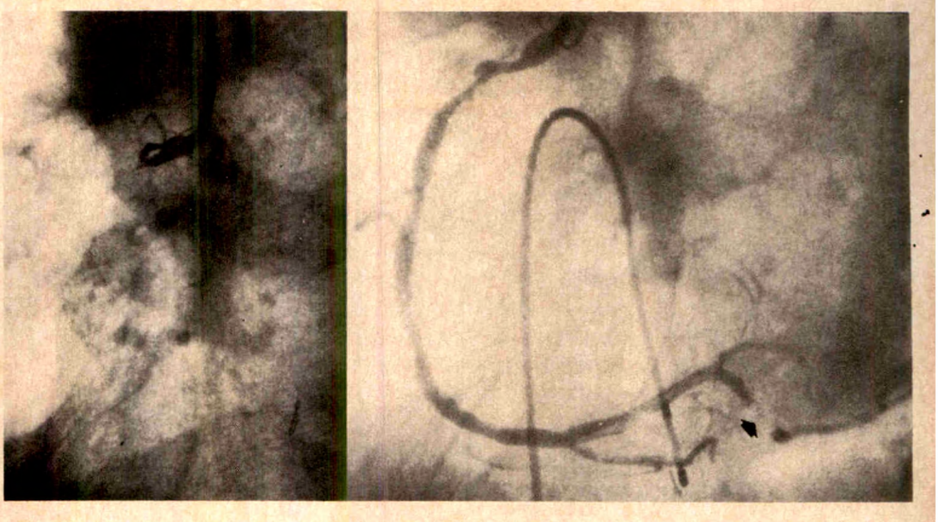

**FIGURE 2. Left,** right coronary angiogram demonstrating complete occlusion in its proximal portion. **Right,** after guide wire probing and intracoronary streptokinase, the right coronary artery was patent with residual stenosis. A filling defect thought to represent the occluding thrombus was seen to move from the area of initial occlusion and lodge in the mid-posterior descending coronary artery (**arrow**).

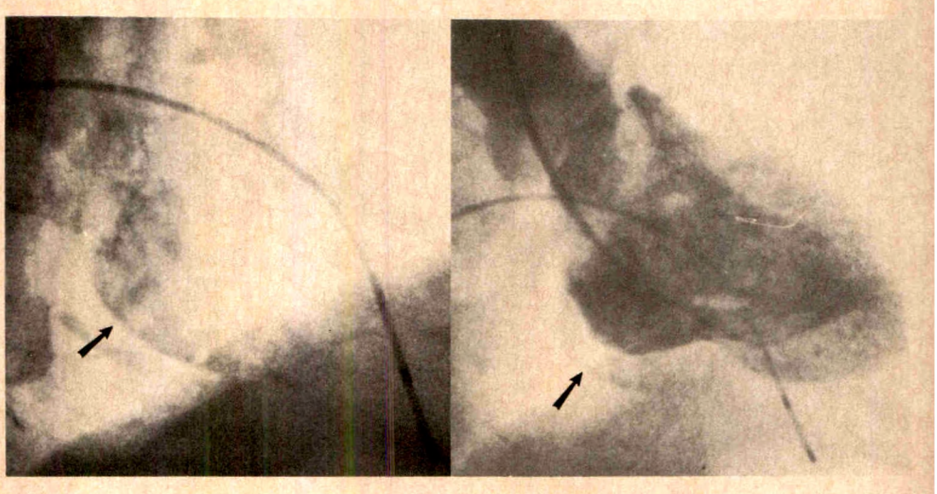

**FIGURE 3.** After the coronary angiogram (Fig. 2, right), contrast medium was seen in the myocardium (**left, arrow**). This intramyocardial contrast medium in the ensuing left ventriculogram (**right, arrow**) was in the subendocardium of the inferobasilar left ventricle in an area of localized akinesia.

*MI, but despite continued patency of the right coronary artery, they subsequently showed incomplete right bundle branch block and suggested posterior extension of the MI.*

*The patient was placed on heparin infusion for 7 days after thrombolysis, and his subsequent hospital course was complicated by a femoral hematoma and transient pericarditis. He was discharged on the 14th hospital day and his subsequent convalescence was uneventful.*

In this patient, who presented with symptoms and electrocardiographic changes of an acute transmural inferior MI, prompt recanalization of the occluded right coronary artery was associated with extravasation of angiographic contrast medium from the reopened right coronary artery into the subendocardium of the posterior basilar left ventricular wall. This subendocardial contrast persisted at least 24 hours.

Experimentally, hemorrhagic MI has been produced by coronary reperfusion after transient occlusion.[3,4] Experimentally, such hemorrhage occurs in areas of the most severe myocardial ischemia where cell injury is already irreversible.[3] In our patient, extravasation of contrast medium was limited to the subendocardium where ischemia would be most severe. It is possible that hemorrhage into already necrotic myocardium may jeopardize adjacent islands of potentially viable myocardium.[4] We are unable to determine whether the production of hemorrhagic MI adversely affected our patient; however, several observations suggest that it did. The inferoposterior left ventricular wall which was

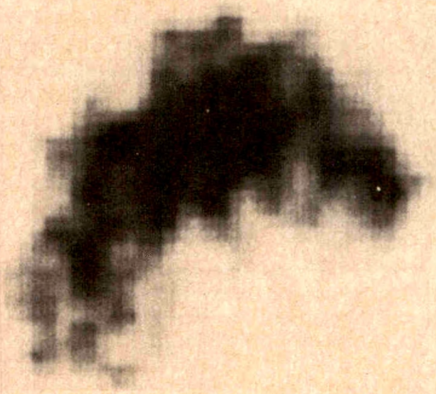

**FIGURE 4.** Resting thallium scan (lateral view) obtained after thrombolysis showing markedly decreased uptake in the inferior left ventricular wall.

hypokinetic as visualized on 2-dimensional echocardiography before reperfusion was akinetic on both echocardiography and angiography after reperfusion. In addition, the apex became hypokinetic despite reperfusion. There was no thallium uptake in the inferior wall after thrombolysis, and the serial electrocardiogram suggested extension of the initial inferior MI to the posterior wall. These observations suggesting no benefit from reperfusion and possible deterioration after thrombolysis did not result from either an inordinate delay in reperfusion or early reocclusion of the artery.

The finding of postreperfusion extravasation of contrast medium into the myocardium may be a useful angiographic sign of the production of hemorrhagic MI by coronary thrombolysis that merits further observation and study.

# Real-Time 2-Dimensional Echocardiographic Visualization of Thrombus on a Björk-Shiley Mitral Valve Prosthesis

## Emergency Cesarean Section and Mitral Valve Replacement in Late Pregnancy

BASIL S. LEWIS, MD, MRCP, FCP(SA), NEARCHOS E. AGATHANGELOU, MD, LUIS A. DOS SANTOS, LMC, and MANUEL J. ANTUNES, MD

Echocardiography is invaluable in the assessment of cardiac valves, but the signs of prosthetic valve dysfunction may be difficult to interpret, especially in patients with metallic valve prostheses.[1–4]

*A 25-year-old woman underwent mitral valve replacement with a 29 mm Björk-Shiley prosthesis. On routine examination 5 years later, she was well and the prosthesis appeared to be functioning normally. She was receiving warfarin (prothrombin index 32%), but because she was then 38 weeks pregnant, warfarin was replaced by intravenous heparin. Five days later the patient had left anterior chest pain and an episode of hypotension. Examination revealed muffling of the prosthetic valve sounds. However, blood pressure soon returned to normal, and on cinefluoroscopy the disc moved normally. Real-time 2-dimensional echocardiography showed a large mass on the ventricular surface of the prosthetic valve disk (Fig. 1). Disc excursion was normal. The left ventricle contracted well, and the left atrium was enlarged 2.5 times the diameter of the aortic root. The diagnosis of prosthetic valve thrombosis with intermittent mitral valve obstruction was made.*

*The clinical state deteriorated. Emergency Cesarean section was performed and a healthy boy was delivered. The chest was opened and cardiopulmonary bypass established. A large, fresh thrombus was present on the ventricular surface of the prosthesis (Fig. 2). The valve was replaced with*

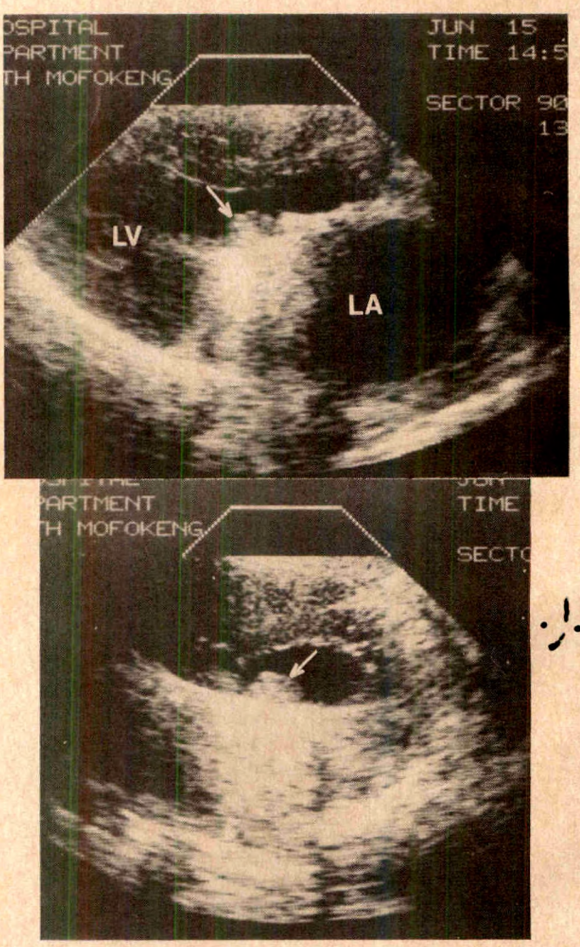

**FIGURE 1. Top,** real-time 2-dimensional echocardiogram (parasternal long-axis view in diastole) showing a mass (**arrow**) on the ventricular surface of the Björk-Shiley disc. LA = left atrium; LV = left ventricle. **Bottom,** parasternal short-axis view (diastolic frame) showing the thrombus (**arrow**) in the left ventricular outflow tract.

*a Hall-Kaster prosthesis, the patient made an uneventful recovery, and both mother and child were discharged well 2 weeks later.*

Two-dimensional echocardiography is useful in identifying masses on bioprosthetic valves,[5] but it is difficult to demonstrate thrombus on the disc of a Björk-Shiley prosthesis because of bright echocardiographic reflections from the valve itself. Serial studies may show changes in the amplitude, velocity, pattern, or timing of disc motion,[2–4,6–8] whereas abnormal left ventricular filling rate[9] may indicate impaired mitral blood flow. In our patient, the major part of the thrombus formed on the ventricular surface of the disc. The echocardiographic beam reached the thrombus before the valve, and we recorded high quality images of the mass, corresponding exactly to the findings at operation. Direct visualization of the thrombus was invaluable because obstruction to blood flow was intermittent. At echocardiography the patient was asymptomatic and cinefluoroscopy gave normal results.

The diagnosis of a clotted mitral valve prosthesis at 38 weeks of pregnancy posed interesting problems in management. The transfer from warfarin to heparin is routine, but we urge great vigilance because thrombosis of the mitral Björk-Shiley prosthesis is not rare.[10] Clinical deterioration in our patient's condition necessitated immediate obstetric and cardiac intervention which were performed successfully at the same operating session.

# Cardiac Rhabdomyosarcoma Presenting as Hypereosinophilic Syndrome

MARTIN J. SULLIVAN, MD, GREGORY P. WANGER, MD, STEVEN A. SCHONFELD, MD, and THOMAS M. BASHORE, MD

We report herein the first patient with intracardiac rhabdomyosarcoma presenting with a clinical syndrome mimicking Löffler's endocarditis[1–4] with profound eosinophilia and refractory congestive heart failure.

From the Department of Medicine and Pathology, Ohio State University, Columbus, Ohio. Manuscript received September 10, 1982; revised manuscript received December 3, 1982, accepted December 6, 1982.

*A 59-year-old white man was well until 4 months before death when fatigue, fever, and the onset of a 35-pound weight loss developed. Electrocardiograms (Fig. 1) 5 days before death showed acute anterior wall injury, right axis deviation, probable right ventricular hypertrophy, nonspecific T-wave changes, and right intraventricular conduction delay. The white blood cell count was 90,000 cells/mm$^3$ with 57% eosinophils. Serial electrocardiograms showed no changes and serial creatine phosphokinase enzymes were normal. Examination 24 hours before death disclosed a supine blood pressure of 80/50 mm Hg, without pulses paradoxicus and sinus rhythm. The neck veins were distended to the angle of the mandible at 90°. The heart sounds were reduced and no murmurs were heard. The patient was transferred to the Ohio State University Hospitals.*

*The electrocardiogram was unchanged and the chest radiograph showed borderline cardiomegaly with clear lung fields. Serum lactate dehydrogenase was 3,010 U/ml (normal up to 440), and creatine phosphokinase was 7 U/ml (normal up to 12 U/ml), increasing 12 hours later to 13 U/ml with 7% MB band. The serum immunoglobulin E (IgE) level was 193 U/ml (normal up to 455). The total eosinophil count was 14,200 cells/mm$^3$. A bone marrow aspirate showed 30% eosinophils with a predominance of mature forms. Right-sided*

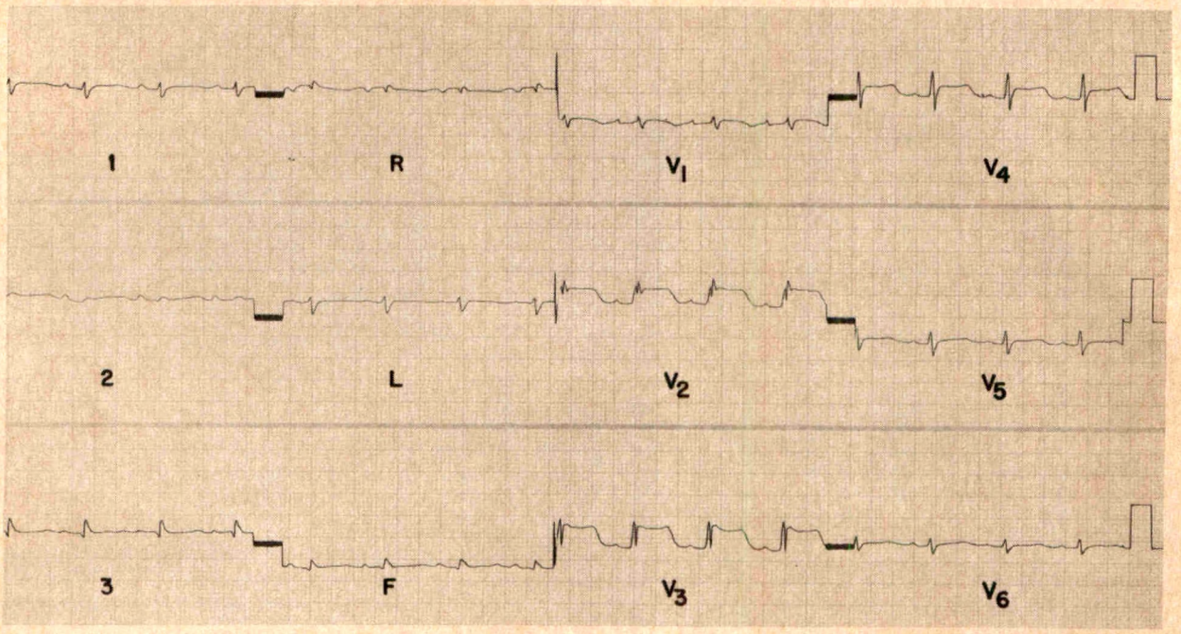

**FIGURE 1.** Twelve-lead electrocardiogram. The unusual, localized anterior epicardial injury pattern is demonstrated.

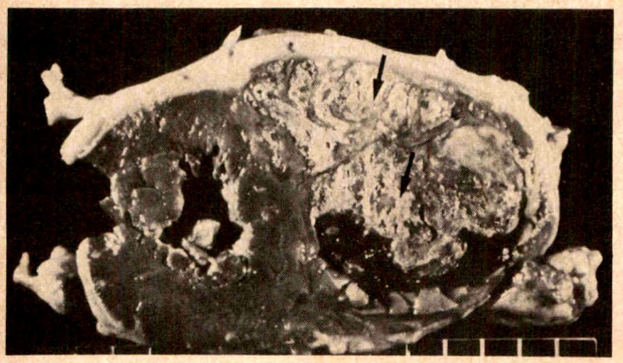

**FIGURE 2.** Gross pathology specimen of the sectioned heart. Extensive infiltration by the cardiacc rhabdomyosarcoma into the right ventricular cavity is evident.

*cardiac catheterization disclosed a right atrial mean pressure of 22 mm Hg and a right ventricular pressure of 33/20 mm Hg with unusual sinusoidal appearing wave forms. The pulmonary trunk could not be entered. A 2-dimensional echocardiogram was of poor quality and showed only right atrial enlargement. The patient died within 24 hours after hospitalization.*

*At autopsy, the heart weighed 910 g. Necrotic tumor arose from the right ventricular free wall and virtually filled the entire right ventricular cavity, with extensive invasion of the right ventricular myocardium and ventricular septum (Fig. 2). Several tumor nodules up to 0.5 cm in diameter were found in the left ventricular wall and hilar lymph nodes. Histologically, the tumor was composed of large cells with irregularly shaped nuclei and prominent nucleoli. Multinucleation and strap cells were present. Special staining with phosphotungstic acid hematoxylin and for nicotinamide adenine dinucleotide in reduced form (NADH) revealed striations characteristic of rhabdomyosarcoma.*

To our knowledge, eosinophilia and rapidly progressive congestive heart failure have never been reported with a primary intracardiac tumor. As the course of these unusual neoplasms might be altered favorably by surgical intervention,[5] the diagnosis should be suspected in patients with eosinophila and profound congestive heart failure, especially when intracardiac mass lesions are identified.

POINT OF VIEW

# How Should We Describe Hearts in Which the Aorta Is Connected to the Right Ventricle and the Pulmonary Trunk to the Left Ventricle?

## A Matter for Reason and Logic

ANTON E. BECKER, MD and ROBERT H. ANDERSON, MD, BSc

There is undoubtedly a need for cataloguing succinctly anomalous hearts in which the aorta is connected to the morphologic right ventricle and the pulmonary trunk to the morphologic left ventricle. Excluding more complex cases in which either the atrial chambers are deformed (splenic syndromes) or the atrial chambers are connected to only 1 ventricular chamber (tricuspid atresia and single ventricle), there are 2 basic chamber arrangements that exist with this discordant ventriculoarterial connection. In the most common pattern the atrial chambers connect concordantly with their appropriate ventricles. In the less common type, a discordant connection is present at both atrioventricular and ventriculoarterial junctions. The need exists for terms that describe precisely these chamber combinations and only these combinations. They previously were termed *complete* and *congenitally corrected transposition*, respectively. Nowadays it is much more usual to see the terms *d*- and *l-transposition* employed for cataloguing these general segmental combinations. We question the latter practice on grounds of necessity and scientific inaccuracy. The old terms *complete* and *congenitally corrected* seemed to us sufficiently precise to negate the need for new ones, particularly when the newer terms, describing relationships, are poorly suited to describe segmental connections. Moreover, this use of relationship terms in a connections fashion was not initially intended by Van Praagh and his colleagues.[1,2]

There is one justifiable criticism of the use of *complete* to qualify transposition. When introduced, the adjective distinguished that variety in which both arteries arose from inappropriate ventricles from another arrangement in which only the aorta was connected to its wrong ventricle ("partial transposition"). If this system were still employed, it could be argued that the ventriculoarterial connection in congenitally corrected transposition was also that of "complete" transposition in the sense that both arteries are connected to inappropriate ventricles. However, we know of no center that now uses this system in its clinical practice. Nowadays, hearts in which both great arteries are connected to the same ventricle are almost invariably known as *double outlet*. The term *complete transposition* is then free to be used specifically and solely to describe those hearts in which the right atrium is connected to the morphologic right ventricle and then to the aorta, whereas the left atrium is connected to the morphologic left ventricle and then the pulmonary trunk. Similarly, congenitally corrected transposition can then be used with scientific precision to describe only those hearts in which the right atrium connects to the morphologic left ventricle and the pulmonary trunk, whereas the left atrium connects to the morphologic right ventricle and the aorta. In these entities, delineated because of abnormal chamber connections, the relations may not always be as anticipated. Ventricular architecture may be unusual; however, these features can then be described in a subsidiary fashion without in any way affecting the basic definition of complete and congenitally corrected transposition.

When we consider the terms *d*- and *l-transposition*, we encounter many more problems, but only when the terms are used inappropriately to describe anomalies defined on the basis of segmental connections. When Van Praagh and colleagues[1,2] introduced the terms, they were meant to describe relations of the great arteries in which the aorta was anterior to the pulmonary trunk and either to its right (d) or its left (l). The terms were not used in isolation but were part of a full segmental description of the heart: for example, *transposition* {*s*, *d*, *d*} or *transposition* {*s*, *l*, *l*}. It so happens that these particular segmental combinations are what could alternatively be called *complete* and *corrected transposition*, respectively. It is a fact that in persons with

From the Department of Pathology, University of Amsterdam, Wilhelmina Gasthuis and the Academic Medical Center, and the Department of Paediatrics, Cardiothoracic Institute, Brompton Hospital, London, United Kingdom. Manuscript received and accepted November 8, 1982.

Address for reprints: Anton E. Becker, MD, Department of Pathology, Academic Medical Center, H2-134, Meibergdreef 9, 1105 Amsterdam Zuidoost, The Netherlands.

usually arranged atrial chambers (solitus), in most cases there is a right-sided aorta in complete transposition and a left-sided aorta in congenitally corrected transposition. But most cases is not all cases. In patients with mirror-image atria (situs inversus), it is the rule to find a left-sided aorta with complete transposition and a right-sided aorta with congenitally corrected transposition. In patients with the usual atrial arrangement, complete transposition is frequently found with a left-sided aorta[3] and congenitally corrected transposition occasionally found with a right-sided aorta.[4] These variations present no problems for description in the system that uses *complete* or *congenitally corrected* as adjectives to qualify the presence of ventriculoarterial discordance. Full segmental notation also copes with them adequately, providing it is assumed that more complex lesions such as tricuspid atresia or double inlet are not present. Thus, complete transposition with usual atrial chambers and left-sided aorta can be described as *transposition* {*s*, *d*, *l*} or congenitally corrected transposition with usual atrial arrangement and right-sided aorta as *transposition* {*s*, *l*, *d*}. What is clear is that such variants as complete transposition with usual atria and left-sided aorta, or complete transposition with mirror-image atria and left-sided aorta, cannot sensibly be described as *d-transposition*. Similarly, congenitally corrected transposition with either mirror-image atria or usual atria and right-sided aorta cannot adequately be catalogued as *l-transposition*. Yet, this is now the approach advocated by some highly respected authorities.[5,6] We suggest that the time has come to pause and take a good and hard look at this increasing habit of using *d-* and *l-transposition* inappropriately. The anomalies to which the terms are applied are described simply and accurately as complete and congenitally corrected transposition, respectively. They also can be accounted for using full symbolic segmental notation as suggested by Van Praagh et al.[7] There is no need to describe them using the terms *d* and *l-transposition in isolation*. It is not a matter of semantic pedantry. It is a matter of introducing precision to and removing ambiguity from the terminology of congenital heart disease. This will ultimately improve the understanding of practitioners and subsequently benefit their patients.

# Q-Wave Infarction Versus S-T Infarction

## Nonspecificity of Electrocardiographic Criteria for Differentiating Transmural and Nontransmural Lesions

DAVID H. SPODICK, MD, DSc

### Nonspecificity of the Electrocardiogram

For several decades cardiologists have considered abnormal Q waves synonymous with transmural myocardial infarction, as distinguished from infarcts characterized only by ST-T abnormalities, labelled "nontransmural" or "subendocardial." Curiously, journal reviewers have not vetoed these misnomers despite repeated marshalling of evidence demonstrating at autopsy that abnormal Q waves occur frequently with anatomically nontransmural infarction and may be absent with transmural infarcts.[1–3] This evidence first appeared about 40 years ago and has consistently been substantiated.[4–19] Indeed, early investigators who reported an electrocardiographic distinction between the 2 anatomic types of infarct failed to prove it on examination of their own illustrations: among 4 electrocardiograms illustrating nontransmural infarcts, 1 shows incomplete left bundle branch block and 3 clearly have pathologic Q waves[15]; among 6 subendocardial infarcts demonstrated pathologically, 2 electrocardiograms show incomplete left bundle branch block, 2 have abnormal (≥0.04 second) Q waves in lead aVF, and 2 were too poorly reproduced to decipher.[5] (This is especially surprising considering that illustrations invariably put the author's "best foot forward.") More recently, among 12 of 24 autopsied subjects with nontransmural infarcts, 10 had QRS changes, 8 with abnormal Q waves (including anatomically small infarcts); the other 12 patients had transmural infarcts, but 5 had no abnormal Q waves.[8] Another recent report confirms postmortem documentation of transmural infarcts with only ST-T changes.[11] In a series of 154 autopsy subjects, most of those with nontransmural infarction had typical QRS changes and many with transmural infarcts lacked pathologic Q waves.[7]

It is possible that some earlier work may have established an *idée fixe* in the mind of cardiologists, despite the early availability of a mass of contrary evidence.[4–6,17,19] Indeed, Wilson, a pioneer in cardiology, and his colleagues[19] demonstrated abnormal Q waves in nontransmural infarction both experimentally and clinically. The perceptive observations of Pipberger and Lopez[20] suggest that the erroneous criteria may have been reinforced by Prinzmetal's experiments of 1954, subsequently invalidated by the same investigator in 1957.

### Conceptual Errors Inhibit Investigation

Whatever the reason for continued confusion regarding their anatomic extent, the pseudospecificity of Q and S-T myocardial infarctions remains a lasting myth. Indeed, investigators of the highest intellect and skill—despite explicitly acknowledging the material cited in References 1 to 3,[21]—write "regardless of the terms used. . . ,"[21] implying that slipshod terminology is unimportant. Such disregard by distinguished colleagues is disturbing. We are not dealing with minor matters such as "ECG" (English) versus "EKG" (Dutch and German). Arguments over terminology would be mindless quibbles if misleading labels did not perpetuate misleading concepts. False terminology does more than semantic damage: it does conceptual damage. If we continue to accept a Q infarct as dependably indicating a transmural lesion, we can inhibit consideration of what it really does mean. Indeed, do Q infarcts and S-T infarcts have distinctive gross anatomy? Given the ultimate nonspecificity of many electrocardiographic findings it should not be surprising that they overlap to such a degree that "transmural" and "nontransmural" are gross misnomers.

### Q Infarcts Versus S-T Infarcts: Differences and Similarities

Although their gross anatomy cannot yet be predicted electrocardiographically, Q-wave and S-T infarcts differ clinically and physiologically. Prodromal symptoms are more frequent with S-T infarcts[22]; vomiting is more frequent with Q-wave infarcts.[18] Q-wave infarction implies more damage as measured by peak creatine phosphokinase levels,[23] with a greater tendency to undergo expansion.[34] Positron emission tomography[25] shows defects with homogeneous depression of tracer

**TABLE I Q-Wave Infarction Versus S-T Infarction: Differences**

| | Q-Wave Infarct | S-T Infarct* |
|---|---|---|
| Fresh thrombosis | More | Less |
| Collateral vessels | Fewer | More |
| Damage | | |
| ↑Enzyme levels | Higher | Lower |
| ↓Tracer concentration (PET) | Homogeneous | Unequal |
| LV wall abnormality,† | More | Less |
| improved by bypass | Less or none | More |
| Tendency to expand | More | Less |
| Prodromal symptoms | Less | More |
| Vomiting | More | Less |
| Atrioventricular and intraventricular blocks | More | Fewer |
| Congestive failure | More | Less |
| Early mortality | More | Less |
| Recurrent infarction | Less | More |

* Without QRS abnormality. † Some studies differ.
PET = positron emission tomography.

**TABLE II Q-Wave Infarction Versus S-T Infarction: Similarities**

| |
|---|
| Both either transmural or nontransmural |
| Number of diseased vessels |
| Degree of occlusion throughout coronary arteries |
| Ejection fraction* |
| Hypotension |
| Ventricular arrhythmia* |
| Late (>2 year) mortality |

* Some studies differ.

accumulation in all Q-wave infarcts as compared with unequal tracer distribution in 23 of 24 S-T infarcts, with tomographic infarct size greater and residual tracer more depressed in Q-wave infarcts.[28] Two-dimensional echocardiograms showed more (100%) regional wall abnormality during Q-wave than S-T infarction (86%).[26,27] Although total mortality may equalize over 5 to 10 years in the 2 groups, early mortality both in the hospital and after discharge is greater with Q-wave infarcts, whereas recurrent infarction and late mortality are much greater with S-T infarcts.[28,30]

Although the number of diseased coronary arteries and the degree of occlusion throughout the system appear equal in both types,[23] fresh coronary thrombosis may be slightly[31] to moderately[10] more frequent with Q-wave infarction. Collateral vessels were demonstrated in 93% of all patients with S-T infarct and 78% with Q-wave infarct who had postinfarction angina, but in only 35% of patients with Q-wave infarct and no subsequent angina.[31] Coronary bypass tends to improve wall motion in S-T infarcts but only in Q-wave infarcts in which transmural fibrosis is absent.[32,33] Some investigators found reinfarction, angina, and late ventricular arrhythmias to occur equally in Q-wave and S-T infarcts, but more akinesis in patients with anterior Q-wave than with anterior S-T infarcts.[34] Yet, other investigators report comparable ejection fractions and wall motion abnormalities.[23] Finally, in a carefully matched, although retrospective, series S-T infarcts produced less congestive failure, fewer intraventricular conduction defects, and fewer atrial tachyarrhythmias; hypotension and ventricular arrhythmias occurred equally.[21] Yet, the same study also reported a statistically equal occurrence of pericarditis.[21] Because meticulous postmortem examination shows that in fresh infarction acute pericarditis always indicates transmural lesions,[10] those non-Q–wave infarcts with pericarditis, although labelled "nontransmural,"[21] certainly represented transmural infarction—more evidence of the electrocardiogram's anatomic nonspecificity.

## Subdivisions Within Q Infarctions and S-T Infarctions

Investigations pertinent to this analysis correlated anatomically transmural and nontransmural infarcts with electrocardiographically Q-wave and S-T infarcts, irrespective of regional distribution.[4–19] Fresh S-T infarcts usually occur with a normal QRS, but may also occur in patients with previous infarction, ventricular hypertrophy, preexcitation, or conduction disturbances producing QRS changes that mask or cancel processes producing new Q waves. Although most Q-wave infarcts are predominantly either inferior or anterior, it is not established whether either location is more likely to be transmural or nontransmural. Yet, location may have clinical importance: overall mortality in some series is worse with anterior infarcts, perhaps because of their tendency to be larger than inferior infarcts.[35,36] In contrast, in the AMIS Study (4,524 participants) total mortality did not differ among infarct locations, including patients who lost abnormal Q waves.[37] Yet, ventricular dysfunction tends to be worse with anterior Q waves.[38,39] Finally, both bundle branch block and significant myocardial failure are more frequent with anterior Q-wave infarcts, whereas sinus bradycardia, atrioventricular block, and atrial arrhythmias are more frequent with inferior Q-wave infarcts.[21]

## Q-Wave Infarcts Versus S-T Infarcts

Tables I and II list the similarities and the many differences between Q-wave and S-T infarction. Q-wave infarcts include posterior infarction appearing as a new anterior R wave.

**Conclusions:** The unfortunate practice of mislabelling Q-wave infarction as "transmural" and S-T infarction as "nontransmural" does not correspond to the pathologic evidence. Q-wave infarcts and S-T infarcts differ clinically, physiologically, and prognostically but cannot be anatomically differentiated by electrocardiography. As with a variety of other loose or erroneous terminologies, the absence of precise labelling interferes with clarity of concept and may inhibit further investigation.[40] When a myocardial infarct is characterized strictly by electrocardiography, it should be described by the only accurate terminology—Q-wave infarct or S-T infarct. Confucious tells us:

> If language is not used rightly, then what is said is not what is meant. If what is said is not what is meant, then that which ought to be done is left undone.

# Randomize the First Patient: Scientific, Ethical, and Behavioral Bases

DAVID H. SPODICK, MD, DSc

With few exceptions,[1] the prospective, randomized controlled trial (RCT) is the optimal test of any therapeutic intervention. Its scientific and practical features and the comparative weaknesses of alternative methods have been analyzed in detail elsewhere.[1,2] Indeed, it has become fashionable to adorn reports of uncontrolled therapeutic trials with explicit (not to say pious) statements declaring the need for an appropriately designed RCT to test the authors' conclusions.[2] Nearly all of these authors never conducted a randomized trial before or since, so that these "escape clauses" may represent less of a victory for principle accepted than for "revision accepted."

Levine[3] recently observed that even distinguished advocates of RCTs could publish an essay insisting on an RCT of a new treatment—lest it gain premature acceptance—and in the very same journal and year report an uncontrolled trial of that treatment. In fairness, their essay had claimed the prior necessity of a "pilot" trial. Since that indeed is traditional practice, the authors undoubtedly were sincere, but were they right? Is a "pilot" trial necessary or even appropriate? Experience shows that it is a diversion that consistently lets the "genie escape from the bottle." Convincing "pilot" trials without appropriate concurrent control series regularly induce enthusiasm for a new cure, producing a pseudoethical compulsion *not* to do an appropriate RCT.[4,5] The traditional stand is, "How can I deny my patients a treatment I *know* (read: "am now convinced") works? In urging randomization ab initio, Chalmers[5] eloquently wrote of the "pernicious influence" of such pilot trials in eliminating or postponing a definitive therapeutic trial.

Randomizing the first patient is supported by 3 cases: scientific, behavioral, and ethical.

## The Scientific Case

The scientific case for initial randomized trials is the very reason for doing any controlled trial—to demonstrate the value of a treatment by optimal comparison with an alternative treatment or no treatment. The counterargument, implying that a fair comparison compels us to first learn how best to use any new medicine or procedure, ignores the fact that learning to use a treatment is entirely feasible—indeed in no way different—when randomizing from the first patient. The investigators do exactly as they would in an uncontrolled trial, but in an RCT the "learning curve" for a new procedure and the "pilot" trial for a new medicine take approximately twice the time (Fig. 1). Yet, unlike the inadequate trials that rely on the investigators' recollections, literature "controls," or even retrospective historical controls (often massively misleading[1] and demonstrably biased in favor of new treatments[6]), an RCT builds a potentially concurrent (that is, prospective), valid (that is, unbiased), control series. The control patients' baseline characteristics make them equally eligible for the new treatment, with randomization distributing unknown and unmeasurable variables. Blinding, when feasible, further reduces bias and prevents premature termination of the trial.

Let us further examine the objection that during the learning phase changes in treatment methods may occur. Although a valid observation, such changes are entirely compatible with randomizing the first patient (Fig. 1). Until satisfied with the level of one's "learning curve" or "pilot" results, investigators in an RCT must either discard the earlier patients in the treatment series or make them a subset for partial comparison—exactly as they would in an uncontrolled trial—because the definitive RCT would proceed from the time the trial method becomes satisfactory. The only loss might be time, a negligible sacrifice in the search for Truth. In return, we ensure an incontestible standard by which to judge the initial results and avoid unseemly haste in applying an inadequately tested treatment. Moreover, the time "sacrifice" is at worst partial and at best ultimately becomes time-saving: time lost in subsequent argument and agitation for definitive trials could far exceed the extra time needed for initial RCTs (Fig. 1).

## The Ethical Case

In conducting an RCT, investigators implicitly declare reasonable hopes for a new treatment and honestly confess no exact knowledge of its short-term, and especially its long-term, effects in human beings, the precise conditions when Patient 1 is recruited. Without valid control patients, subsequent early success *or failure* tends to bias investigators for *or against* the trial treatment, with successes usually getting published. This leads directly to the ethical case.

Physicians are ethically bound always to offer each patient the best available treatment. Yet, with any new trial treatment we cannot know which alternative is best and cannot so advise Patient 1. Indeed, in recruiting patients for a nonrandomized "pilot" trial, the inves-

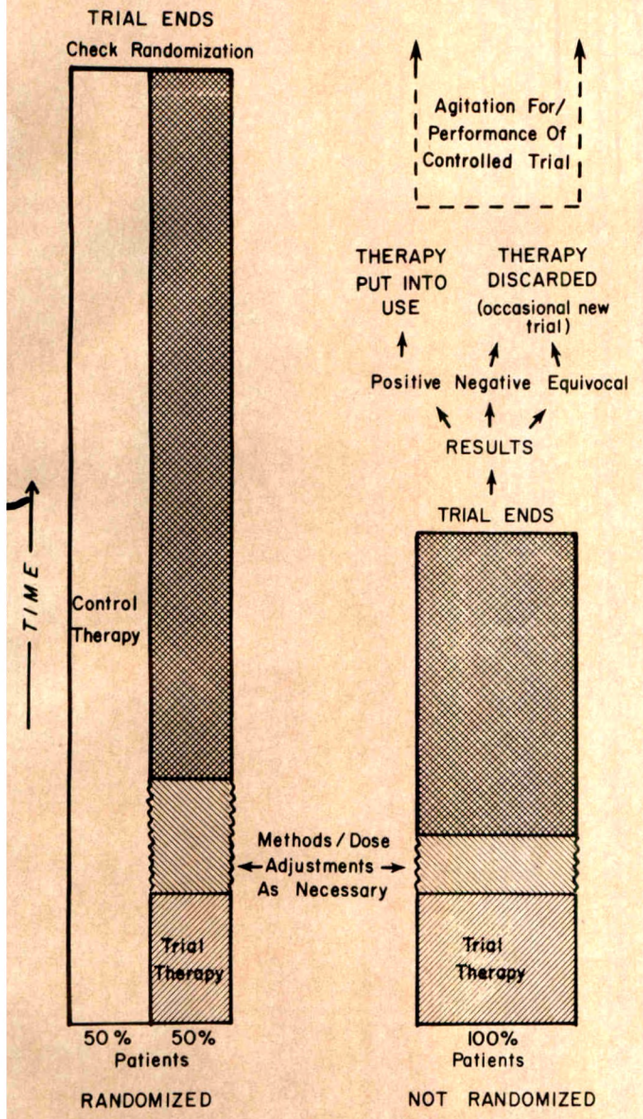

**FIGURE 1.** Concept of controlled trial randomized from the first patient (**left**) versus unrandomized traditional pilot trial (**right**). Time is represented vertically (**arrow**), number of patients horizontally (**width of bars**). The controlled trial includes concurrently randomized control patients (**white half of bar**) absent in the nonrandomized "pilot" trial. Each segment of randomized trial takes twice as long as a "pilot" trial including initiation of therapy, adjustments of methods or dosage, as needed, and continuation of the trial on adjusted therapy. Methods or dose adjustments (**diagonally striped segments**) include the same number of patients, although taking twice as long in randomized trial owing to allocation of 50% of the patients to the control group. The same number of patients are finally studied in each group. At the end of the randomized trial there is a valid control population not available in the unrandomized "pilot" trial. After the "pilot" trial the alternatives are indicated above its endpoint. The randomized trial in theory takes twice as long for the same number of patients, yet the desirability of subsequently performing controlled trials after the "pilot" trial can involve as much or more time.

tigator asks them all to forfeit their right to standard treatment and accept a treatment that he considers not yet sufficiently understood to permit comparison with standard therapy. When uncertain of the precise place of a new treatment, including methodology as well as efficacy and side effects, it seems ethically unjustified to subject every trial patient to it. (Genuinely informed consent would bind honest investigators to state they were "getting the bugs out" and might lose some patients' agreement.) Thus, the RCT is not only scientifically but also ethically superior to nonrandomized "pilot" trials in giving each patient an equal chance to get "best treatment," when we do not know whether "best treatment" will prove to be the new treatment or standard treatment. Once patients are candidly informed that the trial treatment may be better *or worse* than accepted treatment or no treatment, chance alone (that is, random allocation) eliminates bias in allocating them to one or the other.

## The Behavioral Case

Like the scientific case, the behavioral case is intimately bound to the ethical case: if a physician believes what he is doing is best for his patient, he is ethically compelled to do it. Yet this is equally true of witch doctors. Both the witch doctor and the modern physician respond to a personal ethical system when they act on what each considers his best option. Thus, responses to ethical compulsion alone do not ensure valid results. At a recent National Institutes of Health conference on percutaneous transluminal coronary angioplasty, distinguished practitioners of that art, some of whom had published one of the "RCTs are needed" escape clauses (as just cited), stated that they would not in fact do such an RCT because physicians were referring patients to them specifically for the procedure (Spodick DH, commentator. Personal observations, verified by tape transcripts. Bethesda, Maryland, June 11 and 12, 1981). This has been the history of a vast number of new medicines and procedures: early reports, virtually always enthusiastic, from uncontrolled or poorly controlled studies, followed by wide application under pseudoethical barriers to launching a well-controlled trial.

**Conclusions:** The randomized controlled clinical trial is the most powerful and, therefore, the scientifically optimal (hence, ethically optimal) method of demonstrating therapeutic effectiveness and safety. It is feasible to perform appropriately designed randomized prospective investigations beginning with the first trial patient (Fig. 1). This sacrifices only time (later likely to be more than regained) in the search for a real answer, and ensures an ethical approach that gives every patient a 50-50 chance to get best treatment, that is, not to get the new medicine at a time when its precise effects and risk-benefit ratio are not understood. Randomizing the first patient simultaneously avoids unscientific and unethical behavior and prevents premature wholesale application of inadequately tested methods.

## RESULTS OF MEDICAL VERSUS SURGICAL TREATMENT OF UNSTABLE ANGINA PECTORIS

The recent report of the National Cooperative Study Group to Compare Medical and Surgical Therapy[1] is important, useful, and the result of an enormous amount of very hard work. However, the Study Group evidently did not address (or measure) a variable of supreme importance in the prognosis and management of single-vessel coronary disease (left anterior descending [LAD] or otherwise). Two recent cases illustrate this concept.

*Patient A*, a 64-year-old woman, had previously had exercise angina and recent severe repeated rest pain with transient T-wave changes. Angiography showed a severe (>95%) proximal LAD coronary artery lesion without other important disease. The LAD coronary artery was developmentally small, supplying only a small percentage of the heart. She received a prolonged and systematic in-hospital medical trial with repeated attempts at ambulation. We finally gave up, and she had successful surgery.

*Patient B*, a 45-year-old man, had previously had exercise angina and recent severe repeated rest pain, with transient S-T and T-wave changes. Angiography showed a severe (>95%) proximal LAD coronary artery lesion without other important disease. The LAD coronary artery was very large; its main trunk wrapped around the apex and supplied the entire inferoanterior portion of the heart, and numerous large branches ran to the anterior and lateral left ventricle. We estimated that this vessel alone supplied >60% of the left ventricle. Coronary vein graft surgery was promptly recommended and accomplished.

We are convinced that these patients illustrate a concept that must be considered in trials involving prognosis and therapy. If Patient A had had an infarction of most of her diseased vessel's territory, she would probably have had a small but detectable anterior infarction, with acceptable ventricular function afterwards and an excellent prognosis after recovery. If Patient B had had an infarction of most of his diseased vessel's territory and had survived, he would probably have had an enormous anteroseptal transmural infarction, with dismal immediate prognosis and severely impaired function.

"Single-vessel coronary disease" cannot be understood or effectively analyzed without reference to the percentage of the heart so served or its equivalent. Existing methods for measuring this variable need to be perfected and incorporated into future studies. Studies which, by their design, combine "Patient A and Patient B" may be unwittingly concealing important prognostic information.

* Letters (from the United States) concerning a particular article in the *Journal* must be received within 2 months of the article's publication, and should be limited (with rare exceptions) to 2 double-spaced typewritten pages. Two copies must be submitted.

**REPLY:** Drs. Raper and Vetrovec are probably correct in their consideration of a difference in prognosis for the patient with proximal stenosis of a small or large anterior descending coronary artery. We agree with their request that methods for measuring this variable be perfected and incorporated in future studies. In fact, we argue that in addition to location of stenosis, percentage of stenosis, length of stenosis, and number of stenoses in the same vessel influence prognosis. Interestingly, the ongoing National Heart, Lung, and Blood Institute study (Coronary Artery Surgery Study [CASS]) did make substantial changes in recording coronary artery anatomy for comparison in prospective studies.

The study of LAD disease in the presence of unstable angina as reported by the National Cooperative Study Group[1] did not incorporate the described variation in left anterior anatomy. Certainly we as both investigators and clinicians have urged that our study, which we think has had a profound influence on the early management of unstable angina, be used in context and its findings incorporated into patient management as applicable. Thus, the management of each specific patient must continue to be individualized, although studies such as ours should provide an important point of departure for such management.

## LEFT VENTRICULAR ANEURYSM BY ANGIOGRAM: A PROBLEM OF DEFINITION

The prognostic significance of left ventricular (LV) aneurysm from the Coronary Artery Surgery Study (CASS) has been described by Faxon et al.[1] However, the study is plagued by the common denominator in all studies attempting to look at LV aneurysm, namely, definition. In their study, the authors define LV aneurysm as a segment of LV wall protruding abnormally "from the expected outline of the LV chamber." The implication is that this entity contrasts in some way to an akinetic segment of left ventricle. This may or may not be true. An aneurysm to 1 observer may in fact be an akinetic segment to another. Therefore, it is not surprising that Faxon et al found no difference in the mortality of patients with LV aneurysm compared with those without aneurysm, but with an equal degree of LV function. The authors may have been comparing the same group with itself.

The second problem with this study is that it evaluates the angiographic analysis of 15 participating institutions in this cooperative trial. Although there was a 93% interobserver agreement within participating institutions in regard to segmental wall motion abnormality, the authors do not tell us what the agreement was in terms of definition of aneurysm.

Third, although the authors use an angiographic definition of aneurysm, they quote several pathologic studies in defining the natural history of this entity. It is probable that there is a certain degree of discrepancy between angiographic and pathologic aneurysms.

Until an adequate method is determined to account for cardiac motion, which may simulate aneurysmal bulging in a patient with an akinetic segment, the definition of LV aneurysm will remain somewhat arbitrary. Any study that attempts to define the natural history of LV aneurysm will, to a certain extent, be misleading in its conclusions. Thus, any results that are drawn from the study of Faxon et al, I believe, should be taken with extreme caution.

## KNEE-ELBOW POSITION TO DETECT THE AORTIC DIASTOLIC MURMUR OF AORTIC REGURGITATION

Fifteen years ago one of us (DK) tried to convince a group of medical students that a patient had an aortic diastolic murmur. In the classic sitting-up, leaning-forward position, with the breath held in expiration, I heard the murmur but they did not.

I asked the patient to turn to the knee-elbow position and, pressing the stethoscope from below, on his sternum, the murmur became more audible. The first 2 students could hear the murmur easily, but alas the patient became tired and laid himself on his belly. We continued to press the stethoscope from beneath, on the sternum, and the murmur was even more audible.

Since then, when looking for an aortic diastolic murmur we put the patients on their abdomen, turn the head to the side opposite to our standing position, press the stethoscope blindly between the breasts, choose the most audible point, and ask them to stop breathing in expiration.

We find that this is a much more comfortable way to hear the murmur for the patient and for the inexperienced ear, rather than use of the squatting position or isometric exercise, which accentuates the murmur but is noisy. The patient is better able to remain quiet without much distress.

We have been unable to find this method of auscultation previously described.

# Dobutamine/Dobutrex®

## Dobutamine HCl

**Description:** Dobutrex is (±)-4-[2-[[3-(*p*-hydroxyphenyl)-1-methylpropyl] amino]ethyl]-pyrocatechol hydrochloride. It is a synthetic catecholamine.

Molecular Formula: $C_{18}H_{23}NO_3 \cdot HCl$ Molecular Weight: 337.84

The clinical formulation is supplied in a sterile lyophilized form for intravenous use only. Each vial contains 250 mg of dobutamine and 250 mg of mannitol. Hydrochloric acid is used to adjust the *p*H. The *p*H of the reconstituted solution is between 2.5 and 5.5.

**Clinical Pharmacology:** Dobutrex is a direct-acting inotropic agent whose primary activity results from stimulation of the beta receptors of the heart while producing comparatively mild chronotropic, hypertensive, arrhythmogenic, and vasodilative effects. It does not cause the release of endogenous norepinephrine, as does dopamine. In animal studies, dobutamine produces less increase in heart rate and less decrease in peripheral vascular resistance for a given inotropic effect than does isoproterenol.

In patients with depressed cardiac function, both dobutamine and isoproterenol increase the cardiac output to a similar degree. In the case of dobutamine, this increase is usually not accompanied by marked increases in heart rate (although tachycardia is occasionally observed), and the cardiac stroke volume is usually increased. In contrast, isoproterenol increases the cardiac index primarily by increasing the heart rate while stroke volume changes little or declines.

Facilitation of atrioventricular conduction has been observed in human electrophysiologic studies and in patients with atrial fibrillation.

Systemic vascular resistance is usually decreased with administration of dobutamine. Occasionally, minimum vasoconstriction has been observed.

Most clinical experience with dobutamine is short-term—up to several hours in duration. In the limited number of patients who were studied for 24, 48, and 72 hours, a persistent increase in cardiac output occurred in some, whereas the output of others returned toward base-line values.

The onset of action of Dobutrex is within one to two minutes; however, as much as ten minutes may be required to obtain the peak effect of a particular infusion rate.

The plasma half-life of dobutamine in humans is two minutes. The principal routes of metabolism are methylation of the catechol and conjugation. In human urine, the major excretion products are the conjugates of dobutamine and 3-O-methyl dobutamine. The 3-O-methyl derivative of dobutamine is inactive.

Alteration of synaptic concentrations of catecholamines with either reserpine or tricyclic antidepressants does not alter the actions of dobutamine in animals, which indicates that the actions of dobutamine are not dependent on presynaptic mechanisms.

**Indications and Usage:** Dobutrex is indicated when parenteral therapy is necessary for inotropic support in the short-term treatment of adults with cardiac decompensation due to depressed contractility resulting either from organic heart disease or from cardiac surgical procedures.

In patients who have atrial fibrillation with rapid ventricular response, a digitalis preparation should be used prior to institution of therapy with Dobutrex.

**Contraindication:** Dobutrex is contraindicated in patients with idiopathic hypertrophic subaortic stenosis.

**Warnings:** 1. *Increase in Heart Rate or Blood Pressure*—Dobutrex may cause a marked increase in heart rate or blood pressure, especially systolic pressure. Approximately 10 percent of patients in clinical studies have had rate increases of 30 beats/minute or more, and about 7.5 percent have had a 50-mm Hg or greater increase in systolic pressure. Reduction of dosage usually reverses these effects promptly. Because dobutamine facilitates atrioventricular conduction, patients with atrial fibrillation are at risk of developing rapid ventricular response. Patients with preexisting hypertension appear to face an increased risk of developing an exaggerated pressor response.

2. *Ectopic Activity*—Dobutrex may precipitate or exacerbate ventricular ectopic activity, but it rarely has caused ventricular tachycardia.

**Precautions: 1. During the administration of Dobutrex, as with any adrenergic agent, ECG and blood pressure should be continuously monitored. In addition, pulmonary wedge pressure and cardiac output should be monitored whenever possible to aid in the safe and effective infusion of Dobutrex.**

2. Hypovolemia should be corrected with suitable volume expanders before treatment with Dobutrex is instituted.

3. Animal studies indicate that Dobutrex may be ineffective if the patient has recently received a beta-blocking drug. In such a case, the peripheral vascular resistance may increase.

4. No improvement may be observed in the presence of marked mechanical obstruction, such as severe valvular aortic stenosis.

*Usage Following Acute Myocardial Infarction*—Clinical experience with Dobutrex following myocardial infarction has been insufficient to establish the safety of the drug for this use. There is concern that any agent which increases contractile force and heart rate may increase the size of an infarction by intensifying ischemia, but it is not known whether dobutamine does so.

*Usage in Pregnancy*—Reproduction studies performed in rats and rabbits have revealed no evidence of impaired fertility, harm to the fetus, or teratogenic effects due to dobutamine. However, the drug has not been administered to pregnant women and should be used only when the expected benefits clearly outweigh the potential risks to the fetus.

*Pediatric Use*—The safety and effectiveness of Dobutrex for use in children have not been studied.

*Drug Interactions*—There was no evidence of drug interactions in clinical studies in which Dobutrex was administered concurrently with other drugs, including digitalis preparations, furosemide, spironolactone, lidocaine, glyceryl trinitrate, isosorbide dinitrate, morphine, atropine, heparin, protamine, potassium chloride, folic acid, and acetaminophen. Preliminary studies indicate that the concomitant use of dobutamine and nitroprusside results in a higher cardiac output and, usually, a lower pulmonary wedge pressure than when either drug is used alone.

**Adverse Reactions:** *Increased Heart Rate, Blood Pressure, and Ventricular Ectopic Activity*—A 10 to 20-mm increase in systolic blood pressure and an increase in heart rate of five to 15 beats per minute have been noted in most patients. (See Warnings regarding exaggerated chronotropic and pressor effects.) Approximately 5 percent of patients have had increased premature ventricular beats during infusions. These effects are dose related.

*Miscellaneous Uncommon Effects*—The following adverse effects have been reported in 1 to 3 percent of patients: nausea, headache, anginal pain, nonspecific chest pain, palpitations, and shortness of breath.

No abnormal laboratory values attributable to Dobutrex have been observed.

*Longer-Term Safety*—Infusions of up to 72 hours have revealed no adverse effects other than those seen with shorter infusions.

**Overdosage:** In case of overdosage, as evidenced by excessive alteration of blood pressure or by tachycardia, reduce the rate of administration or temporarily discontinue Dobutrex until the patient's condition stabilizes. Because the duration of action of Dobutrex is short, usually no additional remedial measures are necessary.

**Administration and Dosage:** *Reconstitution and Stability*—Dobutrex is incompatible with alkaline solutions and should not be mixed with products such as 5% Sodium Bicarbonate Injection.

Dobutrex may be reconstituted with Sterile Water for Injection or 5% Dextrose Injection. To reconstitute, add 10 ml of diluent to Vial No. 7051, Dobutrex, 250 mg. If the material is not completely dissolved, add another 10 ml of diluent. The reconstituted solution may be stored under refrigeration for 48 hours or at room temperature for six hours.

Reconstituted Dobutrex must be further diluted to at least 50 ml prior to administration in 5% Dextrose Injection, 0.9% Sodium Chloride Injection, or Sodium Lactate Injection. Intravenous solutions should be used within 24 hours.

Solutions containing Dobutrex may exhibit a color that, if present, will increase with time. This color change is due to slight oxidation of the drug, but there is no significant loss of potency during the reconstitution time periods stated above.

*Recommended Dosage*—The rate of infusion needed to increase cardiac output usually ranges from 2.5 to 10 mcg/kg/min (see table). On rare occasions, infusion rates up to 40 mcg/kg/min have been required to obtain the desired effect.

Rates of Infusion for Concentrations of 250, 500, and 1000 mcg/ml

| Drug Delivery Rate (mcg/kg/min) | Infusion Delivery Rate 250 mcg/ml* (ml/kg/min) | 500 mcg/ml† (ml/kg/min) | 1000 mcg/ml‡ (ml/kg/min) |
|---|---|---|---|

| 7.5 | 0.03 | 0.015 | 0.0075 |
| 10 | 0.04 | 0.02 | 0.01 |
| 12.5 | 0.05 | 0.025 | 0.0125 |
| 15 | 0.06 | 0.03 | 0.015 |

*250 mg per liter of diluent
†500 mg per liter or 250 mg per 500 ml of diluent
‡1000 mg per liter or 250 mg per 250 ml of diluent

The rate of administration and the duration of therapy should be adjusted according to the patient's response, as determined by heart rate, presence of ectopic activity, blood pressure, urine flow, and, whenever possible, measurement of central venous or pulmonary wedge pressure and cardiac output.

Concentrations up to 5000 mcg/ml have been administered to humans (250 mg/50 ml). The final volume administered should be determined by the fluid requirements of the patient.

**How Supplied:** Vials Dobutrex® (dobutamine hydrochloride, Lilly), for Injection (lyophilized), equivalent to 250 mg dobutamine, 20-ml size, rubber-stoppered, in packages of 1. [121979]

# An Effective Bioprosthesis for All Positions

Efficient hemodynamic function, even in the smallest sizes, prompted early clinical use of the Ionescu-Shiley Pericardial Xenograft for aortic valve replacement. Recent analysis of clinical data following mitral valve replacement utilizing the Ionescu-Shiley Pericardial Xenograft reveals not only efficient hemodynamic function, but also an extremely low incidence of thromboembolism and thrombosis when compared to other bioprostheses.

In Marian Ionescu's ten year clinical experience with the pericardial valve in the mitral position, a low incidence of thromboembolism and no thrombosis have been achieved without the use of longterm anticoagulation.[1] Additional clinical studies from other institutions have now confirmed his findings.[2,3,4] Efficient hemodynamics, excellent thromboresistance and durability are three important reasons why the Ionescu-Shiley Pericardial Xenograft is an effective bioprosthesis for all positions.[5,6]

A film presenting Ionescu-Shiley Pericardial Xenograft implantation techniques, clinical data and comparative in vitro bioprosthetic function is available for your review. To obtain a copy of the film or for further clinical data, please contact Shiley Incorporated or your Shiley technical representative.

# THE ALPHA UNIVERSE

## ...is the Catapres® universe of central alpha control* for all kinds of hypertensives

**No contraindications** to Catapres— you can prescribe it for:**

- **Asthmatic hypertensives**
  Does not act directly on beta$_2$ receptors of the lungs (blocking these receptors induces bronchospasm).
- **Diabetic hypertensives**
  Lowers blood pressure without impairing oral antidiabetic effectiveness.
- **Hypertensives with renal insufficiency**
  Lowers blood pressure without long-term reduction of cardiac output. (Does not reduce renal perfusion or GFR.)
- **Hypertensives with congestive heart failure**
  Does not depress myocardial contractility.
- **Stress-induced hypertension**
  Inhibits sympathetic nervous activity centrally and does not elevate plasma catecholamines.
- **Elderly hypertensives**
  Recommended in isolated systolic hypertension in the elderly.[1]

*Central alpha-adrenergic stimulation decreases sympathetic outflow from the brain, as shown in animal studies.

**Like any antihypertensive, use with caution in severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

1. Statement on Hypertension in the Elderly, Revised April, 1980. Approved by the National High Blood Pressure Education Program Coordinating Committee.

Tablets of 0.1, 0.2, 0.3 mg

# Catapres®

## (clonidine HCl)

## Hypertension

Please see brief summary of PI for warnings, precautions, and adverse reactions.

# THE ALPHA UNIVERSE

Tablets of 0.1, 0.2, 0.3 mg

**Catapres®**
(clonidine HCl)
**Hypertension**

## Catapres®

**(clonidine hydrochloride)**
**Tablets of 0.1, 0.2, 0.3 mg**

**Indication:** The drug is indicated in the treatment of hypertension. As an antihypertensive drug, Catapres (clonidine hydrochloride) is mild to moderate in potency. It may be employed in a general treatment program with a diuretic and/or other antihypertensive agents as needed for proper patient response.

**Warnings:** Tolerance may develop in some patients necessitating a reevaluation of therapy.
*Usage in Pregnancy:* In view of embryotoxic findings in animals, and since information on possible adverse effects in pregnant women is limited to uncontrolled clinical data, the drug is not recommended in women who are or may become pregnant unless the potential benefits outweigh the potential risk to mother and fetus.
*Usage in Children:* No clinical experience is available with the use of Catapres (clonidine hydrochloride) in children.

**Precautions:** When discontinuing Catapres (clonidine hydrochloride), reduce the dose gradually over 2 to 4 days to avoid a possible rapid rise in blood pressure and associated subjective symptoms such as nervousness, agitation, and headache. Patients should be instructed not to discontinue therapy without consulting their physician. Rare instances of hypertensive encephalopathy and death have been recorded after cessation of clonidine hydrochloride therapy. A causal relationship has not been established in these cases. It has been demonstrated that an excessive rise in blood pressure, should it occur, can be reversed by resumption of clonidine hydrochloride therapy or by intravenous phentolamine. Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of the sedative effect. This drug may enhance the CNS-depressive effects of alcohol, barbiturates and other sedatives. Like any other agent lowering blood pressure, clonidine hydrochloride should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

As an integral part of their overall long-term care, patients treated with Catapres (clonidine hydrochloride) should receive periodic eye examinations. While, except for some dryness of the eyes, no drug-related abnormal ophthalmologic findings have been recorded with Catapres (clonidine hydrochloride), in several studies the drug produced a dose-dependent increase in the incidence and severity of spontaneously occurring retinal degeneration in albino rats treated for 6 months or longer.

**Adverse Reactions:** The most common reactions are dry mouth, drowsiness and sedation. Constipation, dizziness, headache, and fatigue have been reported. Generally these effects tend to diminish with continued therapy. The following reactions have been associated with the drug, some of them rarely. (In some instances an exact causal relationship has not been established.) These include: Anorexia, malaise, nausea, vomiting, parotid pain, mild transient abnormalities in liver function tests; one report of possible drug-induced hepatitis without icterus and hyperbilirubinemia in a patient receiving clonidine hydrochloride, chlorthalidone and papaverine hydrochloride. Weight gain, transient elevation of blood glucose, or serum creatine phosphokinase; congestive heart failure, Raynaud's phenomenon; vivid dreams or nightmares, insomnia, other behavioral changes, nervousness, restlessness, anxiety and mental depression. Also rash, angioneurotic edema, hives, urticaria, thinning of the hair, pruritus not associated with a rash, impotence, urinary retention, increased sensitivity to alcohol, dryness, itching or burning of the eyes, dryness of the nasal mucosa, pallor, gynecomastia, weakly positive Coombs' test, asymptomatic electrocardiographic abnormalities manifested as Wenckebach period or ventricular trigeminy.

**Overdosage:** Profound hypotension, weakness, somnolence, diminished or absent reflexes and vomiting followed the accidental ingestion of Catapres (clonidine hydrochloride) by several children from 19 months to 5 years of age. Gastric lavage and administration of an analeptic and vasopressor led to complete recovery within 24 hours. Tolazoline in intravenous doses of 10 mg at 30-minute intervals usually abolishes all effects of Catapres (clonidine hydrochloride) overdosage.

**How Supplied:** Catapres, brand of clonidine hydrochloride, is available as 0.1 mg (tan) and 0.2 mg (orange) oval, single-scored tablets in bottles of 100 and 1000 and unit dose package of 100.. Also available as 0.3 mg (peach) oval, single-scored tablets in bottles of 100.

For complete details, please see full prescribing information.
Under license from Boehringer Ingelheim International GmbH

*The Alpha Universe*, a painting by Arthur Lidov, commissioned by Boehringer Ingelheim Ltd.

Lidov's work, the second in a series on central alpha action, interprets the Alpha Universe on many levels...the universe of patients who can benefit from the central alpha control of Catapres...the special world of patient/clinician interaction... the internal universe within each patient that determines or modifies his therapy...and the universe of medicine itself. Lidov is a painter whose art invites us to share his own fascination with the creativity inherent in science.

If you like this painting, we would be pleased to send you a handsome reproduction suitable for framing...with our compliments.

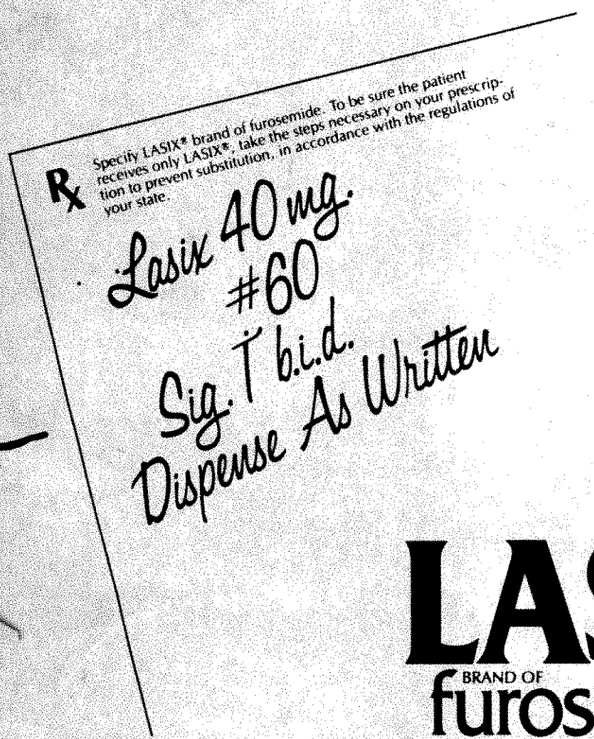
DIGITALIS TOXICITY
– and how to avoid it in CHF:

# Avoid any change in the classic digitalis-Lasix® regimen.

BRAND OF furosemide

Every CHF patient on a digitalis-diuretic regimen runs the risk of digitalis toxicity.



But many patients with impaired renal function are particularly vulnerable because their condition may predispose them to a toxic accumulation of digoxin.

These include the diabetic. The geriatric patient. The patient with renal disease. And the patient with advanced CHF who suffers from hepatic as well as renal complications.

Add to this group the patient on multiple medications with possible drug interactions.

Conditions like these that increase the risk of digitalis toxicity are generally outside the physician's control. But two of the most important *preventive* measures which are not outside the physician's control are precise titration of digitalis, *and the consistent use of one diuretic*.

As to the first, the narrow therapeutic-to-toxic range of digitalis is well known and requires no elaboration.

Naturally, increased renal problems necessitate increased vigilance to any signs of toxicity.

### Why the patient should be maintained on LASIX®

The second precaution is the unvarying use of a single diuretic for a given patient (consistent with proper potassium balance). Thus, if the choice is LASIX®—as it is in most successfully managed CHF cases—the logic behind it is beyond debate. LASIX® is the only diuretic for CHF whose effectiveness has been confirmed in no fewer than 6,000 published papers...which offers the most complete range of dosage forms and strengths for precise titration... and is the most widely available brand of furosemide for filling or refilling your prescription anywhere in the United States. In fact, according to a 1980 nationwide survey,[1] office-based physicians affirmed their confidence in LASIX® by naming it as the medication they prescribe most frequently in office practice.

### Protect your LASIX® prescription: prevent substitution

When you prescribe LASIX®, write the phrase "Do not substitute," or whatever your state requires on the prescription.

---

If you are in doubt about a particular generic furosemide, call the offices of the Food and Drug Administration's Bureau of Drugs, Consumer and Professional Relations staff at 301-443-1016.

---

**Before prescribing, please consult complete product information, a summary of which appears on the following page.**

# LASIX®

TABLETS: 20, 40 & 80 mg

BRAND OF furosemide

## The diuretic of choice for the digitalized patient.

A159

**Lasix®** (furosemide)

A brief summary of the Prescribing Information for Lasix (furosemide) Tablets 20, 40 and 80 mg

**WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.**

**INDICATIONS:** Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

**CONTRAINDICATIONS: Anuria. History of hypersensitivity to the compound.**

**WARNINGS:** Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, $CO_2$, and BUN determinations during first few months of therapy and periodically thereafter, and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions. Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.

There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

**PRECAUTIONS:** As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion; this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

**PREGNANCY:** Pregnancy Category C. Furosemide has been shown to cause unexplained maternal deaths and abortions in rabbits at 2.4 and 8 times the human dose. There are no adequate and well-controlled studies in pregnant women. Furosemide should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

**ADVERSE REACTIONS:** Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

*Laragh's eagerly awaited new book on the silent killer*

# TOPICS IN HYPERTENSION

Edited by

**John H. Laragh, MD**

*Master Professor of Medicine*
*Director, The Cardiovascular Center Chief, Cardiology Division The New York Hospital-Cornell Medical Center*

**644 pages. 36 chapters by 85 internationally known specialists. Illustrated. Comprehensively indexed. $49.00. Available on 30-day approval.**

High blood pressure is no longer only a problem of worldwide interest and relevance. It is now one in which the knowledge base has exploded to the point where the informed physician can do more and more about it in his daily practice...and can apply, to an ever-increasing extent, more sophisticated and individually tailored therapies.

Laragh's TOPICS IN HYPERTENSION places this kind of vital knowledge within instant reach of the physician. It presents a carefully selected array of discussions. It deals in depth with recent breakthroughs in understanding, diagnosing, and treating this problem.

This book is conveniently organized for effective consultation and reading:

- **Section 1** considers recently maturing biochemical and pathophysiologic aspects of the problem.
- **Section 2** deals with new physiologic approaches to diagnosis.
- **Section 3** discusses new perceptions of the clinical and prognostic aspects of hypertension.
- **Section 4** considers in detail the more recently introduced modes of therapy. These new agents presage the beginning of a new era of more selective and specific therapy for increasing numbers of patients.

**YORKE MEDICAL BOOKS** AJCC3
Box C-757, Brooklyn, New York 11205

Send me, on approval, _____ copies of Laragh's TOPICS IN HYPERTENSION at $49.00. I will consult and read this new manual for 30 days, then remit only if I consider it a necessary addition to my library. Otherwise I will return it without further obligation.

☐ Send bill, plus shipping cost.
☐ Payment herewith. Publisher pays shipping. Same return privilege.
☐ Charge my ☐ MasterCard ☐ Visa
☐ Card No. _____ Exp. date _____

Name _____

Address _____

City _____ State _____ Zip _____

*Please add Sales Tax in N.Y. State. Outside Western Hemisphere price is $57.00 and prepayment or credit card number is required. Thank you.*

TO A "DOER"
Your angina patients* can become more active now...with PROCARDIA protection. They'll be pain-free more of the time[1] and find their need for nitroglycerin greatly reduced.[2] They'll be able to work harder, exercise more.[3] And be more active participants in their own lives once again.
feeling better...doing more
PROCARDIA®
(NIFEDIPINE) Capsules 10 mg
*Procardia is indicated for the management of:
• Confirmed vasospastic angina.
• Angina where the clinical presentation suggests a possible vasospastic component.
• Chronic stable angina without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or nitrates or who cannot tolerate these agents. In chronic stable angina (effort-associated angina) Procardia has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.
Please see PROCARDIA® brief summary on next page

*feeling better...doing more*

# PROCARDIA®
## (NIFEDIPINE) *Capsules 10 mg*

## *–Usual effective dosage is 30-60 mg/day*

For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely.

Because Procardia decreases peripheral vascular resistance, careful monitoring of blood pressure during initial administration and titration is suggested. Close observation is especially recommended for patients taking medication known to lower blood pressure.

## *–Offers a favorable safety profile*

Most frequently reported side effects, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%.

**BRIEF SUMMARY**
**PROCARDIA® CAPSULES** For Oral Use
(nifedipine)

**INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA** (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

**II. Chronic Stable Angina (Classical Effort-Associated Angina):** PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in those patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See Warnings.)

**CONTRAINDICATIONS:** Known hypersensitivity reaction to PROCARDIA.

**WARNINGS: Excessive Hypotension:** Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been reported in patients receiving PROCARDIA together with a beta blocking agent who underwent coronary artery bypass surgery using high dose fentanyl anesthesia. The interaction with high dose fentanyl appears to be due to the combination of PROCARDIA and a beta blocker, but the possibility that it may occur with PROCARDIA alone, with low doses of fentanyl, in other surgical procedures, or with other narcotic analgesics cannot be ruled out.

**Increased Angina:** Occasional patients have developed well documented increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases. The mechanism of this response is not established but could result from decreased coronary perfusion associated with decreased diastolic pressure with increased heart rate, or from increased demand resulting from increased heart rate alone.

**Beta Blocker Withdrawal:** Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

**Congestive Heart Failure:** Rarely, patients, usually receiving a beta blocker, have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

**PRECAUTIONS: General: Hypotension:** Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See Warnings.)

**Peripheral edema:** Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

**Drug interactions:** Beta-adrenergic blocking agents: (See Indications and Warnings.) Experience in over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

Digitalis: Administration of PROCARDIA with digoxin increased digoxin levels in nine of twelve normal volunteers. The average increase was 45%. Another investigator found no increase in digoxin levels in thirteen patients with coronary artery disease. In an uncontrolled study of over two hundred patients with congestive heart failure during which digoxin blood levels were not measured, digitalis toxicity was not observed. Since there have been isolated reports of patients with elevated digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing PROCARDIA to avoid possible over- or under-digitalization.

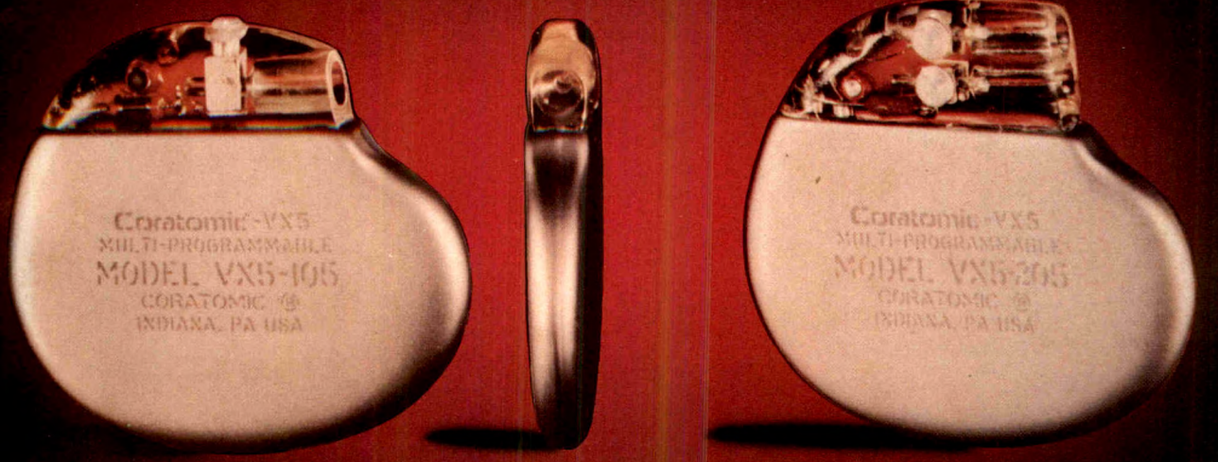
Carcinogenesis, mutagenesis, impairment of fertility: When given to rats prior to mating, nifedipine caused reduced fertility at a dose approximately 30 times the maximum recommended human dose.

Pregnancy: Category C. Please see full prescribing information with reference to teratogenicity in rats, embryotoxicity in rats, mice and rabbits, and abnormalities in monkeys.

**ADVERSE REACTIONS:** The most common adverse events include dizziness or light-headedness, peripheral edema, nausea, weakness, headache and flushing each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA or concomitant antianginal medication. Additionally, the following have been reported: muscle cramps, nervousness, dyspnea, nasal and chest congestion, diarrhea, constipation, inflammation, joint stiffness, shakiness, sleep disturbances, blurred vision, difficulties in balance, dermatitis, pruritus, urticaria, fever, sweating, chills, and sexual difficulties. Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of the disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

**Laboratory Tests:** Rare, mild to moderate, transient elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT, and SGPT have been noted, and a single incident of significantly elevated transaminases and alkaline phosphatase was seen in a patient with a history of gall bladder disease after about eleven months of nifedipine therapy. The relationship to PROCARDIA therapy is uncertain. These laboratory abnormalities have rarely been associated with clinical symptoms. Cholestasis, possibly due to PROCARDIA therapy, has been reported twice in the extensive world literature.



**HOW SUPPLIED:** Each orange, soft gelatin PROCARDIA CAPSULE contains 10 mg of nifedipine. PROCARDIA CAPSULES are supplied in bottles of 100 (NDC 0069-2600-66), 300 (NDC 0069-2600-72), and unit dose (10x10) (NDC 0069-2600-41). The capsules should be protected from light and moisture and stored at controlled room temperature 59° to 77°F (15° to 25°C) in the manufacturer's original container.

# THE VX5 SERIES PACEMAKER

Unipolar Model
VX5-105

Bipolar Model
VX5-205

## 5-Function Programmability in a Super Thin Case

### All of the most needed multi programmable pacing features in a modern, thin unipolar or bipolar design

Compare the Coratomic VX5 Series pacemaker features with any other competitive VVI/VOO multi programmable unit…then go one step further and discuss cost-effective pacing comparison with your Coratomic pacer specialist. You'll be pleasantly surprised on both subjects.

- 5 programmable functions (rate, pulse width, sensitivity, refractory period and amplitude)
- 9 mm thin case
- Ovaloid shape with "velvet grain" finish
- Reliable lithium power source
- Crystal controlled timing to assure ultra stable rates
- 45 grams in weight (unipolar)

- Real time telemetry
- Magnetic rate independent of pacing rate
- Easy to use, easy to read programmer with light weight construction for one hand programming
- Programmer can be used before, during and after implantation to read the pacing rate and pulse width status of the pacer, or to noninvasively change these values.

# The Pacekeeper™

## For steady maintenance following cardioversion of supraventricular, ventricular, and atrial tachyarrhythmias

- Maintains normal sinus rhythm
- Full quinidine cardiodynamics
- Greater gastrointestinal tolerance than with quinidine sulfate*
- Convenient b.i.d. or t.i.d. dosage

*Bibliography available upon request.

# CARDIOQUIN®
## TABLETS
## (quinidine polygalacturonate)

INDICATIONS AND USAGE: CARDIOQUIN Tablets are indicated as maintenance therapy after spontaneous and electrical conversion of atrial tachycardia, flutter or fibrillation and in the treatment of premature atrial and ventricular contractions, paroxysmal atrial tachycardia, paroxysmal A-V junctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when therapy is appropriate, and paroxysmal ventricular tachycardia when not associated with complete heartblock. CONTRAINDICATIONS: History of hypersensitivity to quinidine, complete A-V block, complete bundle branch block or other severe intraventricular conduction defects, myasthenia gravis, arrhythmias associated with digitalis toxicity. WARNINGS: In the treatment of atrial fibrillation with rapid ventricular response, use digitalis to control ventricular rate prior to administration of quinidine. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely high ventricular rate. This potential hazard may be reduced by digitalization prior to administration of quinidine. *Potentially toxic digoxin plasma levels may occur when quinidine is administered concurrently. Consider reducing digoxin dosage and monitoring for digitalis toxicity.* Evidence of quinidine cardiotoxicity (increased P-R and Q-T intervals, 50% widening of QRS, and/or ventricular ectopic beats or tachycardia) mandates immediate discontinuation of the drug, and/or close clinical and electrocardiographic monitoring. NOTE: Quinidine effect is enhanced by potassium and reduced in the presence of hypokalemia. Quinidine should be used with extreme caution in the presence of incomplete A-V block, since complete block and asystole may result. Quinidine may cause abnormalities of rhythm in digitalized patients; therefore, it should be used with caution in the presence of digitalis intoxication. Caution is also called for in patients exhibiting renal, cardiac or hepatic insufficiency because of potential toxic accumulation of quinidine in plasma. PRECAUTIONS: A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncracy to quinidine. ECG monitoring and determination of plasma quinidine levels are recommended when doses greater than 2.5 g/day are administered. Periodic blood counts and liver and kidney function tests should be performed during long-term therapy.

DRUG INTERACTIONS OF QUINIDINE:

| DRUG | EFFECT |
|---|---|
| With anticholinergic drugs | Additive vagolytic effect. |
| With cholinergic drugs | Antagonism of cholinergic effects. |
| With carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics | Alkalinization of urine resulting in decreased excretion of quinidine. |
| With coumarin anticoagulants | Reduction of clotting factor concentrations. |
| With tubocurare, succinylcholine and decamethonium | Potentiation of neuromuscular blockade. |
| With phenothiazines and reserpine | Additive cardiac depressive effects. |
| With hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin) | Decreased plasma half-life of quinidine. |
| With digoxin | Increased plasma concentrations of digoxin (see WARNINGS). |

PREGNANCY: The use of quinidine in pregnancy should be reserved only for those cases where the benefits outweigh the possible hazards to the patient and fetus. NURSING MOTHERS: The drug should be used with caution due to excretion of the quinidine in breast milk. ADVERSE REACTIONS: SYMPTOMS OF CINCHONISM (ringing in the ears, nausea, headaches, and disturbed vision) may appear in sensitive patients after a single dose of the drug. GASTROINTESTINAL: Diarrhea, nausea, vomiting, abdominal pain. CARDIOVASCULAR: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms (including ventricular tachycardia and fibrillation), paradoxical tachycardia, arterial embolism, and hypotension. HEMATOLOGIC: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranulocytosis. CNS: Headache, fever, vertigo, apprehension, excitement, confusion, delirium, syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis. DERMATOLOGIC: Rash, cutaneous flushing with intense pruritus, urticaria. HYPERSENSITIVITY REACTIONS: Angioedema, acute asthmatic episodes, vascular collapse, respiratory arrest, hepatic toxicity. See package insert for Full Prescribing Information.
